The orientation of the scapulae in relation to the thorax and the humerus varies far more than do their hind-limb equivalents, even in the mammals. This variation is perhaps most extreme in the bipedal mammals, the primates (Ashton *et al.* 1976). Their widespread adoption of an arboreal habitat, in which they climb, walk, run and swing, is linked with the development of a highly mobile and prehensile fore-limb, and with similar but much less marked changes in the hind-limb. Perhaps equally to be emphasized is the common habit of *sitting* upright, for in even those primates, such as some baboons, which have largely deserted trees and live a predominantly quadrupedal life on the ground, the arms are released for prehensile and manipulative use, activities of the profoundest significance in the evolution of man.

In modern mammals, the *Eutheria*, the rounded articular 'head' of the humerus is usually directed dorsocaudally and the glenoid socket of the scapula in a reciprocal manner. While this favours the quadrupedal use of the fore-limb it prevents movement of the humerus upwards into the vertical position of the arm so easily and characteristically assumed by primates in reaching upwards above the head. This is associated with a re-orientation of the humeral head relative to its shaft, the head being directed *medially* rather than caudally. Coincident with this reorganization of the shoulder is a change in the maximum diameter of the thorax from dorsoventral to transverse. The former is typical of quadrupeds, the latter of man. This change is coupled with the retention of the clavicle in primate mammals, and with a changed orientation of the scapulae. The medial aspects of these come to face largely ventrally and their glenoid fossae more laterally. These osseous changes, and correlated muscular alterations, are clearly linked with a far freer range of movement at the shoulder joint.

The tubercles and bicipital groove of the humerus share in the migration of its articular head, though to a lesser extent, but the lower end of the bone does not change its transverse orientation (Martin 1932). This means that a radial axis through the centre of the articular head is approximately at right angles to the axis of the lower end in most modern mammals (*Eutheria*) because the head is directed caudally. As it becomes more medial this angle increases above 90°. It is still some 95° in carnivora, rises to about 100° in monkeys, 120° in apes, and ranges from 135° to 165° or more in man. This change in the primate humerus has been regarded as a 'torsion', the angle being termed the *angle of torsion*. The term is perhaps misleading and there is no evidence of any true 'twisting' of the humeral shaft; the spiralling of the radial nerve and its associated groove pre-dates this change. Nor is there any particularly human character in the torsion angle. It reaches 180° (where the axes are parallel) in birds and was apparently nearly as high in mammal-like reptiles, returning to about 90° in the *Metatheria* (marsupials). A few words must be added in regard to the method of recording humeral torsion angles. As defined here the angle is measured between the articular 'axes' of the shoulder and elbow joints. However, Krahl (1944, 1976) has contributed many papers on this subject, and these are sometimes quoted in textbooks. In his method the angle measured is that between the axis of the elbow joint and an orthogonal line relative to the axis of the shoulder joint; his values, therefore, differ by 90° from those cited here. Neither method is completely satisfactory in conceptual terms, but very similar figures are obtained. Krahl's work largely supports the view put forward here, that the change in orientation of the head of the humerus, relative to its lower end, has involved alterations at the proximal end of the bone, and has not been accomplished by an evolutionary twisting of the shaft. Racial and sexual differences have been recorded (Kate 1968).

In the lower extremity the state is like that of the mammal-like reptiles (and birds), in which the two axes are nearly parallel. (In man the femoral head and the long axis of its neck are anteverted about 16° relative to the transcondylar axis of the lower end of the femur.) It is said that this condition has not varied in the lower limb, unlike the upper. This lability of the 'torsion' angle of the humerus may be coupled with the greater variability in fore-limb muscular activity, especially in those groups which demonstrate bipedalism and hence release of the fore-limbs.

The intermediate segments of the two limbs, and their joints with the humerus and femur, show similarities and differences. The differences are greater in bipeds, as would be expected; in quadrupeds the similarities are more evident. Both segments consist of two parallel elements, radius and ulna, tibia and fibula. Primitively both articulate with the single proximal element in each limb, but in mammals in general, as in man, the fibula withdraws from the articulation of the knee. This leaves the *pre-axial* element, the tibia, as the major lever and prop. In the forearm the ulna, the *post-axial* bone, becomes the main force-transmitting strut at the elbow.

Both the elbow and knee are hinge joints in quadruped

mammals, and while this was the primitive tetrapod condition in the knee, the elbow also contained a potentiality for *rotation* from the beginning. The hind-limb turns medially bringing its extensor surface forwards, in which position the foot, hinged at the ankle, projects forwards with its plantar surface on the ground. This is the typical *plantigrade* habit of many quadrupeds—it brings the hind-limb well under the body as a series of hinged levers well adapted for propulsion and body support. It is to be noted that the tibia and fibula are parallel in this position. On the other hand, the *lateral* rotation of the fore-limb which turns the extensor aspect backwards, is accompanied by *pronation* at the elbow bringing the 'hand' forwards, palm downwards to achieve plantigrade locomotion. This brings the pre-axial bone, the radius forwards and medially across the ulna, and the two bones are stabilized in this crossed relation in a large majority of quadrupeds, including all four-*footed* mammals. It should be added that the forearm and foreleg bones show a general tendency to fuse together in such mammals. Such fusions are particularly well marked in those which show a reduction in the number of digits and are usually *digitigrade* (e.g. Ungulata), in which contact with the ground is restricted to the flexor aspects of the tips of their remaining digits.

The primitive rotatory potential at the elbow has been retained and carried further in the primates, in the movements of *pronation* and *supination*, which are essential to the development of manual skills. These movements are impossible in the leg. At the primate elbow, the ulna forms a massive hinge with the humerus but tapers to a relatively small distal end. The extremities of the radius are reciprocal in size and shape—its upper end is small and adapted for rotation, while its lower end is enlarged and carries the hand. Thus, when the radius revolves it takes the hand with it, turning round the distal end of the ulna.

Both wrist and ankle joints are hinges, but adduction and abduction are also possible at the wrist. The *carpus* and *tarsus* are groups of small bones intermediate between the forearm or foreleg and the skeletal components of the digits. They show considerable modification throughout the tetrapod series, and also some divergence from each other. Nevertheless, however modified, both groups are considered to be derived from the same primary arrangement in the primitive *pentadactyl limb* (Bardeleben 1894). This consisted of a proximal row of three elements, a distal row of five, articulating with the bases of the digits, and a central or intermediate group, probably four in number, wedged between these two rows. By fusion, loss and modification in size, shape and articulation, the carpal and tarsal bones display much variation (particularly reduction). Tracing the homologies between the primitive elements and their subsequent transformations (structural and functional) has aroused much controversy (Broom 1901; Wood Jones 1949; Lewis 1964), but a considerable measure of agreement has now been reached. Authorities may disagree in minor details, but the generally accepted homologies are shown in the table below.

The main divergencies between the mammalian carpus and tarsus, apart from greater size of the latter, especially in primates, are three. Firstly, the carpus has usually remained more primitive in retaining a full proximal row, all articulating at the wrist joint; in the tarsus only one of these (the talus) retains this role in most mammals, and hence primates. Secondly, one of the proximal tarsal bones (calcaneus) projects backwards as a lever behind the tibia and fibula; this does not occur in the carpus. Thirdly, the tarsal bones, at their intermediate joints, permit some rotation—inversion and eversion—an adaptation to uneven surfaces. (Such contingencies are met in some fore-limbs by the movements of pronation and supination between the *forearm* bones and by some measure of abduction and adduction at the *wrist*.) In these three modifications the tarsus is less primitive. It is to be emphasized that the evolution of the calcanean lever system is a mammalian, not just a primitive or human modification. Its high development in the human foot, and the fact that other primate feet are more like hands, may give rise even to the superficial assumption that it is a *human* characteristic.

Because of the occasional occurrence of small supernumerary bones, pre- or post-axial in position, in association with the carpus and tarsus, it has been argued that these are evidence of additional digits (Wood Jones 1941), suggesting that the ancestral pattern comprises more than five digits. Known tetrapods appear to be content with the orthodox five, and often many less. The five metacarpal and metatarsal bones originally articulated each with a separate carpal or tarsal, but the latter are reduced to four by

HOMOLOGIZATION OF THE PRIMITIVE TETRAPOD AND HUMAN CARPUS AND TARSUS

	TETRAPOD CARPUS	HUMAN CARPUS		HUMAN TARSUS		TETRAPOD TARSUS	
PROXIMAL ROW	Os Radiale	Scaphoid	Scaphoid minus tubercle	Talus	Navicular minus tubercle	Os Tibiale	PRE-AXIAL
	Os Intermedium	Lunate			Talus	Os Intermedium	
	Os Ulnare	Triquetral		Calcaneus		Os Fibulare	POST-AXIAL
CENTRAL ELEMENTS	Os Centrale	Absent	Tubercle of Scaphoid	Navicular	Tubercle of Navicular	Os Centrale	
DISTAL ROW	Os Carpale 1	Trapezium		Medial Cuneiform		Os Tarsale 1	PRE-AXIAL
	Os Carpale 2	Trapezoid		Intermediate Cuneiform		Os Tarsale 2	
	Os Carpale 3	Capitate		Lateral Cuneiform		Os Tarsale 3	
	Ossa Carpalia 4 and 5	Hamate		Cuboid		Ossa Tarsalia 4 and 5	POST-AXIAL

N. B. Alternative views have been stated for the carpal scaphoid and the tarsal navicular. In each case the most widely accepted view is on the left. In the case of the talus the anomalous persistence of its posterior process as a separate element, an *os trigonum*, may have influenced the orthodox view of the talus as an amalgam of ossa tibiale et intermedium. If it becomes accepted that the talus is merely the os intermedium, the main residual controversies concern the scaphoid and navicular, centred on the possible derivation of each bone's tubercle from the corresponding os centrale. It should be added that the *centrale* element has been shown as singular in this table, though there were probably a variable number of centralia in the ancestral forms.

fusion of the fourth and fifth even in a primate such as man. In mammals with reduced or lost digits the metacarpals and metatarsals are also involved, as well as the phalanges. A minor example of reduction is provided by the Carnivora, whose first digit, pollex or hallux, is degenerate and useless, although it often still carries a claw, an extreme example being the horse, which retains only the middle digit, with a greatly enlarged metapodial bone.

The *metapodial* (metacarpal or metatarsal) *formula* puts these bones in order of length and indicates their number. In man it is usually $2>3>4>5>1$ in the hand, and $1>2>3>4>5$ in the foot. The *phalangeal formula* likewise starts from the first digit—pollex or hallux—and details the number of phalanges in each digit. In many primitive reptiles, for example, it is 2.3.4.5.3. In primitive mammals, it is 2.3.3.3.3. for hand and foot, as in man. In the horse it is 0.0.3.0.0 A *digital formula* denoting the relative projection of the tips of the digits is sometimes employed, especially when comparing the extremities of primates.

Throughout the tetrapods the pollex and hallux evince a tendency to diverge from the other digits, perhaps as a prop. It is believed that some early mammals were arboreal, and could use the hand as primates do, with a grasp between the pre-axial digit and the remaining digits. Among the primates this grasping ability is developed in both hand and foot, although it is absent from the human foot and not always effective in the primate hand. In gibbons, for example, the hand is used rather as a hook in brachiating or swinging from branch to branch, and the thumb does not effectively *oppose* to the other digits; the foot, in contrast, has an excellent grasp. In most primates the distal end of the first metatarsal is not tied by ligaments to the second, which allows the hallux marked freedom of movement. In mankind, however, the first and second metatarsals are so connected, all five being tied by ligaments. The human thumb, on the contrary, is even better developed for *opposition* than in other primates. In this movement the joint between the thumb and its carpal bone—the *trapezium* (the *os carpale 1* of the primitive tetrapod wrist)—is adapted to permit the thumb to flex and rotate towards the fingers. This action can be used as a 'power' grip, when the thumb and fingers wrap around opposite sides of an object such as a branch, weapon, or tool. It can also be used in a 'precision' grip, in which the thumb is opposed to a single finger, often the index, in lighter, more accurate manipulations (Napier 1966).

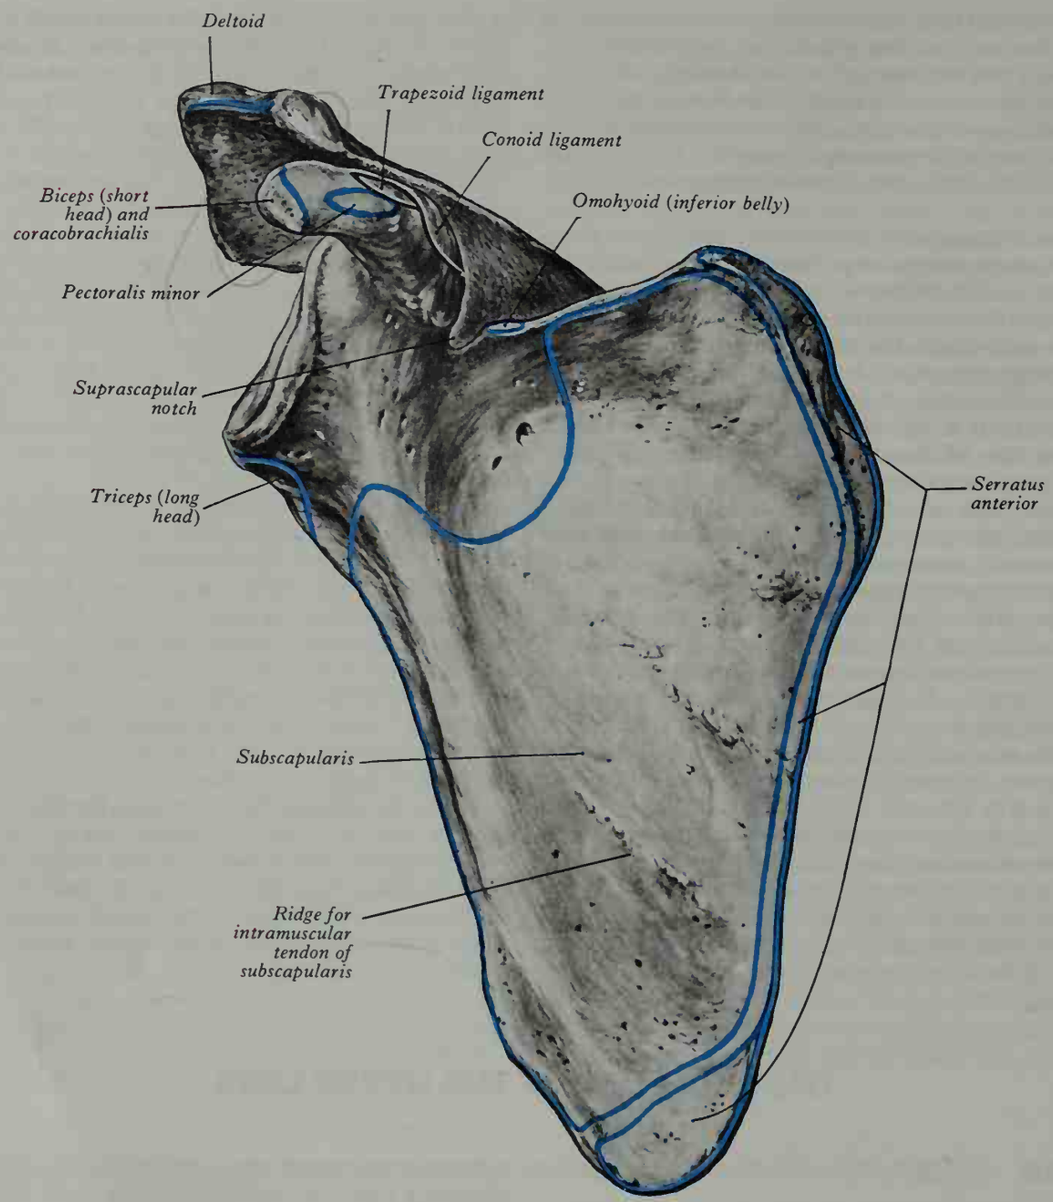
The skeletal elements of the human limbs, especially when compared on the basis of their functional differences and similarities, provide beautiful examples of adaptation. In the leg, the massive, almost immobile pelvic girdle, directly articulated to the axial skeleton, and the limited ball and socket mechanism of the hip, adapted for fore and aft swinging, but allowing some abduction to permit a steady stance in a biped; the hinging joints at the knee and ankle for resilience and power in walking, running and springing, and the powerful lever of the foot, arched for resilience in the final thrust of takeoff and the impact of landing—all these characterize a limb highly developed for *locomotion*.

The arm presents a different system of adaptions, analysable into components, but integrated in action. The scapula floats in a muscular suspension, lightly strutted by a slender mobile clavicle. A shallow ball and socket joint allows a far wider range for the reaching, grasping, 'inquisitive' hand. Flexion, combined with rotation at the elbow, brings the hands within the arena of the eyes, maintaining a steady basis at the wrists for the fine movements of the opposable thumb and highly mobile fingers. Endlessly variable manipulations, involving most delicate muscular adjustments, can thus be developed with the constant feedback of stereoscopic vision.

We see the arm and hand of man at the end of several hundred million years of evolution. Perhaps it is not the 'end', but even were the human upper limb to evolve no further, it has, with an accompanying high development of cerebral control, accomplished such a mastery over man's environment as to deflect the whole course of primate evolution into a new channel (Huxley 1942).

THE SKELETON OF THE UPPER LIMB

The Scapula



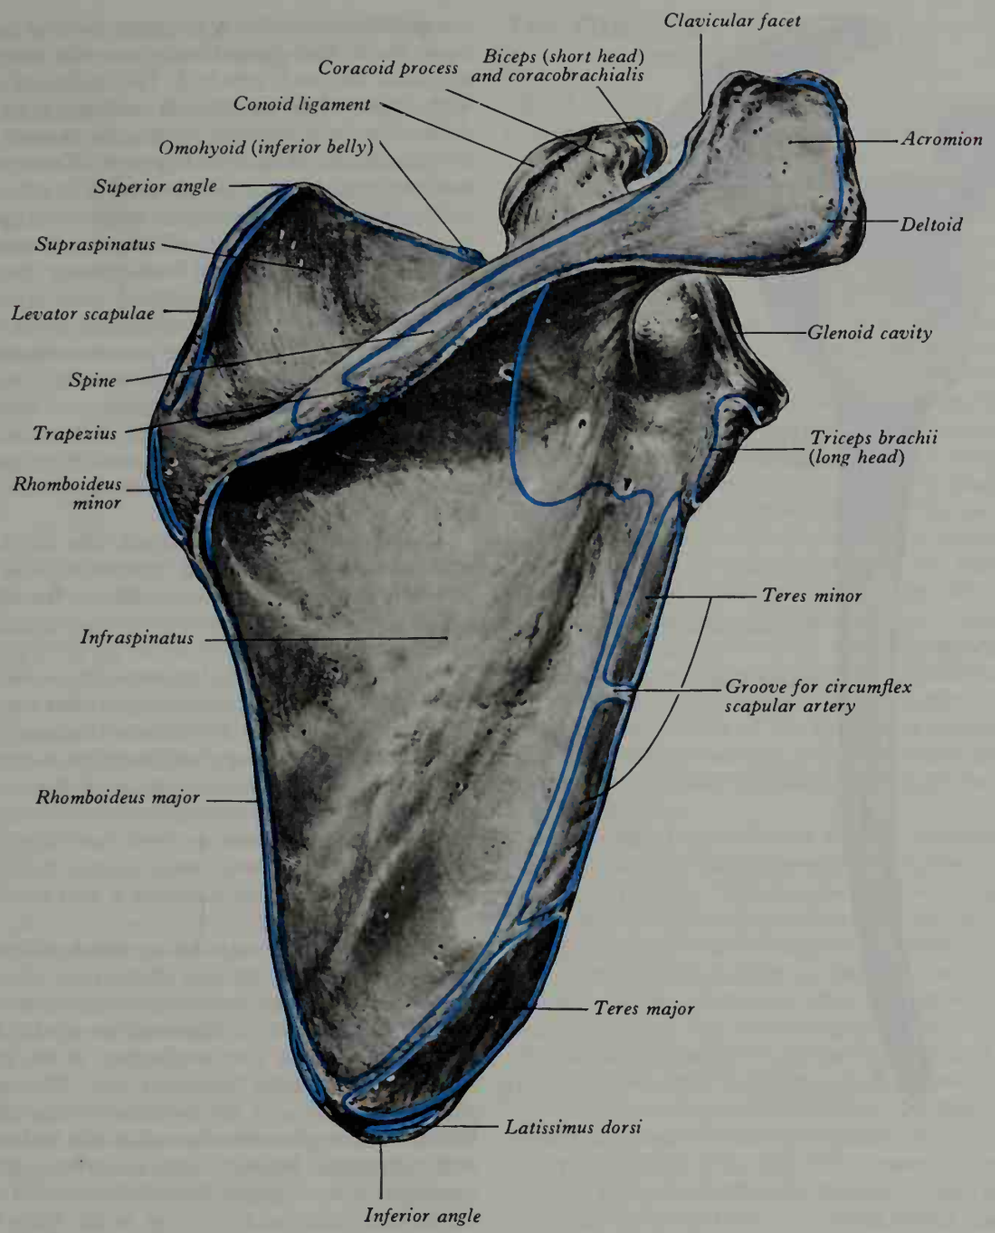
The scapula (**3**.127, 128, 129) is a large, flattened, triangular bone on the posterolateral aspect of the thorax, overlapping parts of the second to the seventh ribs. It has costal and dorsal surfaces, upper, lateral and medial borders, inferior, superior and lateral angles, and three bony processes, the spine, its continuation the acromion, and the coracoid process. The lateral angle is truncated by the glenoid cavity for articulation with the head of the humerus. This part of the bone may be regarded as the head, and it is connected to the plate-like body by an inconspicuous neck. The long axis of the scapula is nearly vertical and the relatively featureless costal surface contrasts with the dorsal surface, which is interrupted by the spine (**3**.129). The bone is very much thickened in the immediate neighbourhood of the lateral border, which runs from the inferior angle below to the glenoid cavity above.

The costal surface (**3**.127), facing medially and forwards when the arm is by the side, is slightly hollowed out, especially above. Near the lateral border it presents a longitudinal, rounded ridge, prominent in the neighbourhood of the neck, but less so below, which is separated from the lateral border by a narrow, grooved area. The *dorsal surface* (**3**.128) is divided into a smaller, upper area and a larger, lower one by a shelf-like projection, the *spine of the scapula*. These two areas communicate with each other through the *spinoglenoid notch*, which lies between the free, lateral border of the spine and the dorsal aspect of the neck of the bone. A flattened strip, for muscular attachments, marks the dorsal surface along the lateral border.

The lateral border of the scapula is a clearly defined, sharp, roughened ridge, which runs sinuously from the inferior angle to the glenoid cavity. At its upper end it widens into a rough, somewhat triangular area, which is termed the *infraglenoid tubercle* (**3**.129). Throughout its whole length the lateral border is thickly covered with muscles and cannot be felt clearly in the living. The lateral border is sometimes described as thick, but the grooved lateral part of the costal surface and frequently the flattened strip along the lateral part of the dorsal surface are incorporated in it. The *medial border* of the scapula extends from the inferior to the superior angle. In its lower two-thirds this border can easily be felt through the skin, but its upper third is more deeply placed and cannot be palpated. The *superior border*, thin and sharp, is the shortest. At its anterolateral end it is separated from the root of the coracoid process by the *suprascapular notch*.

The inferior angle lies over the seventh rib, or seventh intercostal space. It can be felt through the skin and the muscles which cover it and, when the arm is raised above the head, it can be seen to pass forwards round the chest wall. The *superior angle* is placed at the junction of the superior and medial borders, and is obscured by the muscles which cover it. The *lateral angle* is truncated and broadened. It constitutes the head of the bone. On its free surface it bears the *glenoid cavity*, forming the shoulder joint with the head of the humerus. Being shallow, it forms a limited socket for the humeral head. It is narrow above and wider below, and is pear-shaped in outline. Immediately above the glenoid cavity a small roughened area encroaches on the root of the coracoid process, the *supraglenoid tubercle*. The *neck* of the scapula is the constriction immediately adjoining the head. It can be identified most easily on its inferior and dorsal aspects. Ventrally, it can be regarded as extending between the infraglenoid tubercle and the anterior margin of the suprascapular notch.

The spine of the scapula (**3**.128) projects on the upper part of



3.127 The right scapula. Anterior (costal) aspect.

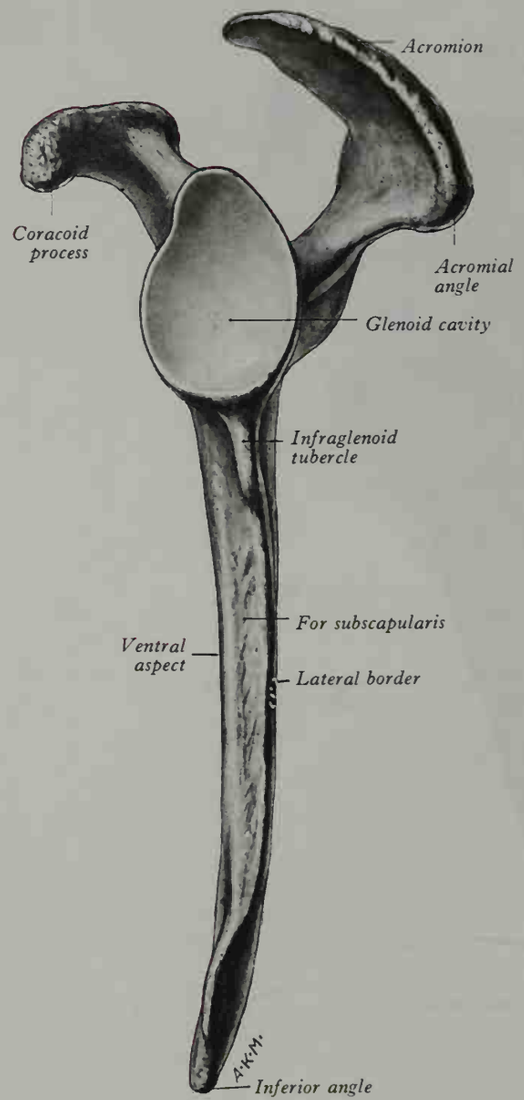
the dorsal surface of the bone, and is triangular in shape. Its lateral border is free, thick and rounded and helps to bound the *spinoglenoid notch*, which lies between it and the dorsal surface of the neck of the bone. Its anterior border joins the dorsal surface of the scapula along a line which runs laterally and slightly upwards from the junction of the upper and middle thirds of the medial border. It should be noted that the plate-like body of the bone is bent along this line, and this fact accounts for the more marked concavity of the upper part of the costal surface. The third border is termed the *crest of the spine*, and is subcutaneous throughout nearly its whole extent. At its medial end the crest expands into a smooth, triangular area. Elsewhere the upper and lower edges and the surface of the crest are roughened by muscular attachments. The upper surface of the spine widens as it is traced laterally, and is slightly concave. Together with the upper area of the dorsal surface of the bone, the upper surface of the spine forms the *supraspinous fossa*. The lower surface is overhung by the crest at its medial, narrow end, but is gently convex in its wider, later portion. Together with the lower area of the dorsal surface of the bone, the lower surface of the spine forms the *infraspinous fossa*, which continues into the supraspinous fossa through the spinoglenoid notch.

The acromion projects forwards, almost at right angles, from the lateral end of the spine, with which it is continuous. The lower border of the crest of the spine becomes continuous with the lateral border of the acromion at the *acromial angle*, which forms a subcutaneous, bony landmark. The medial border of the acromion is short and is marked anteriorly by a small, oval facet, directed upwards and medially, for articulation with the lateral end of the clavicle. The lateral border, tip and upper surface of the acromion can all be felt through the skin without difficulty. An accessory articular facet may occur on the inferior surface of the acromion.

The coracoid process (**3**.127) springs from the upper border of the head of the scapula and is bent sharply so as to project forwards and slightly laterally. When the arm is by the side, the coracoid process points almost straight forwards and its slightly enlarged tip can be felt through the skin, although it is covered by the anterior fibres of the deltoid. It lies about 2·5 cm below the junction of the lateral fourth of the clavicle with the rest of the bone. The supraglenoid tubercle marks the root of the coracoid process where it adjoins the upper part of the glenoid cavity. Another impression is placed on the dorsal aspect of the coracoid process at the point where it changes direction. This gives attachment to the conoid part of the coracoclavicular ligament, which will be mentioned again in connection with the clavicle.

From the costal surface springs the subscapularis (**3**.127), which arises from nearly the whole of this aspect including the grooved area immediately adjoining the lateral border, but excluding the area adjoining the neck of the bone. Small intramuscular tendons are attached to the roughened ridges which subdivide this surface incompletely into a number of smooth areas. The anterior aspect

3.128 The right scapula. Dorsal aspect.



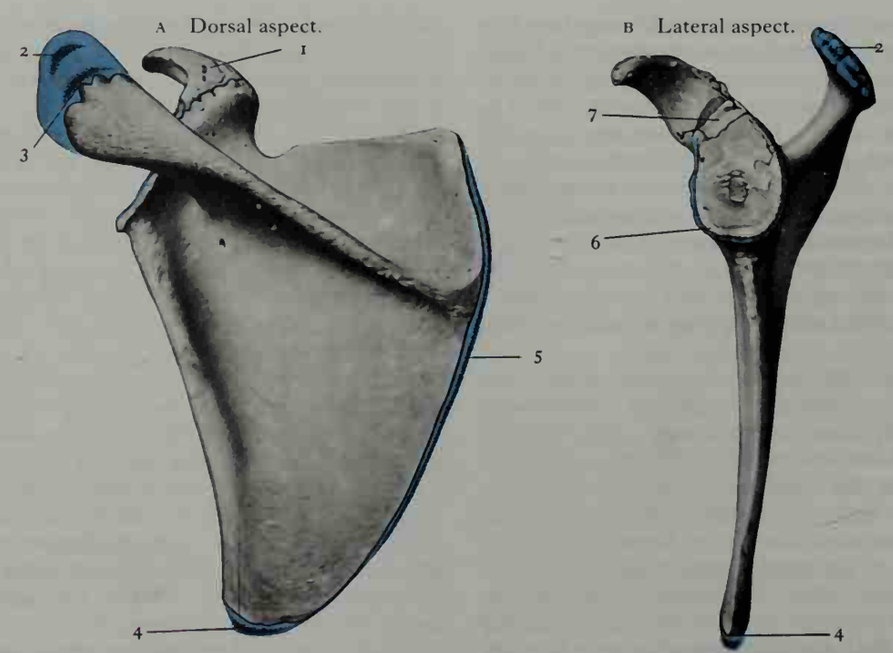
of the neck is separated from the tendon of the subscapularis by a synovial protrusion of the shoulder joint in the form of a bursa. Near the inferior angle a somewhat oval area gives insertion to the lower five or six digitations of the serratus anterior (**3**.127). The remainder of the muscle is inserted into a narrow strip along the ventral aspect of the medial border, which is wider above, where it receives the large first digitation. The longitudinal thickening of the bone near the lateral border provides a lever capable of withstanding the pull of the serratus anterior at the inferior angle during rotation of the scapula forwards. In this movement the glenoid cavity faces more directly upwards and the upper limb is raised from the side and carried above the head against the action of gravity.

On the dorsal surface, the supraspinous fossa in its medial two-thirds is the origin of the supraspinatus, and its margins give attachment to the fascia which covers the muscle. The flattened strip adjoining the lateral border has attached to it, in its upper two-thirds, the teres minor and is grooved, near its midpoint, by the circumflex scapular vessels, which pass between the muscle and the bone as they enter the infraspinous fossa (**3**.128). The lower limit of the origin of the teres minor is indicated by an oblique ridge, which runs from the lateral border to the neighbourhood of the inferior angle and cuts off a somewhat oval area for the teres major. With the exception of an area near the neck of the bone, the rest of the infraspinous fossa, which is hollowed out laterally and convex medially, gives origin to the infraspinatus. The strong infraspinatus fascia passes on to the teres minor and the teres major and sends fascial partitions between them to reach the bone along the ridges which mark the limits of their attachments.

The *lateral border* separates the attachment of the subscapularis from those of the teres minor and major. These muscles project laterally beyond the bone, and together with the latissimus dorsi cover it so completely that it cannot be felt through the skin. The infraglenoid tubercle gives origin to the long head of the triceps brachii. The *medial border* is thin and often angled opposite the root of the spine. A narrow strip, extending from the superior angle to the root of the spine, gives insertion to the levator scapulae. Below this, and opposite the root of the spine, the rhomboideus minor gains insertion. The remainder of the border is taken up by the rhomboideus major (p. 566).

The *upper border* of the scapula is thin and sharp. Near the suprascapular notch the inferior belly of the omohyoid is attached. Bridging the notch is the superior transverse ligament, attached laterally to the root of the coracoid process and medially to the limit of the notch, and the ligament is sometimes ossified. The foramen thus completed transmits the suprascapular nerve to the supraspinous fossa, whereas the suprascapular vessels pass backwards above the ligament.

The *inferior angle* of the scapula is covered dorsally by the upper border of latissimus dorsi, which frequently receives a small slip of origin from this part of the bone. The *superior angle* of



3.129 The left scapula. Lateral aspect.

the scapula is covered by the upper part of trapezius. The *lateral angle* bears the *glenoid cavity* to the margins of which the glenoidal labrum is attached. The surface of the cavity is covered with a layer of hyaline articular cartilage, thinnest at the centre and thickest at the periphery. Its anterior margin gives attachment to the glenohumeral ligaments (p. 457). To the *supraglenoid tubercle* the long head of the biceps brachii is attached.

The *spine of the scapula* gives attachment by its upper and lower surfaces to the supra- and infra-spinatus muscles. The flattened, triangular area at its root lies opposite the spine of the third thoracic vertebra and is played over by the tendon of the trapezius, a bursa intervening to facilitate this. The lower border of the crest is occupied by the posterior fibres of the deltoid. The upper border of the crest receives the insertion of the middle fibres of the trapezius. The lowest fibres of this muscle terminate in a flat triangular tendon which glides over the smooth area mentioned above and inserts into a roughened prominence, erroneously called the *deltoid tubercle*, on the dorsal aspect of the spine lateral to the area.

The *acromion* is subcutaneous over its dorsal surface, being covered only by the skin and superficial fascia. The lateral border, which is thick and irregular, and the tip of the process, as far round as the clavicular facet, give origin to the middle fibres of the deltoid. The medial aspect of the tip gives attachment, below the deltoid, to the lateral end of the coraco-acromial ligament. The articular capsule of the acromioclavicular joint is attached around the margins of the clavicular facet. Behind the facet, the medial border of the acromion gives insertion to the horizontal fibres of the trapezius. The inferior aspect of the acromion is relatively smooth, and together with the coraco-acromial ligament and the coracoid process forms an arch over the shoulder joint. The tendon of the supraspinatus passes below the overhanging acromion and is separated from it and from the deltoid by the subacromial bursae.

The *coracoid process* lies below the clavicle at the junction of the lateral fourth with the rest of the bone and is connected to its under surface by the coracoclavicular ligament. The attachment of the *conoid* part of the ligament has already been considered (p. 354); the *trapezoid* part is attached to the upper aspects of the horizontal part of the process (**3**.127). The superior aspect of the process receives also the insertion of the pectoralis minor. Its lateral border gives attachment to the wider, medial end of the coraco-acromial ligament and, below that, to the coracohumeral ligament. The enlarged tip of the process gives origin to the coracobrachialis, medially, and to the short head of the biceps,

3.130A and B The ossification of the scapula. 1. Coracoid centre. 2. Distal acromial centre. 3. Proximal acromial centre. 4. Centre at inferior angle. 5. Centre for medial border. 6. Glenoid centre. 7. Subcoracoid centre.

laterally. It is covered by the anterior fibres of the deltoid and can be felt only on moderately deep pressure through the lateral border of the infraclavicular fossa.

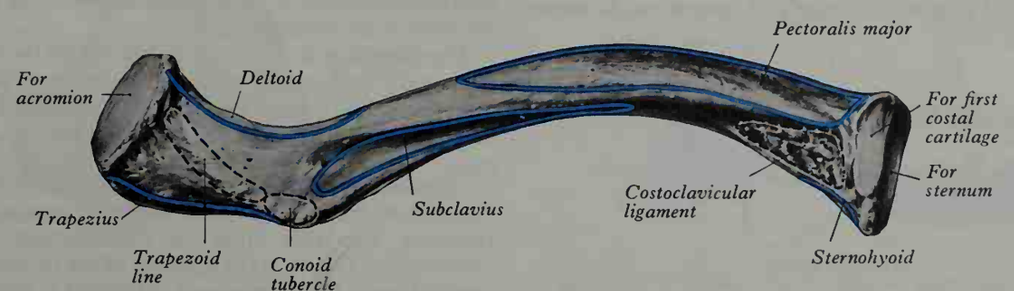
It has recently been emphasized that the presence of a coraco-acromial ligament in man is a trait shared only with other hominoids amongst the anthropoid primates (Ciochou and Corruccini 1977). For comparative studies these authors devised a *coraco-acromial projection index*, which represents the *projection height* (i.e. vertical distance from the supraglenoid tubercle to a line connecting the most lateral points on the tips of the acromion and coracoid process, divided by the *height of the glenoid cavity*. They suggest that their observations reflect the specialized locomotor/feeding adaptations of *Hominoidea*.

The main processes, and thickened parts of the scapula contain cancellous bone; the rest consists of a thin layer of compact bone. The central part of the supraspinous fossa and the greater part of the infraspinous fossa are thin and even translucent; occasionally the bone is deficient in these situations, the gaps being filled by fibrous tissue.

Ossification (3.130A and B). The cartilaginous scapula is ossified from eight or more centres: one in the body, two in the coracoid process, two in the acromion, and one each in the medial border, the inferior angle and the lower part of the rim of the glenoid cavity.

The centre for the body appears in the eighth week of intrauterine life. Ossification begins in the middle of the coracoid process in the first year, or in a small proportion of individuals before birth, and the process joins the rest of the bone about the fifteenth year. At or soon after puberty centres of ossification occur in the rest of the coracoid process (subcoracoid centre), in the rim of the lower part of the glenoid cavity, frequently at the tip of the coracoid process, in the acromion, in the inferior angle and contiguous part of the medial border and in the medial border. A variable area of the part of the glenoid cavity, usually the upper third, is ossified from the subcoracoid centre; it unites with the rest of the bone in the fourteenth year in the female and the seventeenth year in the male. A horseshoe-shaped epiphysis appears for the rim of the lower part of the glenoid cavity; thicker at its peripheral than at its central margin, it converts the flat glenoid cavity of the child into the gently concave fossa of the adult. The base of the acromion is formed by an extension from the spine; the rest of the acromion is ossified from two centres which unite and then join the extension from the spine. The various epiphyses of the scapula have all joined the bone by about the twentieth year.

The Clavicle



The clavicle (3.131, 132) extends almost horizontally across the root of the neck laterally towards the point of the shoulder; it is subcutaneous throughout its whole extent. It acts as a prop which struts the shoulder and enables the limb to swing clear of the trunk; it transmits part of the weight of the limb to the axial skeleton. The *lateral* or *acromial end* of the bone is flattened and articulates with the medial side of the acromion, whereas the *medial* or *sternal end* is enlarged and articulates with the clavicular notch of the manubrium sterni. The *shaft* is gently curved and in shape resembles the italic letter *f*, being convex forwards in its medial two-thirds and concave forwards in its lateral third. The *inferior* aspect of the intermediate third is grooved in its long axis.

The lateral third of the clavicle is flattened and has superior and inferior surfaces, limited by anterior and posterior borders. The *anterior border* is concave, thin and roughened and may be marked by a small *deltoid tubercle*. The *posterior border*, also roughened for muscular attachments, is convex backwards. The *superior surface* is roughened near its margins but smooth centrally, where it can be felt through the skin. The *inferior surface* presents two obvious markings. Close to the posterior border, at the junction of the lateral fourth with the rest of the bone, a prominent tubercle gives attachment to the conoid part of the coracoclavicular ligament and is termed the *conoid tubercle*. From the lateral side of this tubercle a narrow, roughened strip runs forwards and laterally, reaching almost as far as the acromial end (3.132). It is the *trapezoid line* to which the trapezoid ligament is attached.

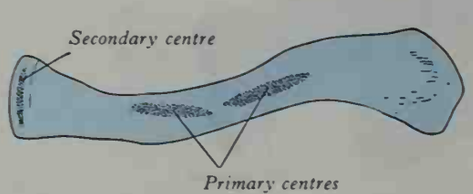
The medial two-thirds of the clavicle is cylindrical or prismatic in form and possesses four surfaces, but the inferior is often a mere ridge. The *anterior surface* is rough over most of its extent but smooth and rounded at its lateral end, where it is the upper boundary of the infraclavicular fossa (p. 567). The *superior surface*, also, is rough in its medial part and smooth laterally. The *posterior surface* is smooth, while the *inferior surface* is marked, near the sternal end, by a roughened oval impression, which is often depressed below the surface. Its margins give attachment to the costoclavicular ligament, which connects the clavicle to the upper surface of the first rib and its cartilage. Rarely, this area is smooth or raised to form an eminence which may articulate with the upper surface of the first rib by means of a synovial joint (Cave 1961). The lateral half of the inferior surface displays a groove in the long axis of the bone.

3.131 The right clavicle. Superior aspect.

3.132 The right clavicle. Inferior aspect.

The acromial end of the clavicle is flattened and has a small oval articular facet, which articulates with the medial aspect of the acromion at the acromioclavicular joint. The facet faces laterally and slightly downwards.

The sternal end of the clavicle is directed medially, and a little downwards and forwards, to articulate with the clavicular notch of the manubrium sterni. The sternal surface is quadrangular (sometimes triangular) and its upper part is slightly roughened for ligamentous attachments. Elsewhere the surface is smooth and articular, extending on to the inferior surface for a short distance, where it articulates with the first costal cartilage. The sternal end of the clavicle projects upwards beyond the manubrium sterni and can be felt, and often seen, in the lateral wall of the jugular fossa.



The *lateral third* of the shaft has attached to it the deltoid at its anterior border and the trapezius on its posterior border. Both encroach on the upper surface. The coracoclavicular ligament, attached to the conoid tubercle and the trapezoid line (**3**.132), transmits the weight of the upper limb to the clavicle. This weight is counteracted by activity of the trapezius which supports the lateral part of the bone (p. 565). From the conoid tubercle the weight is transmitted through the medial two-thirds of the shaft to reach the axial skeleton. Fracture of the clavicle medial to the conoid tubercle interrupts the line of weight transmission, so that practically the whole weight of the limb has to be supported by trapezius. The muscle is unable to meet the demand and the limb therefore drops on the affected side.

The *medial two-thirds* provides attachment anteriorly over most of its extent to the clavicular head of the pectoralis major, and, as a rule, the area is clearly indicated on the bone. The clavicular head of the sternocleidomastoid arises from the medial half of the upper surface, but the marking on the bone is not conspicuous. The smooth, *posterior surface* is devoid of muscular attachments except at its lower part immediately adjoining the sternal end, where the lateral fibres of the sternohyoid arise. Medially, this surface is related to the lower end of the internal jugular vein (from which it is separated by the sternohyoid), the termination of the subclavian vein and the commencement of the brachiocephalic vein. More laterally, it arches in front of the trunks of the brachial plexus and the third part of the subclavian artery. The suprascapular vessels are related to the upper part of this surface. The *inferior surface* gives insertion to the subclavius in the subclavian groove (**3**.132), and to the edges of the groove the clavipectoral fascia, which encloses the muscle, is attached. The posterior lip of the groove runs into the conoid tubercle and carries the fascia into continuity with the conoid ligament. A nutrient foramen occurs at the lateral end of the groove, running in a lateral direction. The nutrient artery concerned is derived from the suprascapular artery. The impression for the costoclavicular ligament is very variable in character.

The margins of the articular facet at the *acromial end* afford attachment to the articular capsule of the acromioclavicular joint.

The roughened, upper part of the *sternal end* provides attachment for the interclavicular ligament, the articular capsule and the articular disc of the sternoclavicular joint. The sternal surface, denuded of its articular cartilage, is rarely smooth and is usually irregular and somewhat pitted.

In women, the clavicle is shorter, thinner, less curved and smoother, and the acromial end is a little below the level of the sternal end; in men it is on a level with, or slightly higher than, the sternal end, with the arm hanging by the side, of course. The midshaft circumference is the most reliable single indicator of sex; but a combination of this with weight and length yields better results (Olivier 1951; Jit and Singh 1966). In those who perform hard manual labour the clavicle is thicker and more curved, and its ridges for muscular attachment are better marked. The clavicle consists of cancellous bone internally, enveloped by a layer of compact bone which is much thicker in the intermediate part than at the ends. Unlike most other long bones it does not possess a medullary cavity.

3.133 Diagram showing the three centres of ossification of the clavicle.

Ossification (**3**.133). The clavicle begins to ossify before any other bone in the body. The shaft is ossified from a pair of primary centres, medial and lateral, which appear in condensed mesenchyme between the fifth and sixth weeks of intrauterine life, and fuse about the forty-fifth day. A secondary centre for the sternal end appears in the late teens, or even early twenties, usually about two years earlier in the female. Fusion probably occurs quickly, but reliable figures are not available. A secondary centre sometimes develops at the acromial end at about 18 to 20, but the epiphysis so formed is always small and rudimentary and rapidly joins the rest of the bone (Todd and D'Erico 1928). In the most recent study of the sternal epiphysis, carried out on 684 Punjabees, ossification occurred from 11 to 19 years (both sexes) and fusion at 18 to 25 years (Jit and Kulkaria 1976). Comparison with other studies suggests racial differences. Assessment by radiological appearances is, of course, not devoid of fallacy.

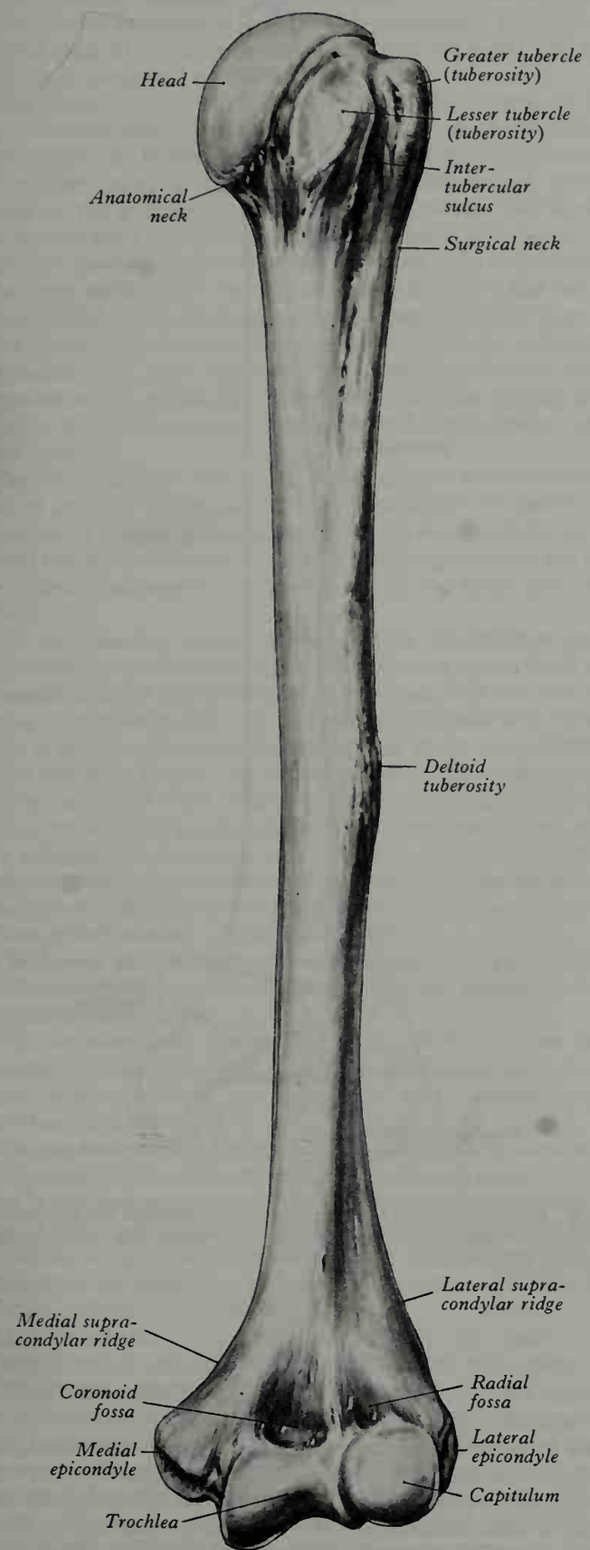
However, the full development of the clavicle is not exclusively by a process of simple intramembranous ossification. In a 14 mm embryo the future clavicle is represented by a band of condensed mesenchyme which extends from the acromion of the scapula to the tip of the first rib, and is continuous with the rudiment of the sternum. In this band medial and lateral zones of early cartilage transformation (so-called 'precartilage') occur, and in the mesenchyme between them two intramembranous centres of ossification for the body appear and soon fuse. The sternal and acromial zones soon transform into true cartilage, into which ossification of the body extends. Growth in length of the clavicle continues by longitudinal, interstitial growth of these terminal masses of cartilage, which develop zones of hypertrophy, calcification and an advancing front of endochondral ossification as in other growth cartilages. Girth increments follow appositional subperichondrial growth of the cartilaginous extremities and continued subperiosteal deposition of bone throughout the shaft. The epiphyses are formed endochondrally and fusion probably occurs as in other long bones, which, in contrast to the clavicle, are *primarily* cartilaginous.

Imperfections of ossification in the clavicle and other primarily intramembranous skull bones, are occasionally encountered together, in the condition of cleido-cranial dysostosis.

The primitive reptilian pectoral girdle comprises a dorsal element—the scapula—and two ventral elements, of which the anterior (cranial) is the precoracoid and the posterior (caudal) is the coracoid. The primitive girdle of the hind-limb also possesses three elements, of which the ilium is homologous with the scapula, the pubis with the precoracoid and the ischium with the coracoid. The clavicle, which is a dermal bone in origin and therefore morphologically distinct from the others, is an additional element in the pectoral girdle and is not represented in the pelvic girdle. It is doubtful whether any trace of the precoracoid persists in the human skeleton, although the presence of two primary centres for the clavicle is regarded by many authorities as an indication that the human clavicle corresponds both to the precoracoid and to the clavicle in the reptilian shoulder girdle. Others believe that the first coracoid centre to appear in man represents the precoracoid element, while the subcoracoid centre is regarded as representing the caudal ventral element in the reptilian girdle.

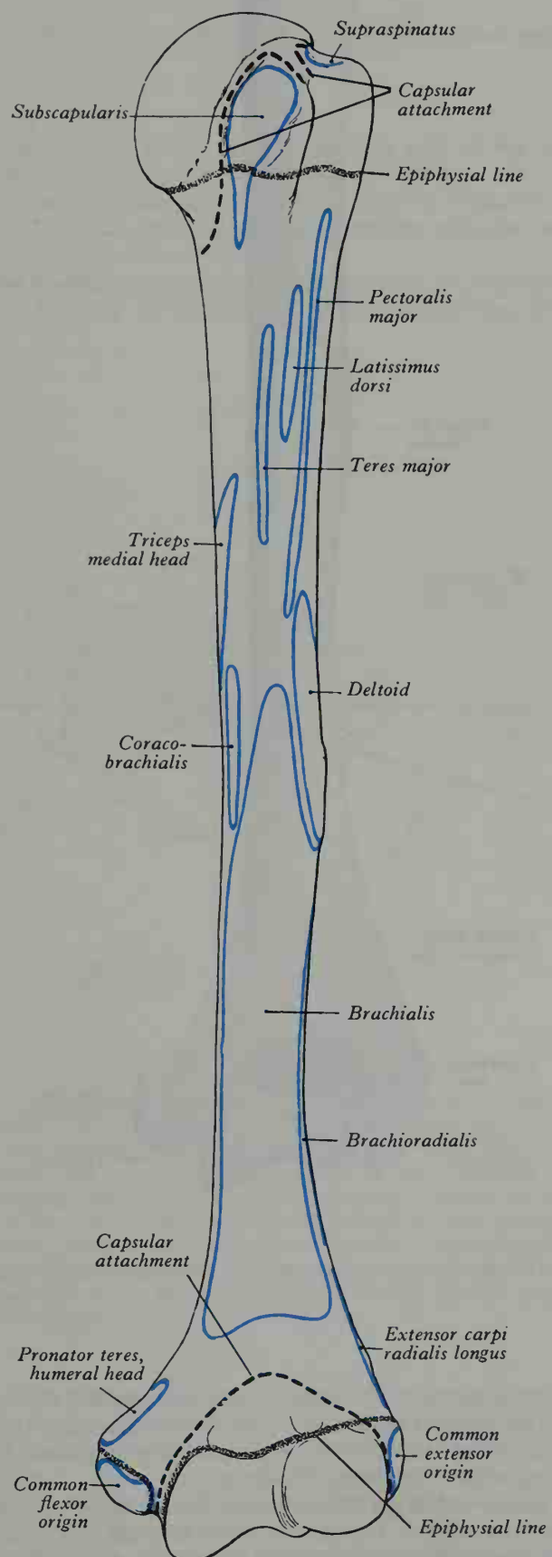
The clavicle is absent in animals in which the forelimbs are used principally or entirely for progression, e.g. the ungulates and carnivores, but it is present and well developed in animals which use the limb for prehension, e.g. many rodents, the primates and man.

Applied Anatomy. The clavicle is often fractured, commonly by indirect violence, the result of force applied to the hand or shoulder. the bone breaks at the junction of its lateral and intermediate thirds, at the junction of the two curves, for this is its weakest part. The consequent deformity is caused by the weight of the arm, which acts on the lateral fragment through the



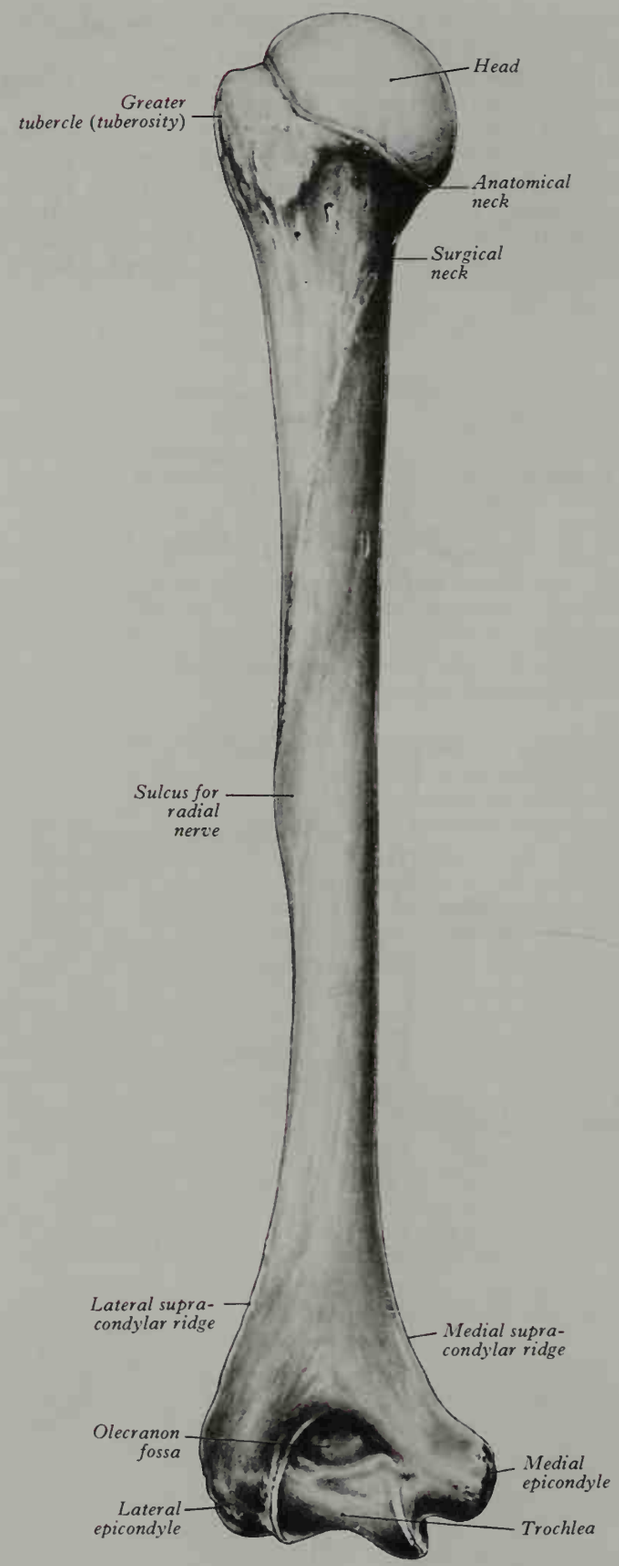
coracoclavicular ligament and draws it downwards. The medial fragment, as a rule, is little displaced.

The Humerus



The humerus (**3**.134–139) is the longest and largest bone of the upper limb. It comprises expanded upper and lower extremities and a shaft. Proximally a round 'head' articulates with the glenoid cavity of the scapula in a ball and socket joint (but *see* p. 456). The lower extremity is loosely termed 'condylar' in form, adapted to the forearm bones at the hinge of the elbow joint.

The upper end of the humerus consists of the articular head, and the greater and lesser tubercles.



The head of the humerus (**3**.134, 135) forms rather less than half a spheroid, and its smooth surface is covered with hyaline articular cartilage. When the arm is by the side, the head is directed medially, backwards and upwards to articulate with the glenoid cavity of the scapula. The humeral articular surface is much more extensive than the glenoid cavity, and only a portion

of it is in contact with the cavity in any one position of the arm.

The anatomical neck directly adjoins the margin of the head and is a slight constriction, which is least apparent in the neighbourhood of the greater tubercle.

The lesser tubercle (tuberosity) is on the anterior aspect of the bone immediately beyond the anatomical neck, and shows a smooth, muscular impression on its upper part. Although thickly covered by the deltoid it can be felt on deep pressure 3 cm below the tip of the acromion. The bony prominence moves under the examining finger when the humerus is rotated. The lateral edge of the lesser tubercle is sharp and forms part of the medial border of the intertubercular sulcus.

The greater tubercle (tuberosity) occupies the lateral part of the upper end of the humerus and is the most lateral bony point in the shoulder region. It projects beyond the lateral border of the acromion and, covered by the deltoid, is responsible for the normal rounded contour of the shoulder. The superior and posterior aspect of the tubercle adjoining the anatomical neck bears three flattened impressions for muscular attachments.

The two tubercles are separated by the **intertubercular**

sulcus. Where the upper extremity joins the shaft is a tapering region called the *surgical neck*. Close to this medially are the axillary nerve and the posterior humeral circumflex artery (3.135).

The shaft of the humerus is almost cylindrical in its upper half but triangular on section below this, where it is compressed in an anteroposterior direction. It can be felt when the arm is grasped firmly, but it is obscured by the strong muscles which clothe it. It presents three surfaces and three borders—which are not everywhere equally obvious.

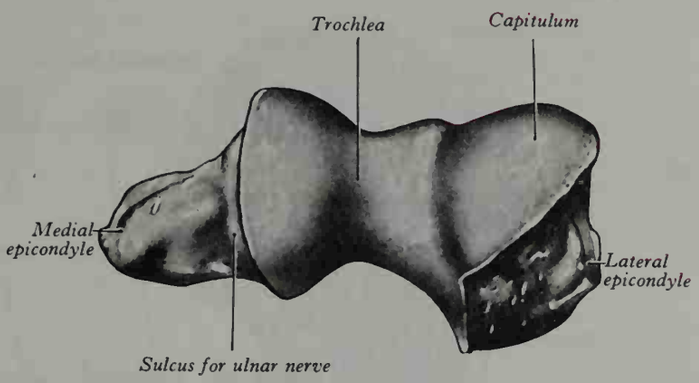
The *anterior border* commences above on the front of the greater tubercle and runs downwards almost to the lower end of the bone. Its upper third forms the lateral edge of the intertubercular sulcus and is roughened for muscular attachments. The succeeding portion is also roughened and forms the anterior limit of the deltoid tuberosity, but the lower half of the border is smooth and rounded.

The *lateral border* is conspicuous inferiorly where its sharp edge is roughened along its anterior aspect. In its middle and upper thirds the border is barely discernible to the eye, but in a well-marked bone it can be traced upwards to the posterior surface of the greater tubercle. About its middle the border is interrupted by a wide, shallow groove which crosses the bone obliquely, passing downwards and forwards from its posterior to its anterior surface. It is termed the *sulcus for the radial nerve*.

The *medial border*, although rounded, is clear in the lower half of the shaft. A little below the middle of the bone it presents a roughened strip, and superiorly it becomes indistinct until it reappears as the medial lip of the intertubercular sulcus. In this situation the border is again roughened and can be traced into the lesser tubercle.

The *anterolateral surface* of the humerus lies between the anterior and the lateral borders. A little above its middle it is marked by a roughened area, tapering to a point below, which is termed the *deltoid tuberosity*. Behind this the groove for the radial nerve runs downwards and fades away on the lower part of the surface.

The *anteromedial surface* is bounded by the anterior and the medial borders of the bone. Rather less than its upper third forms the rough floor of the intertubercular sulcus, but the rest of the surface is smooth. A little below its middle the nutrient foramen, which is directed downwards, opens close to the medial border.



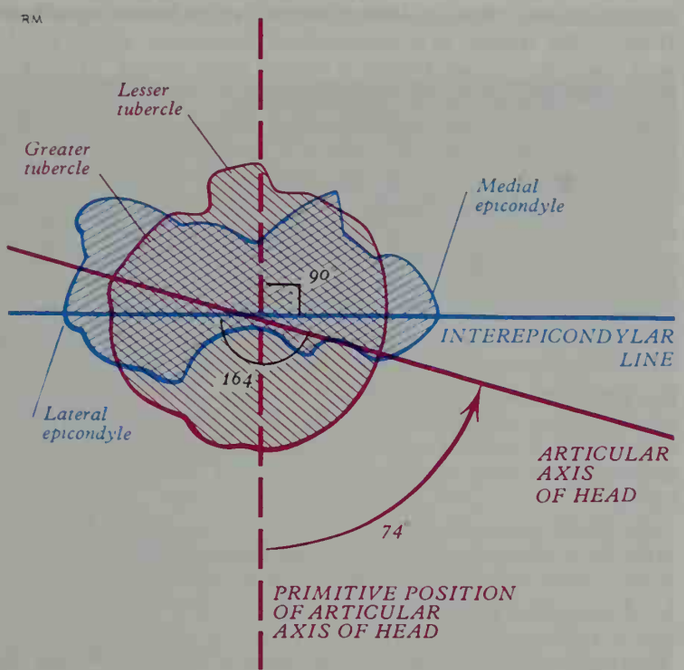
The *posterior surface* lies between the medial and the lateral borders and is the most extensive surface of the three. Its upper third is crossed by a faint ridge, sometimes roughened, which runs obliquely downwards and laterally. The middle third is crossed by the commencement of the groove for the radial nerve. Rather more than the lower third forms an extensive, flattened surface, which widens considerably below.

The lower end of the humerus (3.134, 135, 136), basically a modified *condyle*, is expanded transversely, and presents articular and non-articular parts.

The *articular part* adjoins the radius and the ulna in the formation of the elbow joint. It is divided by a faint groove into a lateral, convex surface, the capitulum, and a medial, pulley-shaped surface, the trochlea.

The capitulum is a rounded, convex projection, considerably less than half a sphere, formed of the anterior and inferior surfaces of the lateral part of the condyle of the humerus but not extending on to its posterior surface. It articulates with the disc-like head of the radius, which lies in contact with its inferior surface in full extension of the elbow but moves on to its anterior surface when the joint is flexed.

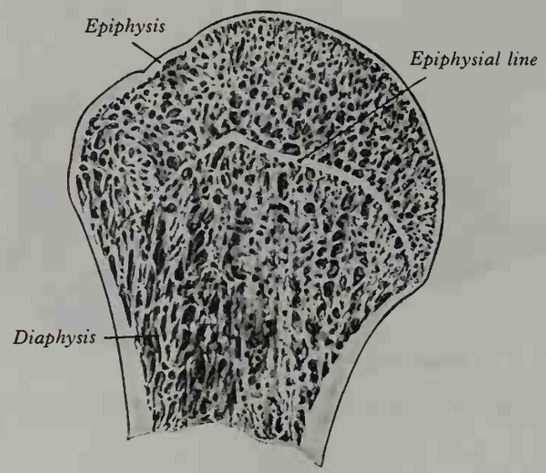
The trochlea is a grooved surface, like part of the circumference of a pulley, which covers the anterior, inferior and posterior surfaces of the condyle of the humerus. On its lateral side it is separated from the capitulum by a faint groove, but its medial margin is salient and projects downwards beyond the rest of the bone. The trochlea articulates with the trochlear notch of the ulna. When the elbow is extended the inferior and posterior aspects of the trochlea are in contact with the ulna, but, as the joint is flexed, the trochlear notch slides forwards on to the anterior aspect and the posterior aspect is then left uncovered. The downward projection of the medial edge of the trochlea is a major factor in determining the angulation which is present between the



3.136 The lower end of the left humerus. Distal (inferior) aspect.

long axis of the humerus and the long axis of the ulna and supinated forearm when the elbow is extended (p. 461).

The *non-articular part* of the condyle of the humerus includes the medial and lateral epicondyles, together with the olecranon, coronoid and radial fossae.



The medial epicondyle is a conspicuous, blunt projection on the medial side of the condyle. It is subcutaneous and easily

3.137 This diagram illustrates the concept of humeral 'torsion'. The left humerus is viewed distally along its length, with its proximal end (*magenta*) superimposed upon the distal (*blue*). The 'axes' of the two extremities are shown at right angles, as in early tetrapods and most quadrupedal mammals. In primates, including mankind, the axis of the head is directed medially, and the angle which this now makes with the 'primitive' anteroposterior position of the axis is the so-called angle of torsion. This is on average 74° in man: some authorities add to this the original angle of 90°, giving a total of 164°. See pp. 351 and 362 for more detailed explanation.

identified through the skin, especially in passive flexion of the elbow. Its posterior surface is smooth and crossed by the ulnar nerve, in a shallow sulcus, as it runs down into the forearm. In this situation the nerve can be felt and rolled against the bone. If the pressure exerted is sufficient, sensations are aroused identical with those produced when the nerve is jarred against the epicondyle. The lower part of the anterior surface of the medial epicondyle bears an impression for attachment of the superficial group of forearm flexor muscles.

The lateral epicondyle is the lateral part of the non-articular

3.138 A longitudinal section through the head of the right humerus in adolescence.

portion of the condyle, but does not project beyond the lateral supracondylar ridge. Its lateral and anterior surfaces display a well-marked impression for the origin of the superficial group of forearm extensor muscles. Its posterior surface, which is slightly convex, can easily be felt through the skin at the back of the elbow. It lies at the bottom of a well-marked depression, which can be seen when the extended elbow is viewed from behind. The lateral border of the humerus terminates at the *lateral epicondyle*, and its lower portion is the *lateral supracondylar ridge*. The medial border of the humerus terminates below at the *medial epicondyle*, and its lowest portion is the *medial supracondylar ridge*.

A deep hollow is situated on the posterior surface of the condyle, immediately above the trochlea. It is the *olecranon fossa*, because it contains the tip of the olecranon of the ulna when the elbow is extended. The floor of the fossa is always thin and may be partially deficient. A similar but smaller hollow lies immediately above the trochlea on the anterior surface of the condyle and is termed the *coronoid fossa*. It provides room for the anterior margin of the coronoid process of the ulna during flexion of the elbow. A very slight depression lies above the capitulum on the lateral side of the coronoid fossa, the *radial fossa*, to which the margin of the head of the radius is related in full flexion of the elbow.

In lower mammals the longest axes of the upper and lower articular surfaces of the humerus make an angle with each other of a little more than 90°. In man, however, the upper end of the humerus appears to have been rotated laterally, so that the angle between the two axes has been increased to about 164° (**3**.137). This angulation is referred to as the *angle of 'humeral torsion'*. It is greater in men than women, in adults than children, and in man than in anthropoid apes. Krahl (1976) claims that the angle also increases with age, up to the time of fusion of the epiphysis (see also p. 351).

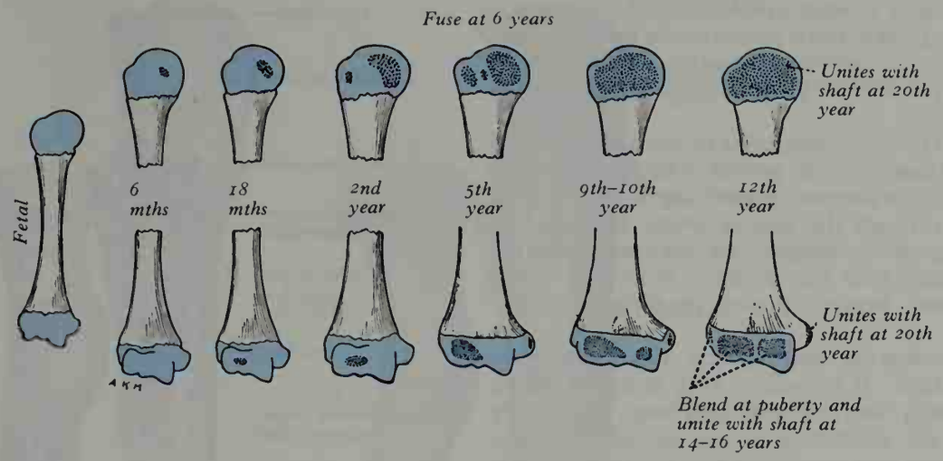
The *articular cartilage* which covers the *head* of the humerus is thickest at its centre and becomes thinner towards the circumference.

The *anatomical neck* gives attachment to the *capsular ligament* of the shoulder joint (**3**.134, 135), except at the upper end of the intertubercular sulcus, where the long tendon of the biceps emerges from the joint. On the medial side, however, the attachment extends downwards for 1 cm or more on to the shaft of the bone.

To the *lesser tubercle* the subscapularis is attached (**3**.134B) and to its sharp lateral margin the transverse ligament of the shoulder joint.

The *greater tubercle* shows three impressions for muscle insertions; the uppermost for supraspinatus, the middle for infraspinatus, the lowest, placed on the posterior surface of the tubercle, for the teres minor (**3**.135B). The projecting lateral surface of the tubercle presents numerous vascular foramina and is covered by the deltoid; a part of the subacromial bursa may cover the upper part of this area and separate it from the muscle.

The *intertubercular sulcus* (bicipital groove) is occupied by the long tendon of the biceps, its accompanying synovial sheath, and an ascending branch from the anterior circumflex humeral artery. The rough, lateral lip of the groove gives insertion to the tendon of the pectoralis major, its floor, to the tendon of latissimus dorsi, and its medial lip, to the tendon of the teres major. The insertion of the pectoralis major extends lower than the insertion of teres major, while the insertion of latissimus dorsi is the least extensive of the three. Below the intertubercular sulcus the anteromedial surface of the humerus is devoid of muscular attachment over a small area, but to its lower half the medial portion of the brachialis is attached (**3**.134B). The roughened strip on the middle of the medial border of the bone gives insertion to the coracobrachialis. Close to the lowest part of the medial supracondylar ridge a narrow area provides attachment for the humeral head of the pronator teres, and the ridge itself to the medial intermuscular septum of the arm.



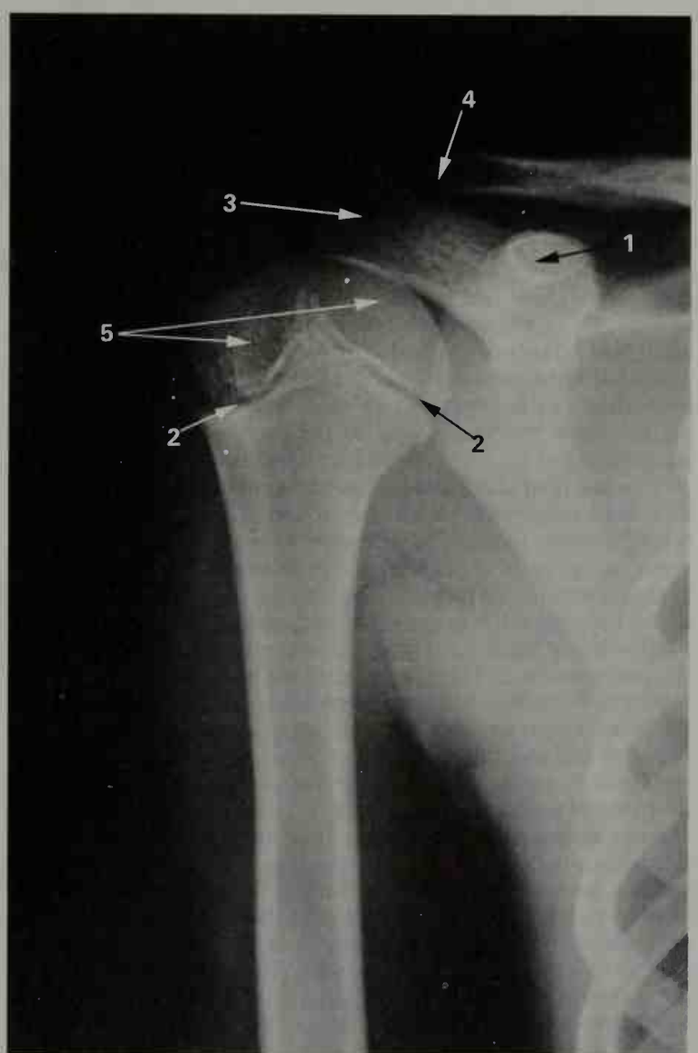
The oblique ridge which crosses the upper part of the *posterior surface* gives origin to the lateral head of the triceps. Above this muscle the axillary (circumflex) nerve and the posterior circumflex humeral vessels wind round this aspect of the bone under deltoid. Below and medial to the origin of the lateral head of triceps, a shallow groove, containing the radial nerve and the profunda vessels, runs downwards and laterally to gain the anterolateral surface of the shaft. The area for the fleshy medial head of the triceps includes a very large part of the posterior surface of the bone. It is an elongated triangular area, the apex of which is on the medial part of the posterior surface above the level of the lower limit of the insertion of teres major. The area widens below and covers the whole dorsal surface almost down to the lower end of the bone (**3**.135B).

The *anterolateral surface* of the humerus is smooth in its upper part, which is covered by the deltoid. A little above the middle of this surface the deltoid is attached to the deltoid tuberosity, and below this the surface is occupied by the lateral fibres of the brachialis, which extend upwards into the floor of the lower end of the radial groove (**3**.135B). The rough anterior aspect of the lateral supracondylar ridge gives origin by its upper two-thirds to brachioradialis and by its lower third to extensor carpi radialis longus. Behind these muscles the ridge is joined by the lateral intermuscular septum of the arm.

The *articular portion of the condyle* of the humerus is curved forwards, so that its anterior and posterior surfaces lie in front of the corresponding surfaces of the shaft. The groove of the trochlea winds backwards and laterally as it is traced from the anterior to the posterior surface of the bone, and it is wider, deeper and more symmetrical posteriorly. Anteriorly, the medial flange of the pulley is much longer than the lateral, and the surface adjoining its projecting medial margin is convex to accommodate itself to the medial part of the upper surface of the coronoid process of the ulna. These asymmetries are, of course, associated with the varying angulation between the humeral and ulnar axes.

The *capsular ligament of the elbow joint* (**3**.134B, 135B), is attached anteriorly to the upper limits of the radial and coronoid fossae, so that both these bony depressions are intracapsular and therefore covered by synovial membrane. It is also attached to the medial non-articular aspect of the projecting lip of the trochlea and to the root of the medial epicondyle. Posteriorly it ascends to, or almost to, the upper margin of the olecranon fossa, which is therefore intracapsular and covered with synovial membrane. Laterally it skirts the lateral borders of the trochlea and capitulum, lying medial to the lateral epicondyle.

The common origin of the superficial group of flexor muscles arises from the epiphysis for the medial epicondyle, entirely outside the articular capsule of the elbow joint. The common origin of the superficial group of extensor muscles of the forearm is attached to the lateral epicondylar part of the lower humeral epiphysis, and as in the case of the flexors, is outside the articular capsule. To a small area on the posterior surface of the lateral epicondyle the anconeus is attached (**3**.135B). The medial epicondyle is directed backwards a little at its extremity, whereas the lateral epicondyle shows a slight trend in the opposite direction.



3.139 Stages in the ossification of the humerus.

It should be observed that when the humerus is at rest by the side, the medial epicondyle lies on a plane which is much posterior to the plane of the lateral epicondyle. In this position the head of the humerus is directed almost equally *backwards* and *medially*, and the posterior surface of the shaft looks laterally and also backwards. Since the glenoid cavity faces forwards, as well as laterally, the humerus is not, in fact, rotated medially *relative to the scapula*, in this position of rest; but it *is* so rotated relative to the position of the arm in the *conventional anatomical position* of descriptive anatomy. This position of the bone must be kept in mind when the movements of the arm and forearm are considered (pp. 458 and 465; see also *Introduction*).

A hook-shaped process of bone, the *supracondylar process*, varying from 2 mm to 20 mm in length, is occasionally found projecting from the anteromedial surface of the shaft of the humerus, about 5 cm above the medial epicondyle. It is curved downwards and forwards, and its pointed end is connected to the medial border, just above the epicondyle, by a fibrous band from which part of the pronator teres arises; the foramen completed by this fibrous band usually encloses the median nerve and brachial artery. Sometimes the nerve travels through it alone, or it may be accompanied by the ulnar artery in cases of high division of the brachial. A groove, occupied by the artery and nerve, usually appears behind the process. This foramen is the homologue of the *entepicondylar foramen* found in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region. These skeletal features are regarded as valuable in assessing racial affinities (p. 238).

Ossification (**3**.139). The humerus is ossified from eight centres—one for each of the following parts: the shaft, the head, the greater tubercle, the lesser tubercle, the capitulum with the lateral part of the trochlea, the medial part of the trochlea, and one for each epicondyle. The centre for the shaft appears near its middle in the eighth week of intrauterine life, and gradually extends towards its ends. Ossification usually commences in the humeral head in the first six months after birth, but just before this in a fifth of individuals. The greater and lesser tubercles begin to ossify in the second and fifth years in males, and about a year earlier in females. By the sixth year the centres for the head and tubercles have joined to form a single large epiphysis, which is hollowed out on its inferior surface (**3**.138) to adapt it to the somewhat conical upper end of the diaphysis. It fuses with the shaft of the humerus about the twentieth year in males, about two years earlier in females. Some observers deny the existence of a centre for the lesser tubercle, perhaps because it is often obscured in the usual anteroposterior views of the shoulder (**3**.140). The lower end is ossified as follows. During the first year ossification begins in the capitulum and extends medially to form the chief part of the articular surface; the centre for the medial part of the trochlea appears in the ninth year in females and tenth year in males. Ossification begins in the medial epicondyle in the fourth year in females and the sixth year in males and in the lateral epicondyle about the twelfth year. The centres for the lateral epicondyle, capitulum and trochlea fuse around puberty and the large epiphysis thus formed unites with the shaft in the fourteenth

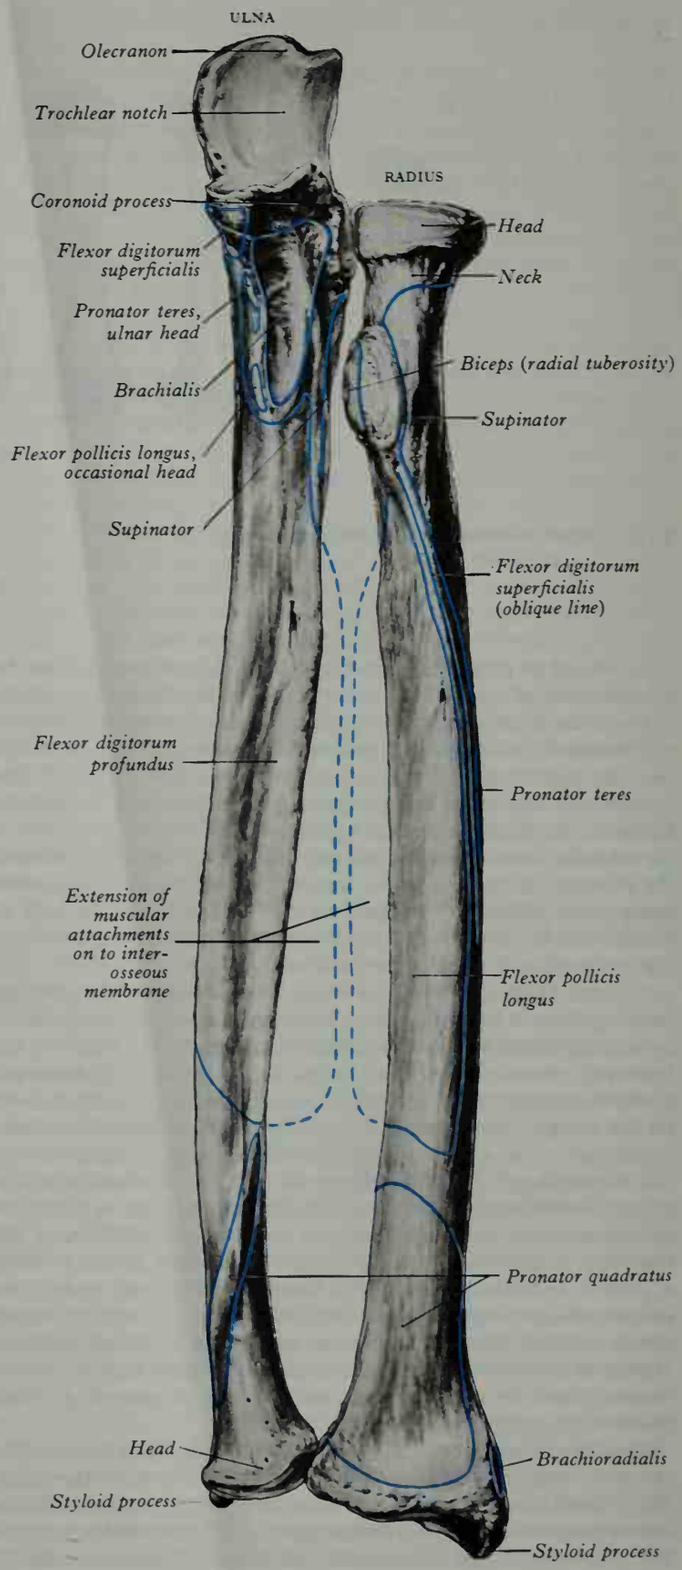
year in females and sixteenth year in males. The centre for the medial epicondyle forms a separate epiphysis, which is entirely extracapsular (**3**.134B, **3**.135B) and is placed on the posteromedial aspect of the epicondyle. It is separated from the rest of the lower epiphysis by a downgrowth from the shaft, with which it unites about the twentieth year.

Applied Anatomy. The upper epiphysis of the humerus joins the shaft later than the lower, and the growth in length of the bone is due predominantly to the proximal growth cartilage. Hence, in cases of amputation through the arm in young subjects, the humerus continues to grow considerably, and the lower end of the bone, which immediately after the operation is covered with a thick cushion of soft tissue, begins to project, rendering the stump conical.

Fractures of the humerus are comparatively common and may occur at almost any level. It is fractured by muscular action probably more frequently than any other long bone; it is usually the shaft, just below the attachment of deltoid, which is thus broken. The radial nerve may be injured as it lies in its groove; rarely it is involved later in the growth of callus. Non-union is frequent and, indeed, commoner than in any other bone except the tibia. Fractures of the upper end of the bone may damage the axillary nerve, while fractures of the medial epicondyle may be complicated by damage to the ulnar nerve. The late fusion of the ossifying medial epicondyle sometimes leads to a fallacious diagnosis of fracture in this region.

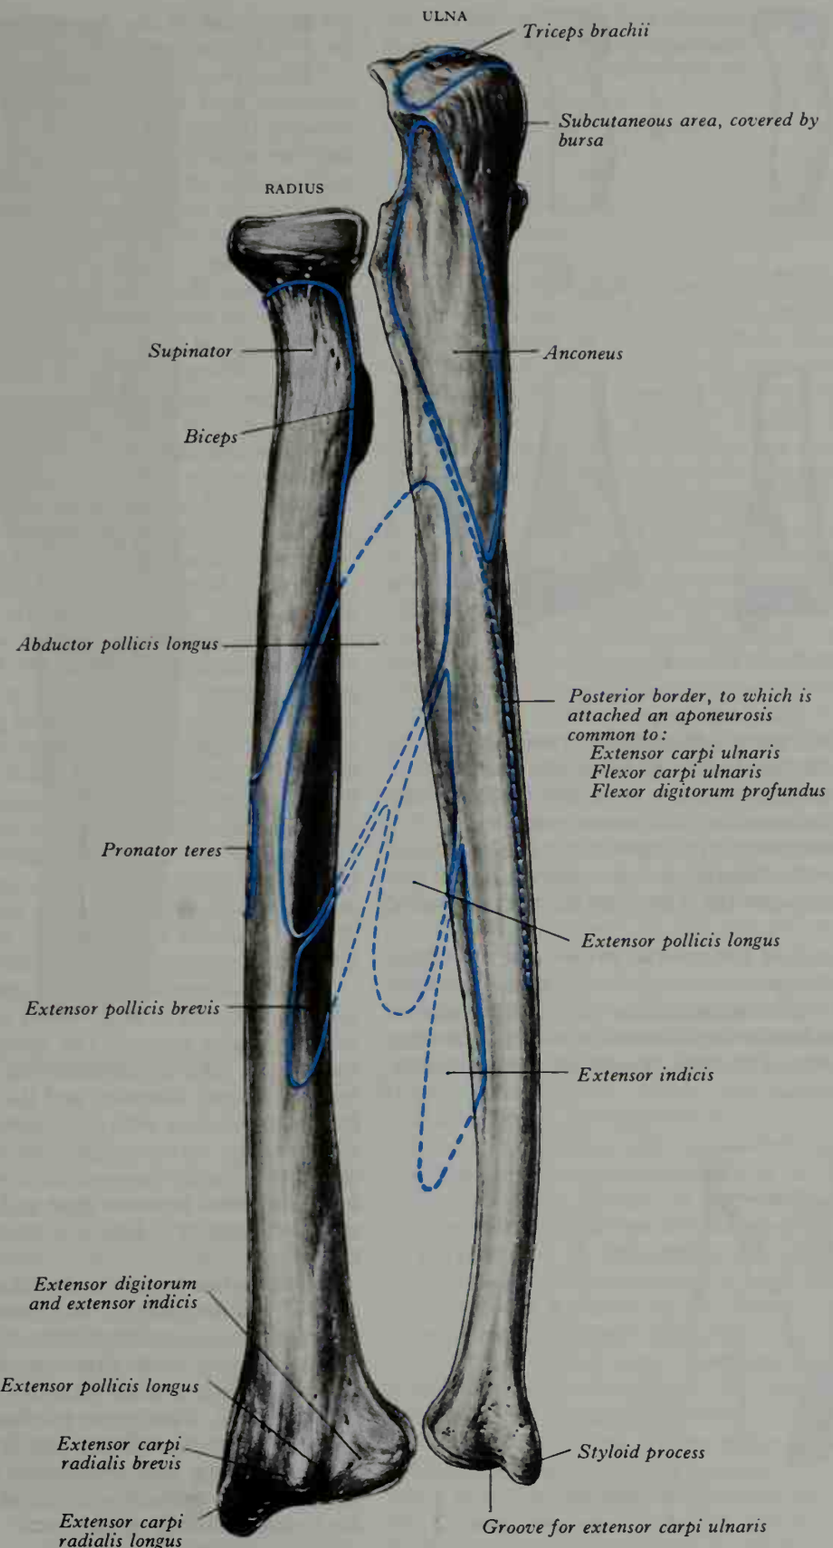


The Radius

The radius (**3**.141–144) is the lateral bone of the forearm. Its upper and lower ends are expanded, but the lower end is much the wider of the two. The shaft increases in breadth rapidly towards the lower end, is convex laterally and is concave forwards in its lower part.

The upper end of the radius includes a head, neck and tuberosity. *The head* is disc-shaped and its upper surface is a shallow cup for articulation with the capitulum of the humerus. The *articular circumference* of the head is smooth and widest medially, where it articulates with the radial notch of the ulna. Its posterior surface can be felt through the skin as it lies at the bottom of a small depression which is visible in the living subject on the lateral side of the posterior surface of the extended elbow. The *neck* of the radius is the constricted part below the head, and is overhung by it, especially on the lateral side. *The tuberosity* is placed below the medial part of the neck. Its posterior part is roughened but anteriorly is usually smooth.

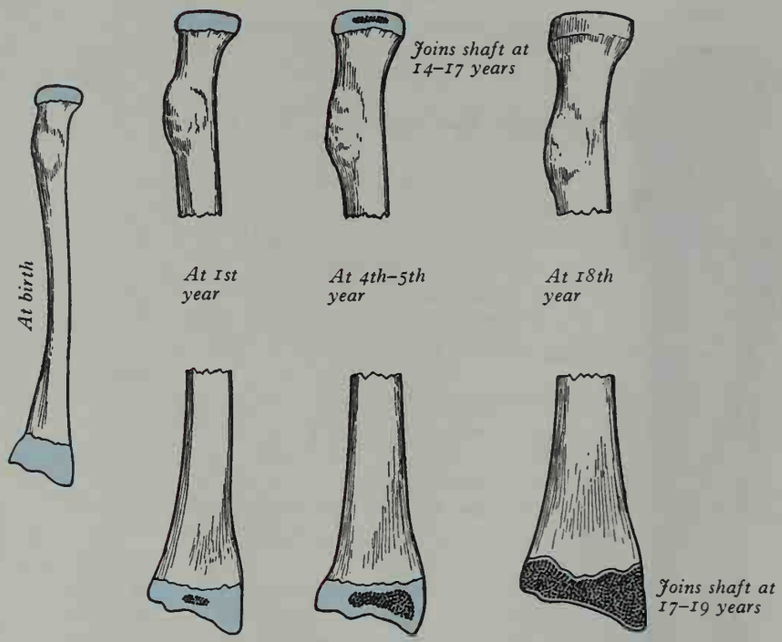
The shaft of the radius is gently curved with the convexity directed laterally. On transverse section it is triangular, but only one of its three margins is sharp, the *interosseous border*, a salient crest, except at its upper end, where it approaches the lower part of the tuberosity. At its lower end it forms the posterior margin of a small, elongated, triangular area, an additional, medial, surface for this end of the bone. To the lower three-fourths of this border the interosseous membrane is attached; it connects the opposed borders of the two forearm bones. The *anterior border* can be recognized without difficulty at its upper and lower ends, but it is rounded and indefinite in the intervening region. It commences just below the anterolateral part of the tuberosity and runs downwards with a lateral inclination. This part is described as the *anterior oblique line* of the radius. The lower part of the anterior border forms a sharp crest along the lateral margin of the anterior surface, and can even be felt through the skin. The *posterior* border is clearly defined in its middle third only. Above, it runs obliquely upwards and medially towards the postero-inferior part of the tuberosity. Below, it forms a rounded ridge which is difficult to trace.



The *anterior surface* lies between the anterior and interosseous borders. It is slightly concave from side to side and curves forwards at its lower end. A little above its middle is a nutrient foramen, directed upwards. The *posterior surface*, which is bounded by the interosseous and the posterior borders, is generally flat but may be slightly hollowed out in its upper part The *lateral surface* is gently convex in all directions. Above, owing

3.141 The bones of the left forearm. Anterior aspect.

to the obliquity of the upper parts of the anterior and posterior borders, it encroaches on the anterior and posterior aspects of the bone, and this widened portion is usually slightly roughened. A finely irregular, rough surface occupies an oval area near the middle of the shaft, but below this the surface of the bone is smooth and featureless.



The lower end of the radius, the widest part, is four-sided on transverse section. Its *lateral surface* is slightly rough and projects downwards beyond the rest of the bone to form *the styloid process*. This projection can be felt through the skin, when the tendons which conceal it in the living body are relaxed. The inferior

3.142 The bones of the left forearm. Posterior aspect.

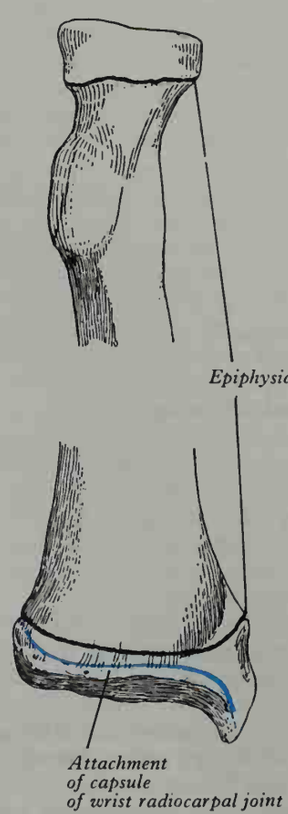
surface of the lower end (**3**.147) is smooth and takes part in the formation of the wrist joint. This *carpal articular surface* is divided by a faint ridge into medial and lateral areas. The medial area is quadrangular, the lateral is triangular and covers the medial side of the styloid process. The *anterior surface* is a thick, prominent ridge, which can be palpated in the living subject, despite the overlying tendons. It is nearly 2 cm above the base of the thenar eminence. The *medial surface* is the *ulnar notch*, a smooth strip, concave from before backwards, for articulation with the head of the ulna in the inferior radio-ulnar joint. The *posterior surface* is marked by the *dorsal tubercle*, which is limited medially by a narrow, oblique groove. It lies in line with the cleft between the index and middle fingers and can readily be felt through the skin. A wide, shallow groove lies lateral to the tubercle and is divided into two parts by a very faint vertical ridge. A similar but undivided groove marks the medial part of the posterior surface.

The upper surface of the *head* and its *articular circumference* are everywhere covered with hyaline cartilage. The upper margin of the head fits into the groove between the capitulum and the trochlea, and, when the forearm is flexed, it invades the radial fossa. The articular circumference joints with the radial notch of the ulna, and in the rest of its extent is surrounded by the annular

3.143 Stages in the ossification of the radius.

ligament, within which it rotates in pronation and supination. The *neck* of the bone is surrounded by the narrower, lower part of the ligament, but is separated from it by a protrusion of the synovial membrane of the superior radio-ulnar joint.

To the rough, posterior part of the *tuberosity* the biceps tendon is attached, but its smooth, anterior part is separated from the tendon by a bursa. A little below the tuberosity the oblique cord is attached to the radius.



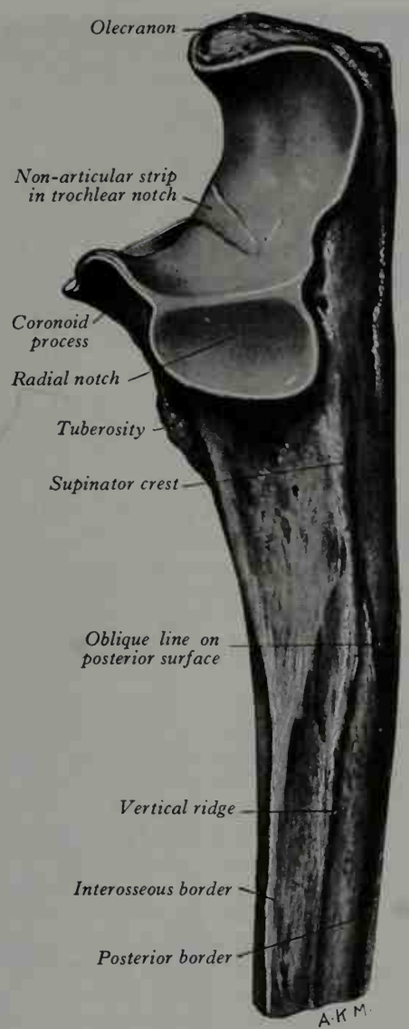
The upper, oblique part of the *anterior border* and a variable portion of the border below provide origin for the thin, expanded radial head of the flexor digitorum superficialis. The conspicuous lower part of the anterior border has attached to it the lateral edge of the extensor retinaculum. The small, triangular area in front of the lower end of the interosseous border and above the ulnar notch is for the deepest fibres of the pronator quadratus.

The upper two-thirds of the *anterior surface* provides an extensive area for the origin of flexor pollicis longus, which conceals the nutrient foramen. The lower fourth of this surface, together with the triangular area on the medial side of the bone, receives the pronator quadratus. The roughened area at the middle of the *lateral surface* is situated at the region of maximum curvature for the attachment of the pronator teres. Above, the surface widens at the expense of the anterior and posterior surfaces, and the elongated V-shaped area (**3**.141, 142) provides insertion for the supinator. Below the insertion of the pronator teres the lateral surface is smooth and covered by the tendons of the radial extensors of the wrist. The upper part of the *posterior surface* gives origin to the abductor pollicis longus, above, and the extensor pollicis brevis, below. The lower part of this surface is devoid of muscular attachments but is closely covered by the extensor pollicis brevis and longus muscles.

The *styloid process* of the radius projects below the ulnar styloid, and its tip is concealed by the tendons of the abductor pollicis longus and extensor pollicis brevis. It gives attachment by its tip to the lateral ligament of the wrist joint. The lateral surface of the radius a little above the styloid process receives the insertion of the brachioradialis and is crossed obliquely, from above downwards and forwards, by the tendons of the abductor pollicis longus and extensor pollicis brevis. The ridge-like *anterior surface* of the lower end gives attachment to the palmar radiocarpal ligament of the wrist joint. The *ulnar notch* is limited below by a smooth ridge to which the base of the articular disc of the inferior radio-ulnar joint is attached. A small protrusion of the synovial membrane of the joint extends upwards in front of the lower end of the interosseous membrane. The lateral, triangular part of the *carpal articular surface* joints with the scaphoid and the medial, quadrangular part with the lateral part of the lunate bone. When the hand is adducted fully the whole of the upper surface of the lunate bone comes into contact with the radius.

The *dorsal tubercle* gives attachment to a slip from the extensor retinaculum and is grooved on its medial side by the extensor pollicis longus tendon. The wide, shallow groove to the lateral side of the tubercle contains the tendons of the extensor carpi radialis longus, laterally, and the extensor carpi radialis brevis, medially, together with the synovial sheaths. The medial part of the posterior surface is grooved by the tendons of the extensor digitorum, but the extensor indicis and the posterior interosseous nerve intervene between them and the bone. To the lower margin of the posterior surface is attached the dorsal radiocarpal ligament.

Ossification (**3**.143, 144). The radius is ossified from three centres: one for the shaft, and one for each end. That for the shaft appears near the middle in the eighth week of intrauterine life. About the close of the first year, ossification begins in the lower end. At the upper end it begins at the fourth year in females and fifth in males. The upper epiphysis fuses with the shaft at the fourteenth year in females and seventeenth in males; the lower epiphysis at the seventeenth and nineteenth years respectively. An additional centre sometimes appears in the tuberosity about the fourteenth or fifteenth year.



3.144 The epiphysial lines of the left radius in adolescence. Anterior aspect. The line of attachment of the articular capsule of the wrist joint is in blue.

The Ulna

The ulna (**3**.141, 142, 145) is the medial bone of the forearm and is parallel with the radius when the forearm is supine. The upper end is thick, strong and hook-like (**3**.145), the concavity of the hook being directed forwards. The lateral border of the shaft is a thin, sharp crest. The bone diminishes in size from its upper to its lower end, which bears a small, rounded enlargement termed the head of the ulna. The shaft is triangular on section.

The bone is not perfectly straight, and shows a slight but appreciable double curve. Throughout its whole length it forms a gentle curve, the convexity of which is directed backwards. In addition, the upper half or more shows a slight curvature to the lateral side, and the lower half or less a similar curvature in the opposite direction.

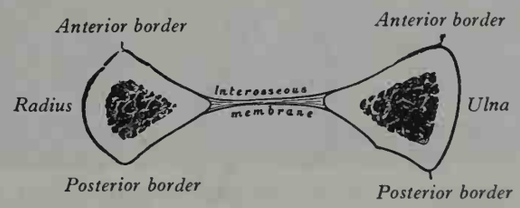
3.145 The proximal part of the left ulna. Lateral aspect.

The upper end of the ulna (3.145) displays two substantial processes, the olecranon and coronoid, and two articular areas, termed the trochlear and radial notches, which articulate, respectively, with the humerus and the radius.

The *olecranon* is the uppermost part of the bone. It is bent forwards at its summit to form a prominent beak, which projects into the olecranon fossa of the humerus when the forearm is extended. Its posterior surface, which is smooth and triangular in outline, can easily be felt through the skin, and its upper border forms the point of the elbow. When the elbow is extended, this border can be felt on, or just above, the line joining the two epicondyles of the humerus, but when the elbow is flexed, it descends, and the three bony points then form the angles of an isosceles triangle. The anterior surface of the olecranon is smooth and articular, and forms the upper part of the trochlear notch. The base of the olecranon is constricted where it joins the shaft, and this is the narrowest part of the upper end of the ulna.

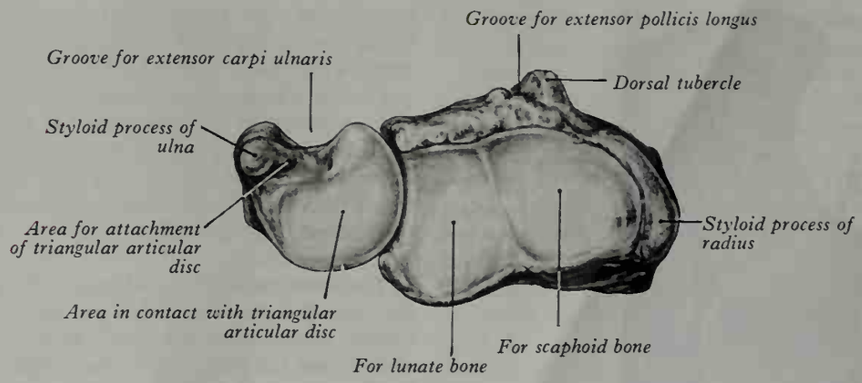
The *coronoid process* is a bracket-like projection from the front of the bone immediately below the olecranon. Its upper surface forms the lower part of the trochlear notch and is therefore smooth and articular. The upper part of the lateral surface presents the shallow *radial notch* for articulation with the side of the head of the radius, and the bone below it is hollowed out to make room for the tuberosity of the radius during the movements of pronation and supination. The anterior surface of the process is triangular in shape and bears on its lower part the rough *tuberosity of the ulna*. The medial border of the process is sharp and bears a small, but prominent tubercle at its upper end.

The *trochlear notch* articulates with the trochlea of the humerus. It is formed by the anterior surface of the olecranon and the superior surface of the coronoid process. The bone is constricted at the junction between these two areas, and they may be separated completely by a narrow, roughened strip. A smooth ridge, which corresponds to the groove of the trochlea, divides the notch into a larger, medial, and a smaller, lateral part. The medial part conforms to the large flange of the trochlea of the humerus.



The *radial notch* (3.145) is an oblong, articular depression on the upper part of the lateral aspect of the coronoid process. It forms a joint with the articular circumference of the head of the radius, and is separated from the lateral part of the trochlear notch by a smooth ridge.

The lower end of the ulna is slightly expanded and comprises the rounded head and the styloid process. The *head* forms a surface elevation on the medial part of the posterior aspect of the wrist when the hand is pronated, and it can be gripped between the finger and thumb when the supinated hand is passively flexed. It presents a convex articular surface on its lateral side for articulation with the ulnar notch of the radius. Its inferior surface (3.146) is smooth and is separated from the carpus by the articular disc of the inferior radio-ulnar joint, which is attached by its apex to the small rough area between the articular surface and the styloid process. The *styloid process* is a short, rounded projection which springs from the posteromedial aspect of the lower end of the ulna. Its tip can be felt through the skin on the posteromedial aspect of the wrist, where it lies about 1 cm above the tip of the styloid process of the radius. On the dorsal surface is a shallow groove between the head and styloid process.



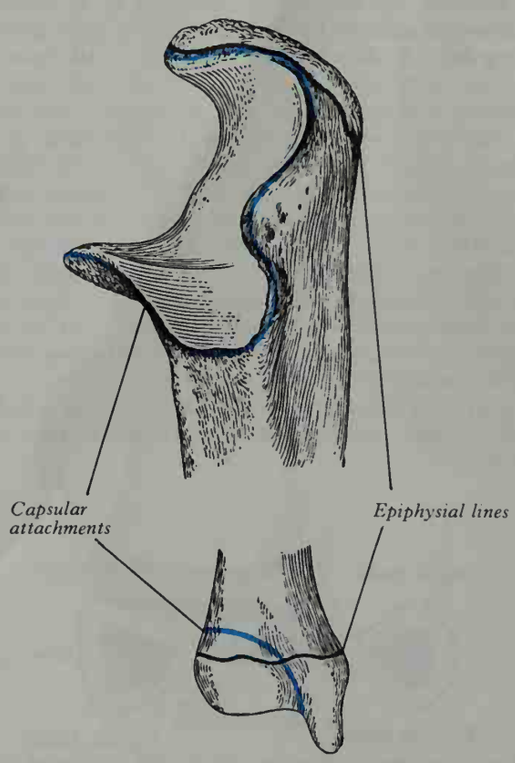
The shaft of the ulna is triangular in section (3.146) in its upper three-fourths, but is almost cylindrical in its lower quarter. The surfaces of the shaft are anterior, posterior and medial; the borders, interosseous, posterior and anterior.

The *interosseous border* is the lateral margin of the bone and forms a conspicuous crest in its middle two-fourths. The upper part is continuous with the posterior border of the depression below the radial notch and is here termed the *supinator crest*; its lower part fades away on the cylindrical, lower portion of the shaft. The *anterior border* is thick and rounded. It commences above medial to the ulnar tuberosity and inclines backwards below, where it can usually be traced to the base of the styloid process. The *posterior border*, also thick and rounded, commences at the apex of the posterior aspect of the olecranon and curves laterally as it decends. Below, very indistinct, it descends to the styloid process. Throughout its whole length this border can easily be felt through the skin. It lies in a longitudinal furrow, which is seen best when the elbow is in full flexion.

The *anterior surface* of the ulna (3.141), between the interosseous and anterior borders, is grooved, sometimes deeply, in its long axis. A little above the middle of the bone on this surface is the nutrient foramen (3.141), which is directed upwards and transmits a branch of the anterior interosseous artery. Its inferior part is crossed obliquely by a rough strip, of variable prominence, which runs downwards from the interosseous border to the anterior border. The *medial surface* is bounded by the anterior and posterior borders. Convex from side to side, it is smooth and featureless. The *posterior surface* (3.142) lies between the posterior and interosseous borders. It is divided into three areas, of which the uppermost is limited by an oblique line—not always easily discernible—which runs upwards and laterally from the junction of the middle and upper thirds of the posterior border to the posterior end of the radial notch (3.145). The region below this line is divided into a larger medial and a narrower lateral strip by a vertical ridge, usually distinct in its upper three-fourths but less clear below.

3.146 A transverse section through the left radius and ulna, showing the attachment of the antebrachial interosseous membrane. Superior aspect.

3.147 The distal ends of the right radius and ulna. Distal (inferior) aspect.



The upper surface of the *olecranon* gives attachment, in front, to the capsular ligament of the elbow joint, in its roughened posterior two-thirds, to the tendon of the triceps. Occasionally these two areas are separated by a smooth bursal area. Its medial surface is marked in its upper part by a rough elevation, the site of attachment of the posterior and oblique bands of the ulnar collateral ligament of the elbow joint and the ulnar head of flexor carpi ulnaris. Its lower part is smooth and gives origin to the uppermost fibres of the flexor digitorum profundus. The lateral surface of the process, and the adjoining part of the posterior surface of the shaft down to the oblique line already mentioned (**3**.145), affords attachment to the anconeus. Its posterior surface is separated from the skin by a bursa.

To the anterior surface of the *coronoid process*, including the tuberosity of the ulna, is attached the brachialis. Its medial border is sharp, and a small, rounded tubercle is situated at its upper end to which are attached the oblique and anterior bands of the ulnar collateral ligament of the elbow joint and the lowest part of the humero-ulnar head of the flexor digitorum superficialis. Below the tubercle the margin gives origin to the ulnar head of the pronator teres. An ulnar head of the flexor pollicis longus may arise from the lateral or, more rarely, the medial border of the coronoid process (Martin 1958). The medial surface of the process is concave and has attached to it fibres of the flexor digitorum profundus. The anterior border of the radial notch provides attachment to the annular ligament of the radius, the posterior attachment of which is usually marked by a rough ridge at or just behind the posterior margin of the notch. The depressed area below the notch is limited behind by the *supinator crest*; the supinator arises from the crest and from much of the depression anterior to it.

The part of the *trochlear notch* formed by the olecranon is, typically, divided into three areas. Of these the most medial faces forwards and slightly medially and is hollowed out to fit the medial flange of the humeral trochlea: the intermediate area is flattened and fits the lateral flange of the trochlea; the most lateral area, which forms a narrow strip directed to the radial side, comes into contact with the trochlea only when the elbow is extended. The constriction of the articular surface is more pronounced than the constriction of the base of the olecranon. The resulting small non-articular parts of the anterior surface of the olecranon are covered in the fresh specimen and in life by tag-like processes of the synovial membrane which contain a little fat (**4**.44). The coronoid part of the trochlear notch is divided into medial and lateral parts, which correspond, respectively, to the medial and intermediate parts of the olecranon area. Of these the medial is hollowed out much more than the lateral, in conformity with the convexity of the medial flange of the trochlea (*see* carrying angle, p. 462). The medial and anterior borders of this area give attachment to the medial and anterior portions of the capsular ligament of the elbow joint.

The subcutaneous *posterior border* of the ulna gives attachment to the deep fascia of the forearm, which acts, in its upper three-fifths, as an additional origin for the flexor carpi ulnaris, and in its middle third as an additional origin for the extensor carpi ulnaris. Both these muscles are therefore connected to the posterior border. The *interosseous border*, except at its upper end, gives attachment to the interosseous membrane. The rounded *anterior border* is covered in its upper three-fourths by the flexor digitorum profundus, which is attached to it.

The *anterior surface* gives origin in its upper three-fourths to the flexor digitorum profundus. In the same extent the muscle arises also from the anterior border and the *medial surface*, extending upwards on to the medial sides of the coronoid process and the olecranon. The rough strip which crosses the lower fourth of the anterior surface marks the attachment of the pronator quadratus. The anconeus is inserted into the *posterior surface* above the oblique line already mentioned, and extends upwards on to the lateral aspect of the olecranon. The narrow strip between the interosseous border and the vertical ridge affords partial origin to three of the deep muscles of the forearm. The abductor pollicis longus arises from its upper fourth, and a ridge may separate this area from the succeeding fourth, which gives attachment to the extensor pollicis longus. The extensor indicis is

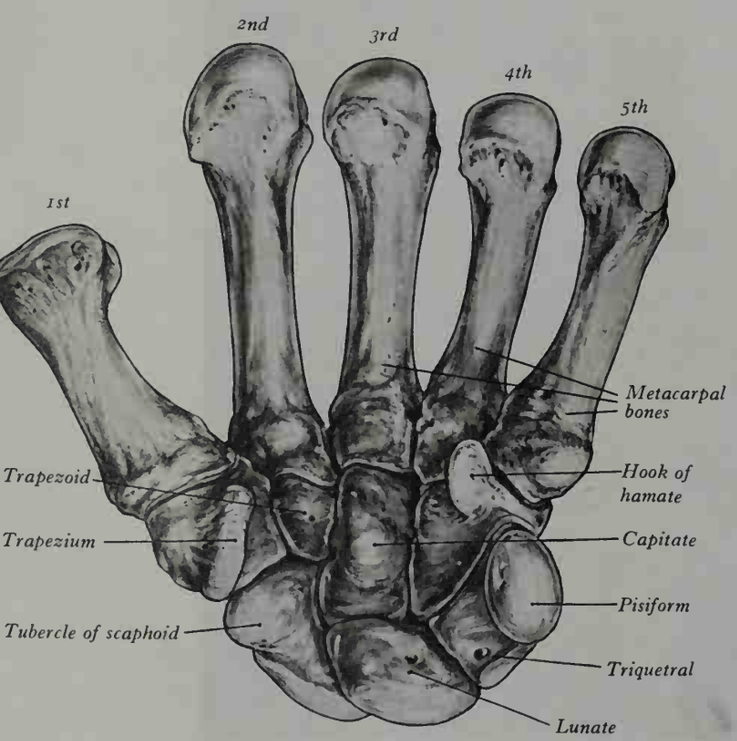
attached to the third quarter of this area. The broad strip to the medial side of the vertical ridge is devoid of muscular attachments but is covered by the extensor carpi ulnaris, the tendon of which occupies the groove on the posterior aspect of the lower end of the bone. The ulnar collateral ligament of the wrist joint is attached to the tip of the *styloid process*. The articular disc separates the *head* of the ulna from the medial part of the lunate bone and, in adduction of the hand, from the triquetral bone.

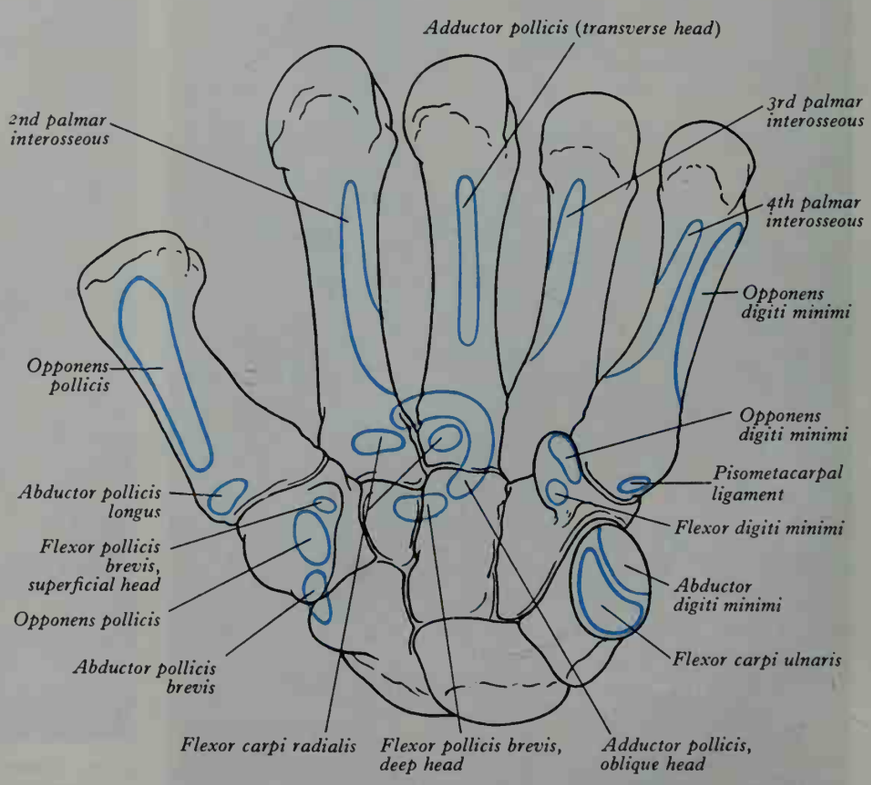
For an account of the vascularization of the ulna consult Fischer *et al.* (1974).

Ossification (**3**.148, 151). The ulna is ossified from three centres: one each for the shaft, the lower end, and the proximal part of the olecranon. Ossification begins near the middle of the shaft, about the eighth week of intrauterine life, and soon extends through its greater part. In the fifth year in females and sixth in males the centre for the lower end appears in the middle of the head, and extends into the styloid process. The lower part of the olecranon is ossified by an upward extension of the shaft. The remainder is ossified from two centres; the lower forms the upper part of the trochlear surface; the upper is a thin scale-like epiphysis on top of the process (Porteous 1960). The latter appears in the ninth year in females and eleventh in males, and the whole of the upper epiphysis has joined with the shaft by the fourteenth year in females and sixteenth in males. The lower epiphysis of the ulna unites with the shaft in the seventeenth year in females and the eighteenth in males. All these dates are, of course, subject to some variation.



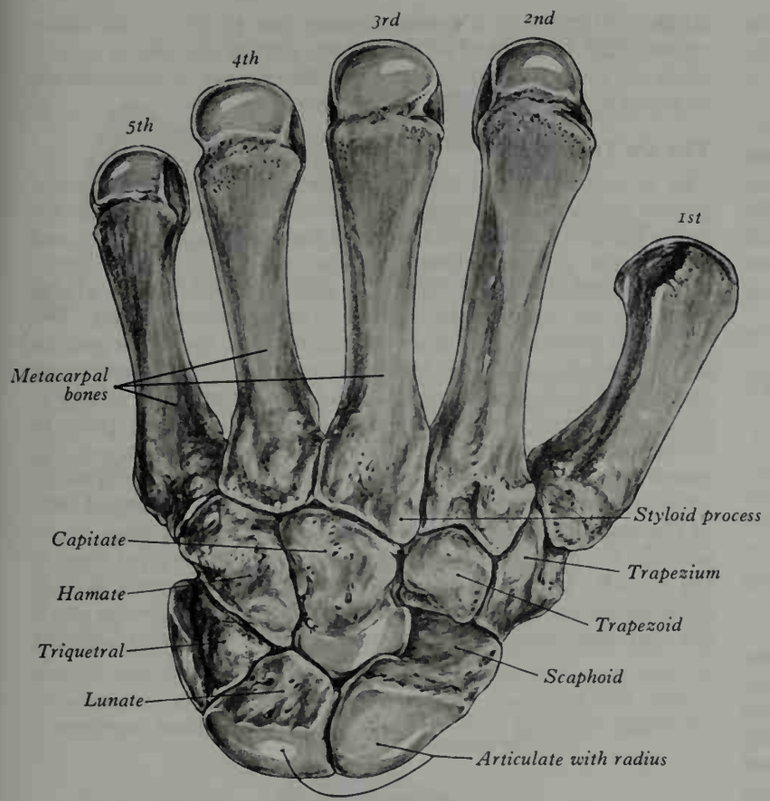
3.151 Stages in the ossification of the ulna. The diagram is simplified in relation to the epiphysial ossification of the olecranon, which is held to have two centres (*see* Porteous 1960 and the description in the text).

THE SKELETON OF THE HAND

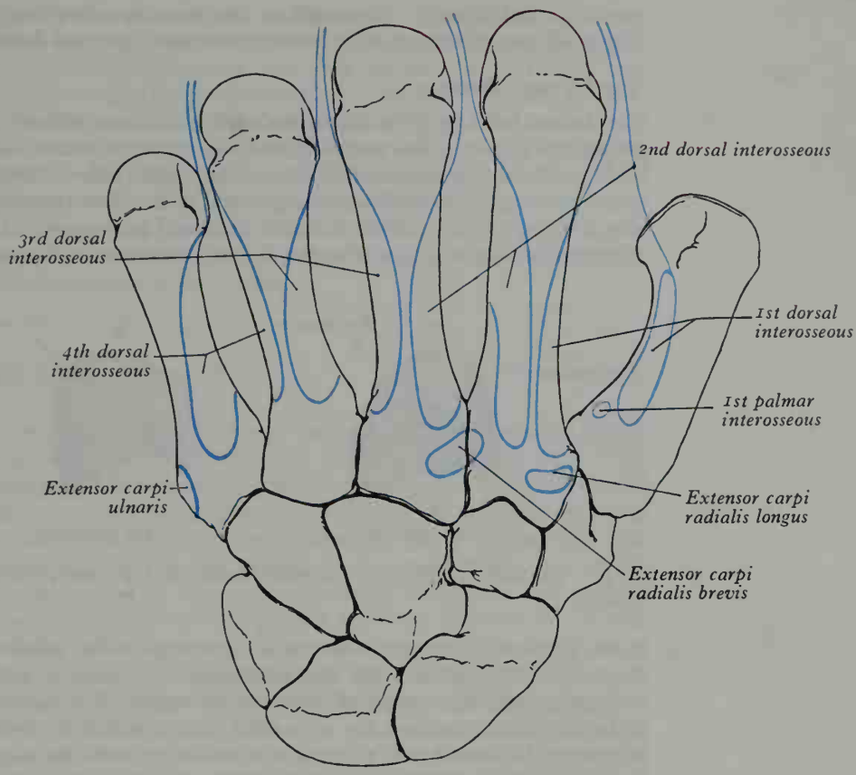


The skeleton of the hand has three segments: (1) the carpal or wrist bones, (2) the metacarpal bones of the palm, and (3) the phalanges or bones of the digits. In the description which follows, the terms *proximal* and *distal* will be used to the exclusion of the terms *superior* and *inferior* hitherto employed, and in addition the terms *palmar* and *dorsal*, which are self-explanatory, will be utilized instead of *anterior* and *posterior*.

The Carpus



General features. The carpus (**3**.152, 153) is composed of eight bones, which are arranged in proximal and distal rows, each containing four elements. The bones of the proximal row, from lateral to medial side, are the *scaphoid, lunate, triquetral* and *pisiform*; those of the distal row, the *trapezium, trapezoid, capitate*



3.152A The carpal and metacarpal bones of the left hand. Palmar aspect.

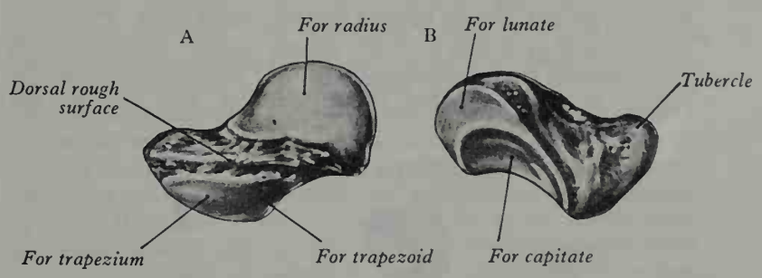
3.153A The carpal and metacarpal bones of the left hand. Dorsal aspect.

3.153B Muscle attachments to the carpal and metacarpal bones of the left hand. Dorsal aspect.



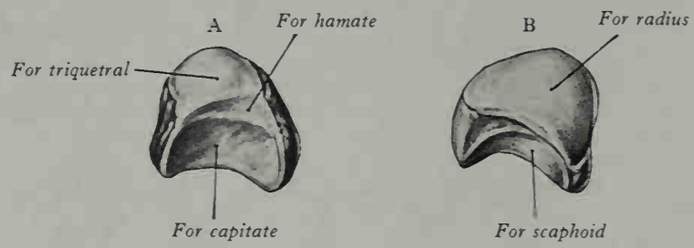
and *hamate*. The pisiform is on the palmar surface of the triquetral and is separated from the other carpal bones, all of which articulate with their immediate neighbours. The other bones of the proximal row form an arch convex proximally, which articulates with the radius and the articular disc of the inferior radio-ulnar joint. The concavity of the arch is directed distally and forms a recess into which fit the proximally projecting parts of the capitate and hamate bones. In this way the two rows are adapted to each other strongly and yet without sacrifice of all movement.

The dorsal surface of the carpus is gently convex from side to side, but the palmar surface is a deep concavity, the *carpal groove*, partly owing to the presence of certain ventral projections on its lateral and medial borders. The medial border of the concavity is formed by the *pisiform bone* and the *hamulus*, a hook-like process on the palmar surface of the *hamate* bone. The pisiform lies in the medial part of the proximal border of the muscular hypothenar eminence which forms the medial part of the palm, and its position in front of the triquetral makes it easy to feel. The hook of the hamate is concave on its lateral side; its tip can be identified in the living subject 2·5 cm distal to the pisiform and in line with the radial border of the ring finger. In this situation the superficial division of the ulnar nerve can be rolled from side to side over this bony point. The projecting lateral border of the carpal groove is formed by the *tubercle of the scaphoid* and the *tubercle of the trapezium*. The former is on the distal part of the anterior surface of the scaphoid and can be felt—and sometimes seen—as a small, rounded knob, in the medial part of the proximal border of the muscular thenar eminence ('ball' of the thumb), which forms the lateral part of the palm. The tubercle of the trapezium is a rounded ridge which runs vertically across the anterior surface of the bone, being slightly hollowed out on its medial side. It lies immediately distal and slightly lateral to the tubercle of the scaphoid, and can be felt only on deep pressure. The carpal groove is converted into an osseofibrous *carpal tunnel* by a strong fibrous retinaculum attached to the bony margins. the tunnel transmits the flexor tendons and median nerve to the hand (*see* p. 1102). The fibrous retinaculum increases the strength of the carpus and the efficiency of the flexor muscles. The palmar and dorsal surfaces of the carpal bones, apart from the triquetral and pisiform, are rough for the attachment of ligaments (radiocarpal, intercarpal and carpometacarpal).

The Individual Carpal Bones

The Scaphoid Bone

The scaphoid bone (**3**.154) is the largest element in the proximal row and lies with its long axis directed distally, laterally and slightly forwards. Its tubercle is a rounded elevation on the distal part of the *palmar surface* and is directed anterolaterally. It gives attachment to the flexor retinaculum and a few fibres of the abductor pollicis brevis, and is crossed by the tendon of the flexor carpi radialis. The *dorsal surface* is rough and slightly grooved, and is narrower than the palmar surface. It is pierced by a number of small nutrient foramina and in a small proportion of cases (13 per cent) these are restricted to the distal half of the bone (Obletz and Halbstein 1938). The *lateral surface*, also narrow and roughened, has attached to it the radial collateral ligament of the wrist joint. The remaining surfaces of the bone are articular. The *radial surface* is convex and is directed proximally and laterally. The *lunate surface* is a flattened, narrow semilune, directed medially. The *capitate surface*, large and concave, is directed

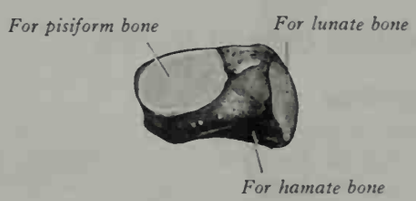


3.154 The left scaphoid bone. A—dorsal and B—palmar aspects.

medially and distally. The *surface for the trapezium and the trapezoid bone* forms a continuous convex area, directed distally.

The Lunate Bone

The lunate bone (**3**.155), distinguished by its crescentic outline, articulates between the scaphoid and the triquetal bones in the middle of the proximal carpal row. The rough *palmar surface*, almost triangular in outline, is larger and wider than the rough, *dorsal surface*. The smooth, convex, *proximal surface* articulates with the radius and the articular disc of the distal radio-ulnar



3.155 The left lunate bone. A—distomedial and B—proximolateral aspects.

joint. The *lateral surface* is narrow and presents a flat, semilunar facet for articulation with the scaphoid. The *medial surface* articulates with the triquetral and is almost square. It is separated from the distal surface by a curved ridge, which is usually somewhat hollowed out (**3**.155) for articulation with the edge of the hamate bone, when the hand is adducted. The *distal surface* is deeply concave to accommodate the medial part of the head of the capitate bone.

The Triquetral Bone

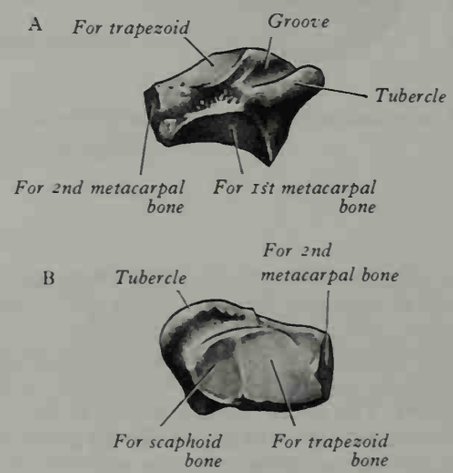
The triquetral bone (**3**.156), somewhat pyramidal in shape, is distinguished by an oval, isolated, smooth facet for articulation with the pisiform, which marks the distal part of its rough, *palmar* surface. The *medial* and *dorsal surfaces* are confluent. Rough distally for the attachment of the ulnar collateral ligament of the

3.156 The left triquetral bone. Palmar aspect.

wrist joint, this aspect is smooth in its proximal part, which articulates with the articular disc of the distal radio-ulnar joint in full adduction of the hand. The *hamate surface*, directed laterally and distally, is a concavoconvex area, broad proximally and narrow distally. The *lunate surface*, almost square, is directed proximally and laterally.

The Pisiform Bone

The pisiform bone (**3**.157) is shaped like a pea with one flattened surface, which is its only articular facet. This is on the *dorsal surface* of the bone to articulate with the triquetral, and its long axis runs distally and laterally. The non-articular part of the bone tends to project distally beyond the articular surface. The flexor carpi ulnaris is attached on the palmar surface and distally its continuations are the pisometacarpal and pisohamate ligaments. Hence in its relationship to this tendon, the pisiform has

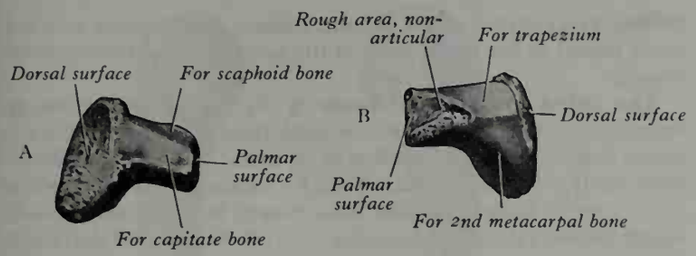


3.157 The left pisiform bone. Dorsal aspect.

all the attributes of a sesamoid bone (*see* p. 417). The flexor retinaculum is attached to the palmar part of the lateral aspect, while the abductor digiti minimi and the extensor retinaculum are attached to the medial and distal aspects.

The Os Trapezium

The os trapezium (**3**.158) is characterized by the tubercle and groove which mark its rough, *palmar surface*. The groove, medial to the tubercle, lodges the tendon of the flexor carpi radialis, and its margins give attachment to the two layers of the flexor retinaculum (**5**.76 and p. 583). The *tubercle* is obscured to a large extent by the origin of the muscles of the thenar eminence. The opponens pollicis arises from its middle part, the flexor pollicis brevis distally and the abductor pollicis brevis proximally (**3**.152B). The elongated, rough, *dorsal surface* is closely related to the radial artery, before it passes forwards into the palm to become the deep palmar arch. The *lateral surface* also is large and rough for the attachment of the radial collateral ligament of the wrist joint and the capsular ligament of the carpometacarpal joint of the thumb. A large *saddle-shaped (sellar) surface* faces disto-laterally for articulation with the base of the metacarpal bone of the thumb. The most distal part of the bone projects slightly between the bases of the first and second metacarpal bones and is covered with a small, quadrilateral facet which is directed distally

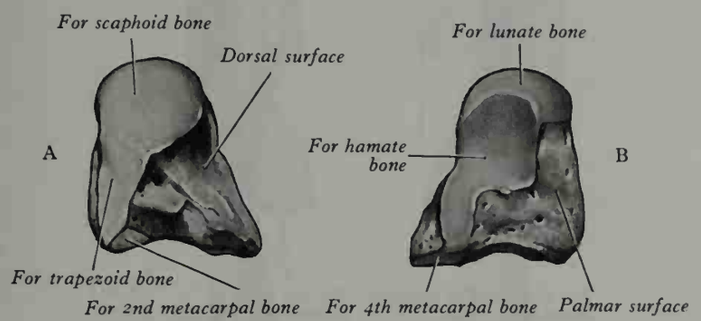


3.158 The left trapezium. A—palmar and B—proximomedial aspects.

and medially to articulate with the base of the second metacarpal bone. The medial surface is a large, gently concave facet for articulation with the trapezoid. The proximal surface is occupied by a small, slightly hollowed-out facet, which articulates with the scaphoid. In view of its great contribution to the mobility of the pollex, the distal, metacarpal articular surface of the trapezium has attracted particular attention. The ridge or 'summit' which fits the concavity of the first metacarpal base, extends in a palmar direction but also somewhat laterally, making an angle of about 60° with the plane of the second and third metacarpals (Kuczynski 1974; see also pp. 471 and 593). The movements of abduction and adduction occur in the plane of the axis of this ridge. The trapezial ridge is shorter than the corresponding metacarpal groove, and the contours of both vary reciprocally along their axes, being more curved near to the base of the second metacarpal and assuming a longer radius of curvature in a direction away from this. The two surfaces are not completely congruent, and the area of close contact probably moves towards the palm in adduction and reverses in abduction (*see* p. 471).

The Trapezoid Bone

The trapezoid bone (**3**.159) is small and irregular in shape. The *palmar surface* is rough, narrow and considerably smaller than the rough, *dorsal surface*; it is continued for a short distance on to the lateral aspect. The *distal surface* articulates with the grooved base of the second metacarpal bone. Triangular in outline, it is convex from side to side and concave from before backwards. The *medial*

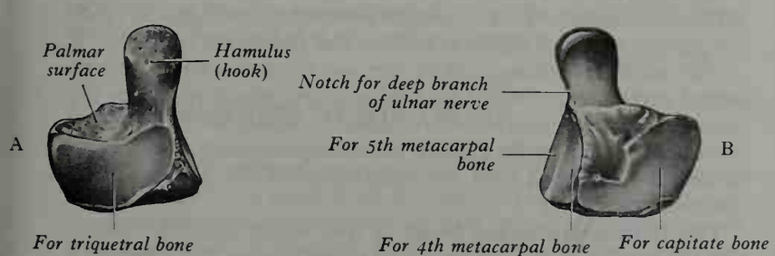


3.159 The left trapezoid bone. A—proximomedial and B—distolateral aspects.

surface articulates with the distal part of the capitate bone, by means of a slightly concave facet. The *lateral surface* articulates with the trapezium and the *proximal surface* with the scaphoid bone.

The Capitate Bone

The capitate bone (3.160), the largest of the carpal bones, articulates with the base of the third metacarpal bone; it is therefore central in position. The *distal surface*, roughly triangular, forms a concavoconvex facet for this articulation. Its lateral border carries a concave strip which articulates with the medial side of the base of the second metacarpal bone, and its dorsomedial angle usually bears a small facet for the fourth metacarpal bone. The convex *head* projects into the concavity



3.160 The left capitate bone. A—lateral and B—medial aspects.

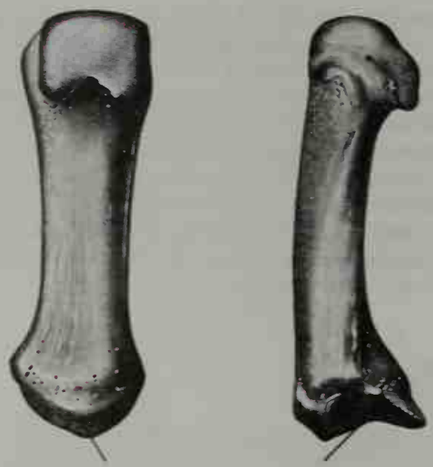
formed by the lunate and scaphoid bones. Its *proximal surface* articulates with the lunate and its *lateral surface* with the scaphoid. The facet for the scaphoid is usually continuous with the facet for the trapezoid on the distal part of the lateral surface of the bone, but the two may be separated by a rough interval. The *medial surface* presents a large facet for the hamate bone, deeper proximally than it is distally where a part of the surface is non-articular. The *palmar* and *dorsal surfaces* are roughened for carpal ligaments; the dorsal is the larger.

The Hamate Bone

The hamate bone (3.161) is cuneiform and has a hook-like process, the *hamulus*, which projects from the distal part of its rough, *palmar surface*. The concavity of the hamulus is directed to the lateral side, and takes part in the formation of the carpal tunnel. To its tip is attached the flexor retinaculum. The distal aspect of the base of the hamulus occasionally shows a slight transverse groove in contact with the deep, terminal branch of the ulnar nerve. The rest of the *palmar surface*, like the *dorsal surface*, is

3.161 The left hamate bone. A—medial and B—lateral aspects.

rough for the attachment of ligaments. The *distal surface* is divided into two articular surfaces by a faint ridge: of these, the smaller, lateral facet articulates with the base of the fourth, and the larger, medial facet with the base of the fifth metacarpal bone. The *proximal surface* is the thin margin of the wedge and usually bears a narrow facet which comes into contact with the lunate bone where the hand is adducted. The *medial surface* is covered by a broad articular strip, convex proximally and concave distally, for the triquetral bone. The *lateral surface* articulates with the capitate bone by means of a facet which covers all but the distal and palmar angle of the surface.

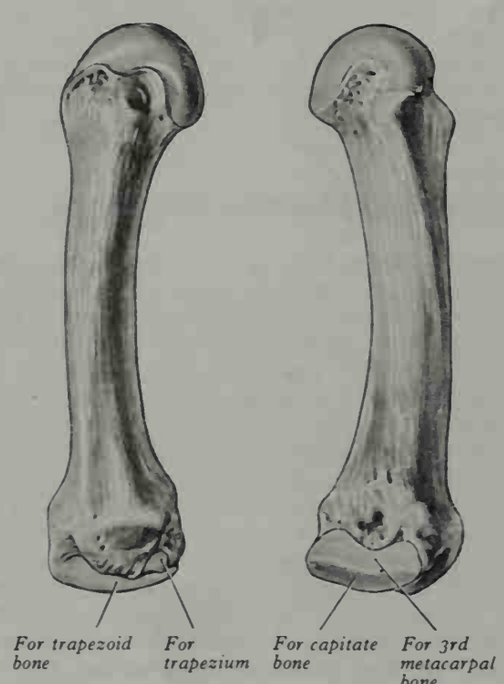


The Metacarpus

The metacarpus (Singh 1959) consists of five metacarpal bones, conventionally numbered from lateral to medial side. The metacarpals are miniature long bones, each possessing a rounded head, a shaft and an expanded base. The *heads* are distal ends and articulate with the proximal phalanges. Their oblong, articular surfaces are convex, the degree of convexity being less in the transverse than in the anteroposterior direction, and extend farther proximally on the palmar surface, than on the dorsal, especially at the margins. The prominence of the knuckles is produced by the metacarpal heads. The *bases* of the metacarpals are their expanded proximal ends, which articulate with the distal row of the carpus and with one another, save that the first metacarpal bone is isolated and does *not* articulate with the second metacarpal bone. The *shafts* are concave longitudinally on their palmar surfaces, forming a hollow containing certain palmar muscles. The dorsal surface of each presents a flattened triangular area in its distal part, continued proximally as a rounded ridge. These flattened areas can be felt on the back of the hand immediately proximal to the knuckles.

The medial four metacarpal bones lie side by side, but the first metacarpal bone lies on a more anterior plane and is rotated medially round its long axis through an angle of 90°. Hence its morphologically *dorsal* surface is directed to the *lateral* side, its radial border forwards, its palmar surface medially, and its ulnar border dorsally. By virtue of this position the thumb moves medially in front of the palm when it is flexed and it can be rotated into opposition with each of the fingers in turn. This ability to oppose the thumb to the fingers is rendered possible by the rotation of the bone medially. It is the most important factor in rendering the hand an efficient instrument for prehension, for, when an object is grasped in the hand, the fingers encircle it from one side and the thumb from the other, and the power of the grip is increased very greatly thereby. Lewis (1977) has recently contributed an extended anatomical, functional and morphological study of the human metacarpals and their articulations with the carpus and phalanges, in explanation of the evolution of human mammalian skills.

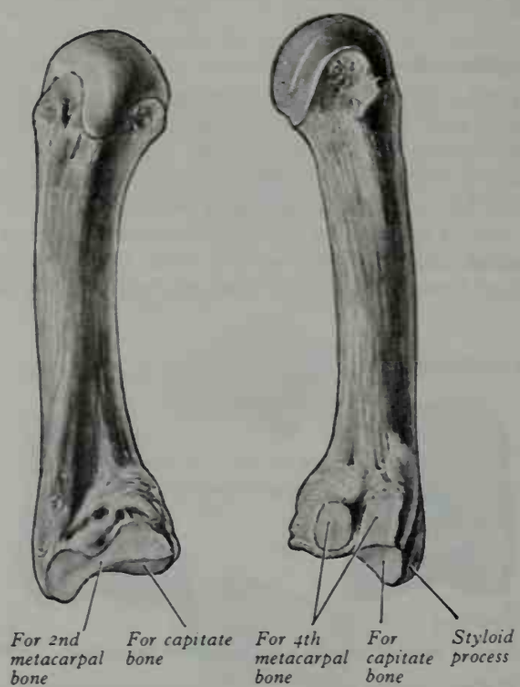
The Individual Metacarpal Bones



The first metacarpal bone (3.162) is shorter and stouter than the others. Its dorsal surface can be felt to face laterally; its long axis passes distally and laterally, diverging from its neighbour. The *shaft* is flattened and its dorsal surface is uniformly broad and convex from side to side. The palmar surface is concave in its long axis and is subdivided by a rounded ridge into a larger lateral and a smaller medial part. The opponens pollicis is attached to the radial border and adjoining palmar surface; the radial head of the first dorsal interosseous muscle arises from the ulnar border and the adjoining palmar surface. The *base* presents a concavoconvex surface for articulation with the trapezium (p. 471). On its lateral side the abductor pollicis longus is attached to it; its ulnar side and adjoining shaft gives origin to the first palmar interosseous muscle (p. 590). The *head* is less convex than the heads of the other metacarpal bones, and also in contrast to them is broader from side to side than from palmar to dorsal surface. On its palmar surface the ulnar and radial angles are enlarged to form two articular eminences, on each of which a sesamoid bone glides.

3.162 The first right metacarpal bone. Palmar and lateral aspects.

The second metacarpal bone (3.163) is the longest and its base is the largest. The *base* is characteristically grooved in a dorso-palmar direction for articulation with the trapezoid; the groove is bounded medially by a deep ridge, the edge of which articulates with the capitate bone. The lateral side of the base, nearer the dorsal than the palmar surface, bears a small, quadrilateral facet for the trapezium. Immediately behind this, i.e. on the lateral part of the dorsal surface of the base, a small rough impression marks the attachment of extensor carpi radialis longus. On the palmar surface is a small tubercle or ridge for one insertion of the flexor carpi radialis. The medial side of the base articulates with the lateral side of the base of the third metacarpal bone by a strip-like facet, constricted at its middle.



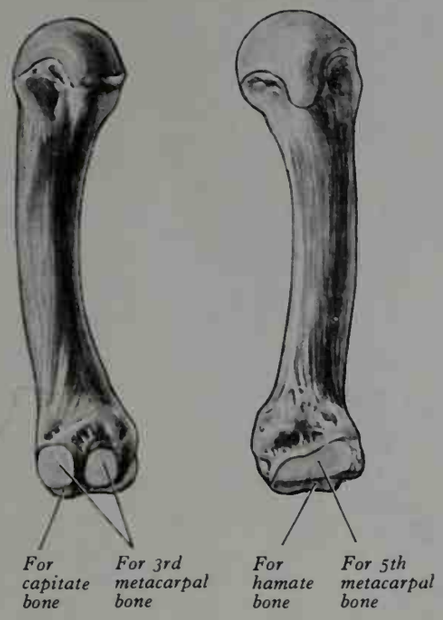
The *shaft* is prismoid in form and curved so as to be convex dorsally in its long axis and concave towards the palm. It has medial, lateral and dorsal surfaces. The dorsal surface is broad near the head but narrows into a ridge as it approaches the base. This surface is covered by the extensor tendons of the index finger; its converging borders begin at two little tubercles, one on each side of its head; collateral ligaments are attached to these (p. 472). The *lateral surface* inclines dorsally at its proximal end: it gives origin to the ulnar head of the first dorsal interosseous muscle. The *medial surface* inclines similarly and is divided into two nearly parallel strips by a faint ridge. Of these, the more

3.163 The left second metacarpal bone. Dorsolateral and medial aspects.

palmar gives origin to the second palmar interosseous and the more dorsal to the radial head of the second dorsal interosseous muscle.

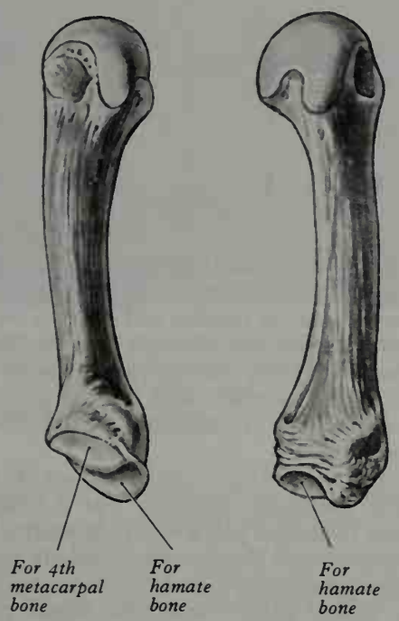
The third metacarpal bone (3.164) has a distinguishing feature in the short *styloid process*, projecting proximally from the radial side of the dorsal surface of its base. The *base* articulates, proximally, with the capitate bone by means of a facet which is convex in its palmar portion but concave in its dorsal portion, where it covers the styloid process. The lateral aspect of the base is marked by a strip-like facet, constricted at its middle, for articulation with the metacarpal bone of the index. On its medial side it articulates with the base of the fourth metacarpal bone by means of two small, discrete oval facets. Sometimes the more palmar facet is absent, and less frequently the two may be

3.164 The left third metacarpal bone. Lateral and medial aspects.



connected by a narrow bridge along the medial border of the base. The palmar surface of the base receives a slip from the flexor carpi radialis tendon, while its dorsal surface, immediately beyond the styloid process, gives insertion to the extensor carpi radialis brevis.

The *shaft* resembles that of the index metacarpal. Its lateral surface gives origin to the ulnar head of the second dorsal interosseous muscle and its medial surface to the radial head of the third dorsal interosseous muscle. The palmar ridge which separates these two surfaces gives origin, in its distal two-thirds, to the transverse head of the adductor pollicis. Its dorsal surface is covered by the extensor tendon of the middle finger.



The fourth metacarpal bone (3.165) is shorter and thinner than the second and third. It can be identified by its *base*. The lateral aspect bears two oval facets for articulation with the third metacarpal bone (*vide supra*). Of these the more dorsal is usually (but not always) the larger, and its proximal part comes into contact with the capitate. The medial aspect is marked by a single elongated facet for the fifth metacarpal bone. The proximal surface articulates with the hamate bone by a quadrangular facet, the palmar aspect of which is convex and the dorsal concave.

The *shaft* resembles that of the second metacarpal, but its lateral surface is traversed by a faint ridge, which separates the origin of the third palmar interosseous muscle from the origin of the ulnar head of the third dorsal interosseous muscle. The medial surface has attached to it the radial head of the fourth dorsal interosseous muscle.

The fifth metacarpal bone (3.166) differs from the rest in that the medial surface of its *base* is non-articular and presents a tubercle for the insertion of the extensor carpi ulnaris. The

3.165 The left fourth metacarpal bone. Lateral and medial aspects.

3.166 The left fifth metacarpal bone. Lateral and medial aspects.

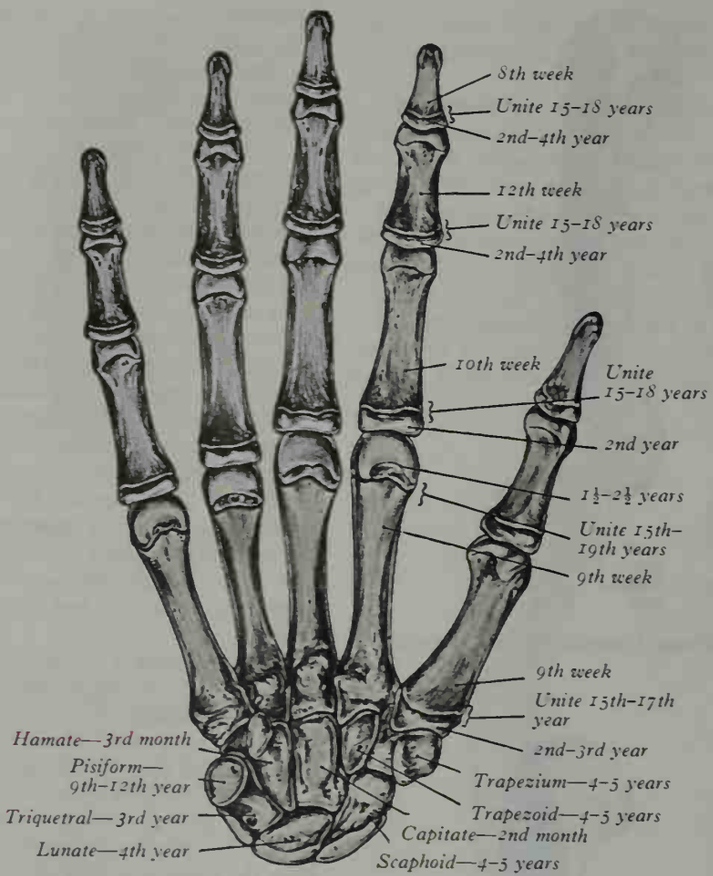
proximal surface of the base is a facet, concave from side to side and convex from its palmar to its dorsal aspect, for articulation with the hamate. Its lateral aspect presents an elongated strip-like facet for the fourth metacarpal bone.

The *shaft* is characterized by the fact that the triangular area on its dorsal surface reaches almost to the base and only the lateral surface inclines dorsally at its proximal end. The medial surface gives insertion to the opponens digiti minimi; the lateral surface is divided by a longitudinal ridge, sometimes quite sharp and distinct, into a palmar strip for the origin of the fourth palmar interosseous muscle, and a dorsal strip for the origin of the ulnar head of the fourth dorsal interosseous muscle.

The Phalanges of the Hand

There are fourteen phalanges, three in each finger and two in the thumb. Each has a head, shaft and base or proximal end. In each the *shaft* tapers to its distal end and its dorsal surface is convex from side to side. The palmar surface is flattened from side to side, but is gently concave forwards in its long axis. The *bases* of the *proximal phalanges* are marked by concave, oval facets for articulation with the heads of the metacarpal bones. Their *heads* are smoothly grooved like pulleys and encroach farther on the palmar than dorsal surfaces. To conform to the shape of the head of the proximal phalanx, the *base* of the *middle phalanx* is marked by two small, concave facets separated by a smooth ridge. The head of the middle phalanx also is pulley-shaped and the *base* of the *distal phalanx* conforms to it. The head of the distal phalanx is non-articular, but is marked on its palmar surface by a rough, horseshoe-shaped *tuberosity*, to which connective tissue strands attach the soft tissues (pulp) of the finger tip.

In addition to providing attachment for the ligaments of the joints in which they participate, the phalanges afford attachment to numerous muscles. The base of the distal phalanx gives attachment on its palmar surface to the corresponding tendon of the flexor digitorum profundus and on its dorsal surface to the extensor digitorum. The sides of the middle phalanx receive the insertion of the flexor digitorum superficialis tendon (p. 575) and the fibrous flexor sheath. Its base gives attachment on its dorsal surface to a part of the extensor digitorum tendon. To the sides of the proximal phalanx the fibrous flexor sheath is connected. Its base receives, laterally, part of the insertion of the corresponding dorsal interosseous, and medially another dorsal interosseous (p. 589).



The phalanges of the little finger and the thumb differ in certain respects from the other three. The medial side of the base of the proximal phalanx of the little finger receives the insertion of the abductor digiti minimi and the flexor digiti minimi. The base of the proximal phalanx of the thumb receives on its dorsal surface the tendon of the extensor pollicis brevis, on its lateral side the abductor pollicis brevis, the flexor pollicis brevis and the lateral part of the oblique head of the adductor pollicis, and, on its medial side, the transverse and the remainder of the oblique head of the adductor pollicis; the latter is sometimes conjoined with the first palmar interosseous muscle (p. 589). The margins of the proximal phalanx of the thumb are not sharp like those of the other digits, as the fibrous sheath is not so strongly developed as it is in the other digits.

Ossification of the Bones of the Hand (3.167, 168, 169, 170)

The carpal bones are usually cartilaginous at birth but centres of ossification may be present in the capitate and hamate. Each bone is usually ossified from one centre; the capitate first and the pisiform last, but the order in which the other carpal bones ossify is subject to considerable variation. The capitate begins to ossify in the second month, the hamate at the end of the third, the triquetral in the third *year*, the lunate during the fourth and the scaphoid, trapezium and trapezoid in the fourth year in females and fifth in males; the pisiform commences to ossify in the ninth or tenth year in females and the twelfth in males. Though the foregoing is the most common order of ossification there are considerable variations according to sex (Garu and Rohmann 1960), nutrition and, possibly, race. (For literature in respect of race consult Shakir and Zaini 1974, and Wingerd *et al.* 1974.)

Occasionally an additional bone, named the *os centrale* (p. 352), is found between the scaphoid, trapezoid and capitate bones. During the second month of intrauterine life it is represented by a small cartilaginous nodule which usually fuses with the cartilaginous scaphoid. Sometimes the styloid process of the third metacarpal bone is detached and forms an additional ossicle. Occasionally, the lunate and triquetral elements may fuse; a considerable range of other fusions and accessory ossicles have been described (O'Rahilly 1953, 1956).

Each **metacarpal bone** is ossified from two centres, a primary centre for the shaft and a secondary centre for the base or proximal end of the first and for the head or distal end of each of the other four. Ossification begins in the middle of the shaft about the ninth week of intrauterine life. The centres for the heads of the second, third, fourth and fifth metacarpals appear in that order during the second year in females and between one and a half and two and a half years in males. They unite with the shafts about the fifteenth or

3.167 The bones of the hand of a child, indicating the general plan of ossification.

3.168 Radiograph of hand at 2½ years (male). Note early stages of ossification in epiphyses at proximal ends of phalanges and first metacarpal, at distal ends of remaining metacarpals and radius, and in the capitate, hamate, and lunate bones. The last is more usually preceded by the centre for the triquetral. Compare with **3**.169 and **3**.170.

sixteenth year in females and eighteenth or nineteenth year in males. The base of the first metacarpal begins to ossify in the latter part of the second year in females and early in the third year in males. It unites before the fifteenth year in the former and seventeeth year in the latter (Joseph 1951). The foregoing figures represent, of course, a select and limited group. For wider assessments of the range of variability consult Modi (1957) and Krogman (1962).

The metacarpal bone of the thumb is ossified like a phalanx and therefore some anatomists consider that the thumb skeleton consists of three phalanges and not of a metacarpal bone and two phalanges; others believe that the distal phalanx represents fused middle and distal phalanges, a condition occasionally observed in the little toe (Broom 1930). (When the thumb possesses *three* phalanges, the metacarpal bone has a distal, as well as a proximal epiphysis. The metacarpal occasionally bifurcates distally; in these circumstances the medial branch, which has no distal epiphysis, bears *two* phalanges, whereas the lateral branch possesses a distal epiphysis, and *three* phalanges—Nicholson 1937.) The presence of an epiphysis only at the distal end of a typical metacarpal may be associated with the greater range of movement which the metacarpophalangeal joint enjoys. In the thumb, on the other hand, it is the carpometacarpal joint which possesses the wider range of movement, and the presence of a basal epiphysis in the first metacarpal bone may be attributable to this fact. However, a distal epiphysis also is present occasionally in the first, and a basal or proximal epiphysis sometimes occurs in the second metacarpal.

Growth studies of the phalanges of 1,700 children, aged 1 to 18 years, suggested that the hypothesis noted above, that the pollicial metacarpal is a proximal phalanx (as first suggested by Vesalius in 1543), may still be a valid possibility. The latter postulated view, however, does not take account of earlier observations that the so-called distal epiphysis of the first metacarpal bone is usually (if not always) a prolongation of the diaphysis into the terminal unossified cartilage, rather than a separate centre of ossification. A recent review of the earlier literature concerning such 'pseudo-epiphyses' has corroborated this description (Haines 1974).

3.169 Radiograph of hand at 6½ years (male). Note the more advanced state of the centres of ossification already visible in **3**.168, and additional centres in the distal ulnar epiphysis and in the triquetral, scaphoid, trapezium and trapezoid carpal bones.

The phalanges are each ossified from two centres: a primary centre for the shaft, and a secondary or epiphysial centre for the proximal extremity. Ossification of the shafts occurs as follows: distal phalanges in the eighth or ninth week, proximal phalanges in the tenth and middle phalanges in the eleventh or later week of intrauterine life. Epiphysial centres appear in the proximal phalanges early in the second year in females and in the latter half of the second year in males, and in the middle and distal phalanges in the second year in females and in the third or fourth year in males. All these epiphyses unite with the shafts about the fifteenth to sixteenth year in females and the seventeenth to eighteenth year in males.

Applied Anatomy. The scaphoid is the most frequently fractured of the carpal bones. As a rule, the fracture runs at right angles to the long axis of the bone. Following fracture through its proximal part or through the 'waist' of the bone, non-union is by no means uncommon and may, in some cases, be due to the fact that the proximal fragment, which is devoid of nutrient foramina in 13 per cent of cases (p. 371), has been cut off from its blood supply.

Dislocation forwards of the lunate bone is not uncommon and it is often associated with fracture of the scaphoid. The displaced lunate bone may compress the median nerve against the flexor retinaculum.

THE SKELETON OF THE LOWER LIMB

The Innominate Bone

The innominate or hip bone (**3**.171, 172) is large, irregularly shaped, constricted in the middle and expanded above and below. Its *lateral surface* near its middle bears a deep, cup-shaped hollow, termed the *acetabulum*, which articulates with the rounded head of the femur. Below and in front of the acetabulum the bone presents a large, oval, or triangular gap, the *obturator foramen*. Above the acetabulum the bone forms a wide, flattened plate, with a long, curved upper border termed the *iliac crest*.

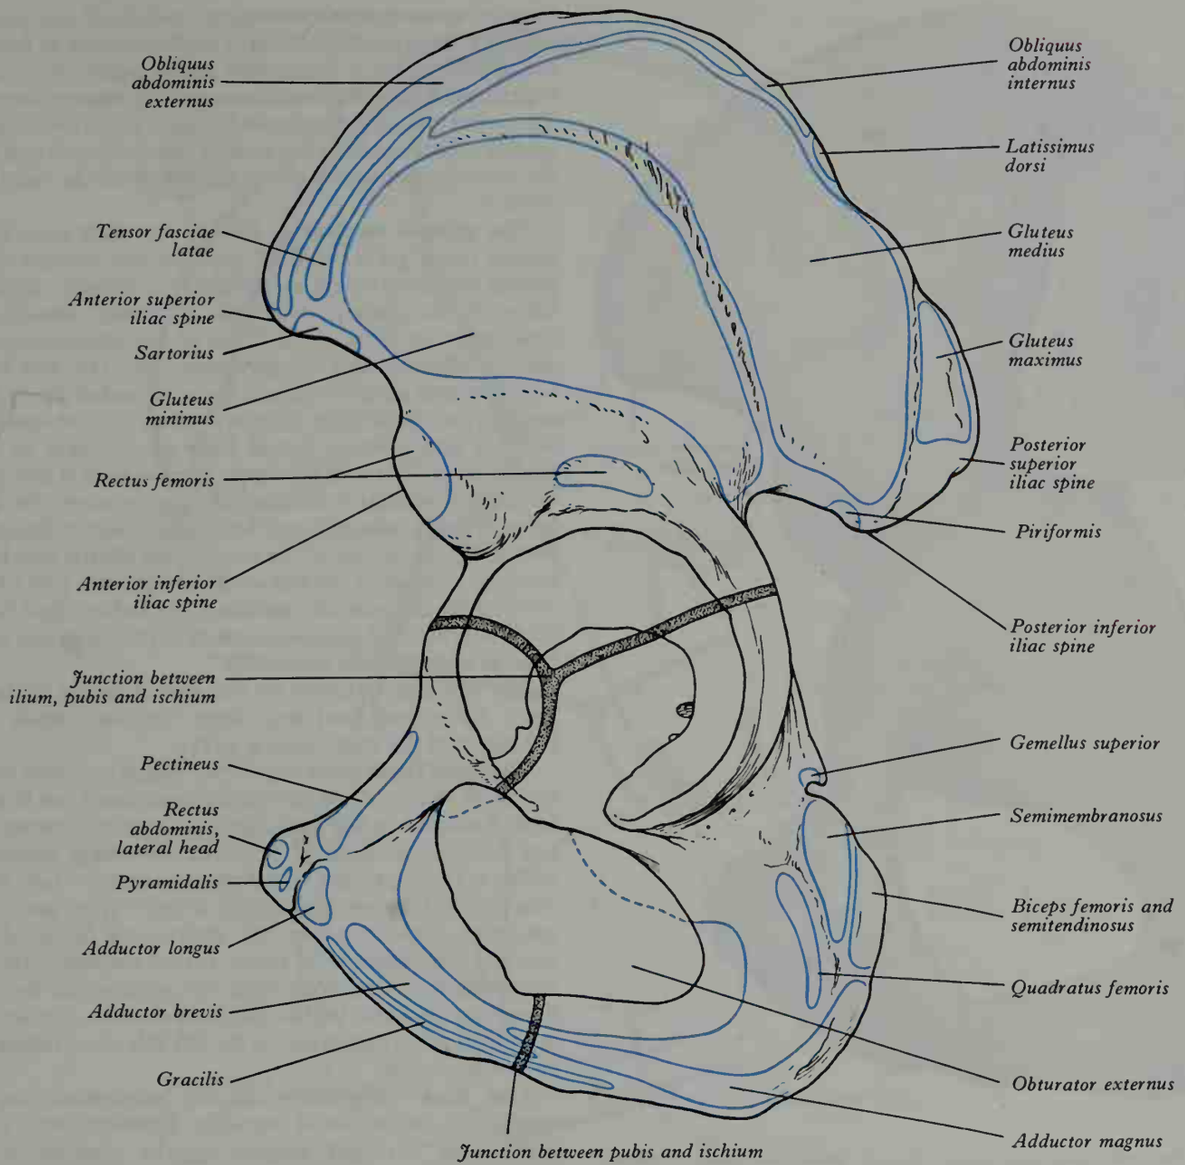
The hip bone articulates in front with the corresponding bone of the opposite side and the two bones form the pelvic girdle of the lower limbs (p. 351). Each consists of three parts, named the **ilium**, the **ischium** and the **pubis**, which are connected by cartilage in the young subject but are united by bone in the adult; the union of the three parts takes place in the walls of the acetabulum. The lines of fusion are shown as stippled bands in illustrations **3**.171B, 172B. The *ilium* includes the upper part of the acetabulum and the expanded, flattened area of bone above it; the *ischium* includes the lower part of the acetabulum and the bone below and behind; the *pubis* forms the anterior part of the acetabulum and separates the ilium from the ischium in this situation; in addition, it forms the anterior part of the lower portion of the hip bone and meets the pubis of the opposite side in the median plane.

3.171A The left innominate bone. Lateral (external) aspect. Compare with Key, **3**.171B.

The Ilium

The ilium, so named because it supports the *flank*, possesses two extremities and three surfaces. The lower extremity is the smaller and forms rather less than the upper two-fifths of the articular surface of the acetabulum; the upper extremity is greatly expanded to form the *iliac crest*. The surfaces are the gluteal, sacropelvic, and the iliac fossa. The *gluteal surface* is directed backwards and laterally and is an extensive rough area; the *iliac fossa* is smooth and gently hollowed out and occupies the anterior and upper part of the medial aspect of the ilium; the *sacropelvic surface* also is placed on the medial aspect and lies behind and below the iliac fossa, separated from it by a ridge, termed the *medial border*.

The iliac crest, the upper border of the ilium, is convex upwards, but sinuously curved, being concave inwards in front and concave outwards behind. Its anterior and posterior extremities project a little beyond the bone below and are termed respectively the anterior and the posterior superior iliac spines. The *anterior superior spine* lies at the lateral end of the fold of the groin and is easily felt in the living; the *posterior superior spine* cannot be felt, but its position may be indicated by a dimple, about 4 cm lateral to the second spinous tubercle of the sacrum above the medial part of the buttock. Morphologically the crest consists of a long ventral and a shorter dorsal segment. The ventral segment forms rather more than the anterior two-thirds of the crest and is associated with alterations in the form of the ilium which were necessitated by the adoption of the erect attitude; the dorsal segment forms rather less than the posterior third of the crest and can be identified in all land vertebrates. The ventral segment of the crest is bounded by *outer* and *inner* lips, enclosing a rough *intermediate zone*, which is narrowest at its middle and becomes wider both in front and behind. The *tubercle of the crest* (**3**.171A) is a prominent projection on the outer lip about 5 cm or more behind and above the anterior superior spine. The dorsal segment presents two sloping surfaces separated by a well-marked ridge, which terminates in the posterior superior spine. The highest point of the crest, which is a little behind its midpoint, is on the same level as the interval between the spines of the third and fourth lumbar vertebrae.



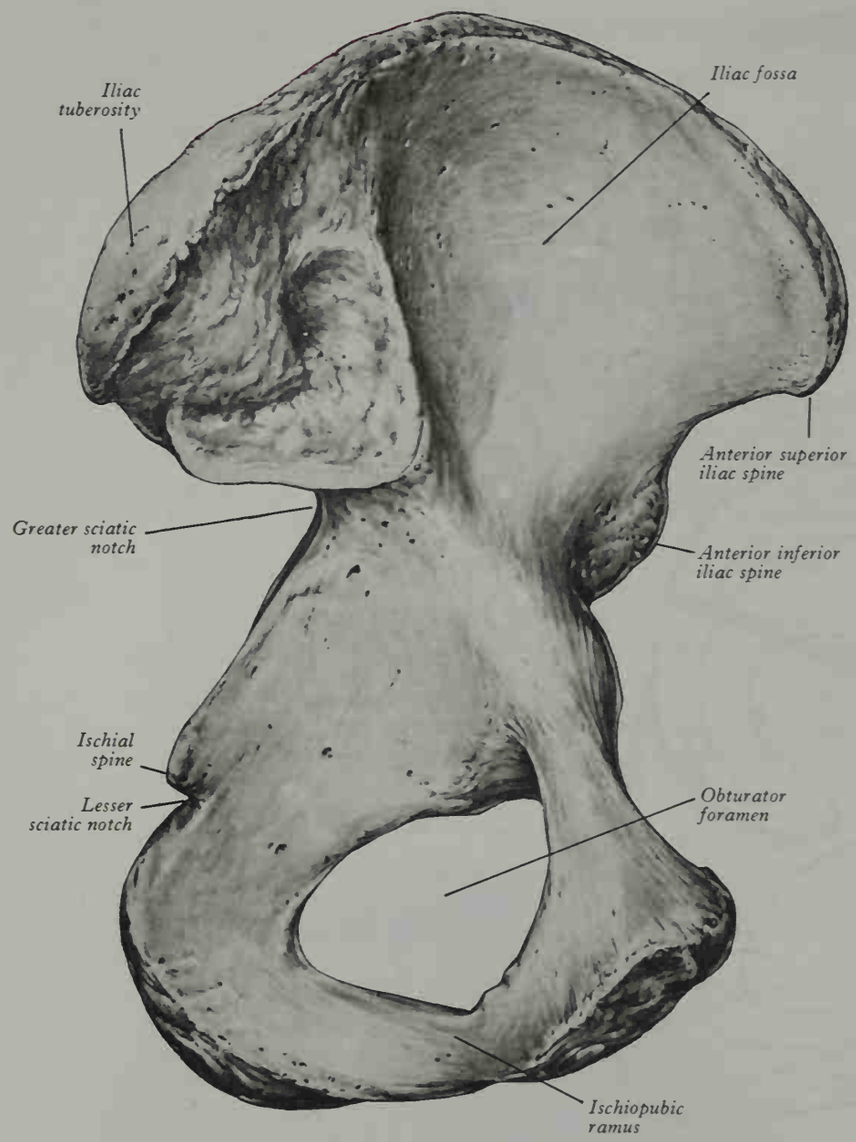
The *lower end* of the ilium will be described with the acetabulum (p. 383).

The *anterior border* of the ilium descends to the acetabulum from the anterior superior spine. Its upper part is rounded and concave forwards; its lower part presents a roughened projection, the *anterior inferior iliac spine*, which lies immediately above the anterior part of the acetabulum.

The *posterior border* is irregularly curved (**3**.172B). It commences at the posterior superior spine and runs at first downwards and forwards, with a backward concavity, forming a small notch. At the lower end of the notch the bone presents a wide, low projection, the *posterior inferior iliac spine*, where the posterior border makes a sharp bend. It then runs almost horizontally forwards for about 3 cm and finally turns downwards and backwards to become continuous with the posterior border of the ischium. As a result the posterior border shows a deep *greater sciatic notch*, which is bounded above by the ilium and below by the ilium and ischium (**3**.172B).

The *medial border* separates the iliac fossa from the sacropelvic surface. Indistinct near the crest, it is roughened in its upper part, then sharp and clear-cut where it bounds the articular surface for the sacrum, and finally smooth and rounded. The latter portion forms the *arcuate line*; at its inferior end it reaches the posterior part of the *iliopubic (iliopectineal) eminence*, which marks the union of ilium and pubis.

The gluteal surface (**3**.171A) faces backwards and laterally in its posterior part, and laterally and slightly downwards in front. It is bounded above by the iliac crest, below by the upper border of the acetabulum, and in front and behind by the anterior and posterior borders. The surface is rough and curved, being convex in front and concave behind, and marked by three uneven ridges,



3.171B Key to **3**.171A the stippled bands indicate the limits of the iliac, pubic and ischial parts of the bone.

the posterior, anterior and inferior gluteal lines. The *posterior gluteal line*, which is the shortest, begins above on the external lip of the crest about 5 cm in front of its posterior extremity and ends below, a short distance in front of the posterior inferior spine. Its upper part is usually distinct, but inferiorly it is ill-defined and frequently absent. The *anterior gluteal line*, the longest of the three, begins about the middle of the upper margin of the greater sciatic notch and runs upwards and forwards to become confluent with the outer lip of the crest a little in front of the tubercle. The *inferior gluteal line*, which is rarely a well-marked feature, begins a little above and behind the anterior inferior spine and curves backwards and downwards to end near the apex of the greater sciatic notch. Between the inferior gluteal line and the margin of the acetabulum there is a rough, shallow groove on the bone. Behind the acetabulum the lower part of the gluteal surface becomes continuous with the posterior surface of the ischium. The site of the union of these two elements is marked by a low elevation.

The iliac fossa is the hollow of the anterior and upper part of the internal aspect of the ilium. It is limited above by the iliac crest, in front by the anterior border, and behind by the medial border, which separates it from the sacropelvic surface. The surface is smooth and gently concave and forms the posterolateral wall of the greater pelvis. Below, it is continuous with a shallow groove (**3**.172A) bounded laterally by the anterior inferior spine and medially by the iliopubic eminence.

The sacropelvic surface (**3**.172A) is the posterior and lower part of the medial aspect of the ilium. It is bounded behind and below by the posterior border, in front and above by the medial border, and above and behind by the iliac crest. It is subdivided into three areas, viz., the iliac tuberosity, the auricular surface and the pelvic surface. The *iliac tuberosity* is an extensive, roughened area which lies immediately below the dorsal segment of the iliac crest. It bears cranial and caudal depressions separated by an oblique ridge and is connected to the sacrum by the interosseous sacroiliac ligament. The *auricular surface* (**3**.172A) is placed immediately below and in front of the tuberosity, and articulates with the lateral mass of the sacrum. It is shaped like an ear, the wide expanded portion lying above and in front, and the lobule below and behind, covering the medial aspect of the posterior inferior spine. Its edges are clearly defined, but the surface, although articular, is finely roughened and irregular. The *pelvic surface* lies below and in front of the auricular surface and helps to form the wall of the lesser pelvis. It comprises an upper and a lower portion. Its upper part faces downwards and lies between the margin of the auricular surface and the upper border of the greater sciatic notch; its lower region faces inwards and is separated from the iliac fossa by the arcuate line. The line of union of the ilium with the ischium is completely obliterated on this surface.

The iliac crest corresponds to the lower limit of the waist and provides attachment for the lateral muscles of the abdominal wall, fasciae and muscles of the lower limb, and muscles and fasciae of the back (**3**.171B, 172B). The *outer lip* of the ventral segment

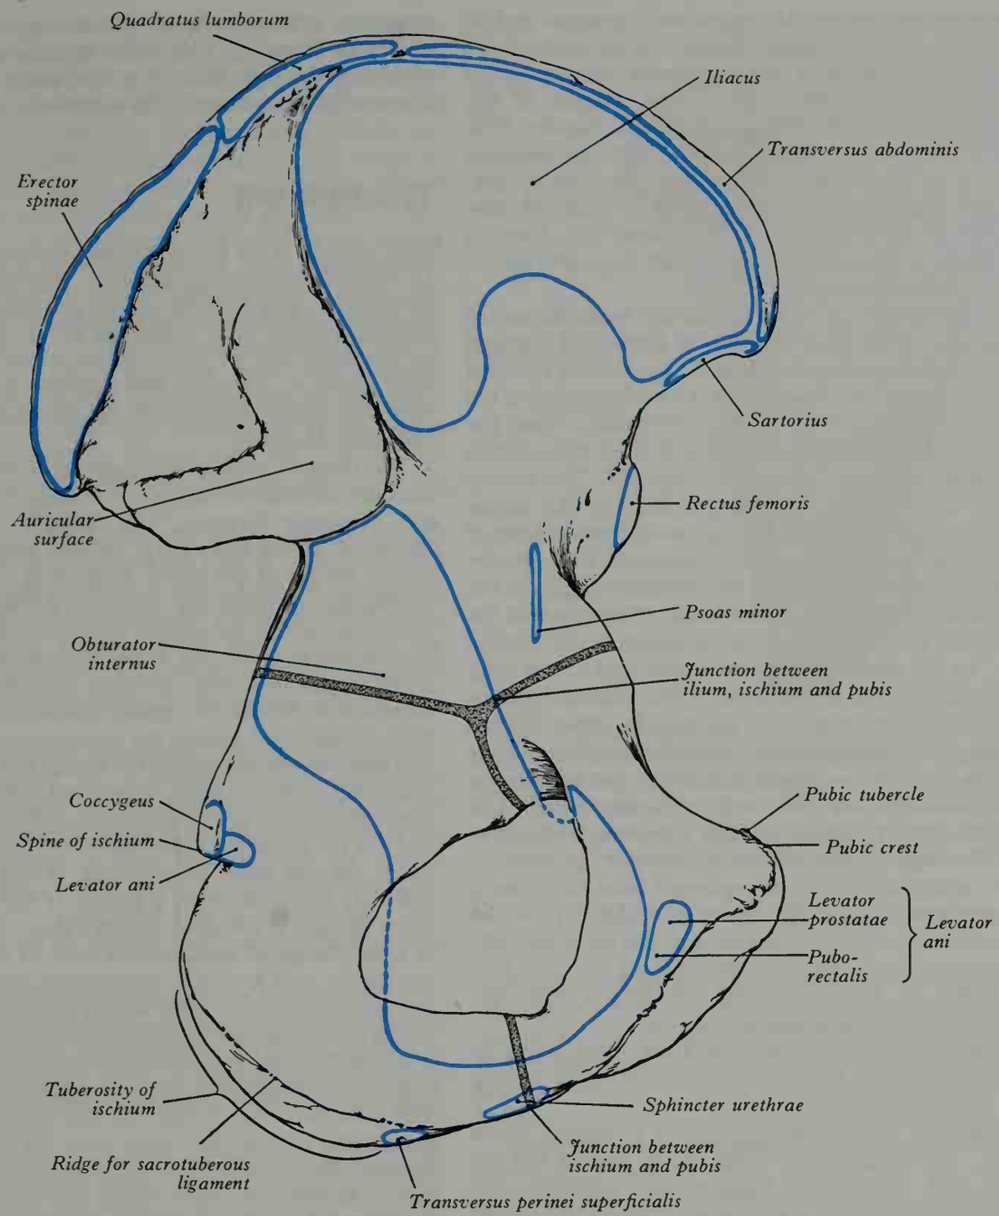
3.172A The left innominate bone. Medial (internal) surface. Compare with Key, **3**.172B.

(p. 378) gives attachment to the fascia lata, including the iliotibial tract; in front of the tubercle of the crest the tensor fasciae latae arises: in its anterior two-thirds it provides insertion for the lower fibres of the external oblique; just behind its highest point the lowest fibres of the latissimus dorsi arise. An interval of variable size intervenes between the posterior limit of the attachment of the external oblique and the anterior limit of the latissimus dorsi; in this situation the crest forms the base of the lumbar triangle. The *intermediate line* gives origin to the internal oblique. The *inner lip* in its anterior two-thirds provides attachment for the transversus abdominis, and behind that to the lumbodorsal fascia and the quadratus lumborum. The dorsal segment of the iliac crest (p. 378) gives origin on its lateral slope to the highest fibres of the gluteus maximus, on its medial slope to the erector spinae and, along its medial margin, to the interosseous and dorsal sacroiliac ligaments.

The anterior superior spine provides attachment for the lateral end of the inguinal ligament and below that sartorius, which extends downwards for a short distance on the *anterior border*. The **anterior inferior spine** is divided indistinctly into two areas. To the upper the straight head of the rectus femoris is attached. The lower covers the inferior part of the spine and extends in a lateral direction along the upper margin of the acetabulum; it is a rough triangular impression for the iliofemoral ligament.

To the upper part of the **posterior border** the upper fibres of the sacrotuberous ligament are attached. In front of the posterior inferior spine (i.e. on the upper border of the greater sciatic notch), it gives origin to fibres of piriformis and, in front of that on the upper border of the greater sciatic notch, it is related to the superior gluteal vessels and nerve as they emerge from the pelvis. The lower part of the posterior border (i.e. the lower margin of the greater sciatic notch) is covered by the piriformis and is related to the sciatic nerve, although the nerve lies for the most part on the ischium.

The gluteal surface is divided into four areas by the three gluteal lines (**3**.171A and B). (*a*) The area behind the posterior gluteal line gives origin in its upper roughened part to the upper fibres of the gluteus maximus; its lower, smooth part gives attachment to some of the fibres of the sacrotuberous ligament and the iliac head of the piriformis. (*b*) The area between the posterior and anterior gluteal lines, bounded above by the iliac crest, gives origin to the gluteus medius. (*c*) The area between the anterior and inferior gluteal lines gives origin to the gluteus minimus. (*d*) The area below the inferior gluteal line is marked by numerous vascular foramina. The groove above the acetabulum gives origin to the reflected head of the rectus femoris, and the area adjoining the rim of the acetabulum affords attachment to the articular capsule of the hip joint. The greater part of this area is covered by the gluteus minimus, but behind and below in the neighbourhood of the site of union of the ilium and ischium, the bone is related to the piriformis.



The vascular foramina on the gluteal aspect of the ala of the ilium sometimes lead into large vascular canals within the substance of the bone (Sirang 1973).

The iliac fossa in its upper two-thirds provides origin for the iliacus (**3**.172B), which covers the lower third but is not attached to it. Branches of the iliolumbar artery run between the muscle and the bone, and one of them enters the large nutrient foramen which is often present at the postero-inferior part of the fossa. The groove between the anterior inferior spine and the iliopubic eminence is occupied by the converging fibres of the iliacus laterally and tendon of psoas major medially; the tendon is separated from the bone near the acetabulum by its synovial bursa. On the right side the iliac fossa contains the caecum and the terminal part of the ileum, on the left side the terminal part of the descending colon.

The iliac tuberosity of the sacropelvic surface gives attachment to the dorsal sacroiliac ligaments and, immediately behind the auricular surface, to the interosseous sacroiliac ligament. The upper and anterior part of the tuberosity gives attachment to the iliolumbar ligament, and this area lies immediately below the medial part of the origin of the quadratus lumborum from the iliac crest. **The auricular surface** articulates with the auricular surface of the sacrum and is reciprocally curved (p. 473). Its anterior and inferior borders are sharp and give attachment to the ventral sacroiliac ligament. The lower part of the **pelvic surface** between the inferior margin of the auricular surface and the upper margin of the greater sciatic notch is often marked by a roughened groove, which is termed the *pre-auricular sulcus*; it gives attachment to the lower fibres of the ventral sacroiliac ligament. This sulcus is more often well marked in the female than the male. However, the unreliability of the presence of this sulcus in determination of sex is shown by a study of 237 Indian pelves, as in other races (Jit and Gandhi 1966). For further pertinent analyses, however, consult Finnegan and Faust (1974), and Finnegan (1978). Lateral to the sulcus the bone sometimes gives origin to fibres of the piriformis. The rest of the pelvic surface gives origin to the upper half or less of the obturator internus.

The Pubis

The pubis forms the ventral part of the innominate bone and meets the opposite pubis in the median plane to form a cartilaginous joint, the pubic symphysis. It possesses a body, which lies anteriorly, a superior ramus, which passes upwards and backwards to the acetabulum, and an inferior ramus, which passes backwards, downwards and laterally to unite with the ramus of the ischium on the medial side of the obturator foramen.

3.172B Key to **3**.172A. The stippled bands indicate the limits of the iliac, pubic and ischial parts of the bone.

The body is compressed from before backwards and presents anterior, posterior and symphysial (or medial) surfaces and a free upper border termed the *pubic crest*. The *anterior surface* faces downwards, forwards and slightly laterally in the upright posture; rough in its upper and medial parts, it presents a smooth surface elsewhere. It is directed towards the lower limb and affords attachment for the medial group of muscles of the thigh. The *posterior surface* is smooth and faces upwards and backwards, forming the anterior wall of the pelvis minor; it is related to the urinary bladder. The *symphysial surface* is an elongated oval area, covered with cartilage in the recent state and articulating with the opposite pubis at the pubic symphysis. When denuded of cartilage it presents, in the elderly, an irregular surface, marked by a number of small ridges and furrows or by small nodular elevations; but these appearances show wide variations at different ages (Todd 1920, 1921; Brooks 1955; Suchey 1979). The forensic application of such observations is obvious. The *pubic crest* is the rounded upper border of the body. It is projected forwards and overhangs the upper part of the anterior surface (**3**.171A). Its lateral extremity forms a rounded projection termed the *pubic tubercle*. Both the crest and the tubercle can be felt through the skin, but the latter is obscured in the male by the spermatic cord, which crosses its upper aspect as passes upwards from the scrotum to pierce the abdominal wall.

The superior ramus of the pubis springs from the upper and lateral part of the body, and passes backwards, upwards and laterally above the obturator foramen to reach the acetabulum. It is triangular on section and has three surfaces and three borders. The *pectineal surface* is directed forwards and slightly upwards. Triangular in outline, it extends from the pubic tubercle to the iliopubic eminence (**3**.171A). It is bounded in front by a rounded ridge termed the *obturator crest*, and behind by a sharp edge termed the *pecten pubis* (*pectineal line*), which together with the pubic crest constitutes the pubic part of the *linea terminalis* (i.e. the anterior part of the pelvic brim). The *pelvic surface*, which is directed upwards, backwards and medially, is smooth and featureless; it is narrow at its lateral extremity where it is continuous with the posterior surface of the body. It is bounded above by the pecten pubis and below by a sharp edge which forms the *inferior border*. The *obturator surface* is directed downwards and backwards, and is crossed from behind forwards and downwards by a groove termed the *obturator groove*. It is bounded in front by the obturator crest and behind by the inferior border.

The inferior ramus springs from the lower and lateral part of the body and passes backwards, downwards and laterally to unite with the ramus of the ischium on the medial side of the obturator foramen. The site of union may be marked by a localized thickening, often difficult to identify in the adult bone. The ramus

has two surfaces and two borders. The *anterior* or *external surface* is continuous above with the anterior surface of the body of the pubis; it faces the thigh and is roughened for muscular attachments. It is bounded laterally by the margin of the obturator foramen and medially by a rough anterior border. The *posterior* or *internal surface* is continuous above with the posterior surface of the body, and is transversely convex from side to side. Its medial part is often prominently everted in male subjects (**3**.180) and is connected to the crus of the penis. It is directed medially towards the perineum. Its lateral part is smooth and is directed upwards towards the pelvis.

The pubic tubercle provides attachment for the medial end of the inguinal ligament; it lies in the floor of the superficial inguinal ring and is crossed by the spermatic cord. The ascending limbs of the loops of the cremaster are attached to the tubercle and to the anterior wall of the sheath of the rectus abdominis. From the lateral part of the **pubic crest** arises the lateral head of the rectus abdominis, and from the bone below the pyramidalis. The medial part of the crest is crossed by the medial head of the rectus abdominis, which arises from an interlacement of fibres in front of the upper part of the pubis and pubic symphysis. The *anterior surface* of the body is directed towards the adductor region of the thigh. A roughened strip, usually wider in the female, marks the medial part of the surface and gives attachment to the ventral pubic ligament. In the angle between the upper end of this strip and the pubic crest the rounded tendon of the adductor longus takes origin. At a slightly lower level the gracilis arises from a linear origin close to the medial border of the body and extending downwards on to the inferior ramus. Lateral to the gracilis the adductor brevis arises from the body and the inferior ramus. The lateral part of the anterior surface, and the adjoining portions of both rami provide origin for the obturator externus (**3**.171B).

The *posterior surface* of the body is separated from the urinary bladder by the retropubic pad of fat. About its middle it provides origin for the anterior fibres of the levator ani, and more laterally the obturator internus arises from this surface and extends on to both rami. Medial to the origin of the levator ani, the puboprostatic ligaments are attached to the bone.

The *pectineal surface of the superior ramus* gives origin, along its upper part, to the pectineus, which covers the rest of the surface (**3**.171B) but is not attached to it.

The pecten pubis, which forms the upper boundary of the pectineal surface, is a salient, sharp ridge. At its medial end the conjoint tendon and the lacunar ligament are attached, and throughout the rest of its extent it affords attachment to a strong fibrous band often termed the *pectineal ligament* (p. 552). About its middle it receives the insertion of the psoas minor when present. The *pelvic surface* is smooth and is not covered with muscle or fascia. It is separated from the parietal peritoneum only by the intervening subperitoneal tissue, in which the lateral umbilical ligament runs downwards and forwards across the ramus and, near its lateral end, the ductus deferens passes backwards. The *obturator groove* on the obturator surface is converted into a canal by the upper borders of the obturator membrane, the obturator internus and the obturator externus. It transmits the obturator vessels and nerve from the pelvis to the thigh, where they emerge under cover of the pectineus. The *obturator crest* (**3**.171B) at its lateral end gives attachment to some of the fibres of the pubofemoral ligament.

To the *outer surface of the inferior ramus* are attached the gracilis, the adductor brevis and the obturator externus, named from the medial to the lateral side. In addition, the origin of the adductor magnus usually extends from the ramus of the ischium on to the lower part of the inferior ramus of the pubis in the interval between the adductor brevis and the obturator externus. The *inner surface* is divided into a medial, an intermediate and a lateral area, but they are not separated from one another by clear-cut markings on the bone. The medial area faces downwards and medially and is in direct contact with the crus penis; it is limited above and behind by an indistinct ridge which gives attachment to the inferior fascia of the urogenital diaphragm (p. 562). The intermediate area is related to the dorsal nerve of the penis and the internal pudendal vessels and the fascial sheath in which they are enclosed, and it may give origin to some of the inner fibres of the sphincter urethrae. From the lateral area arise fibres of the obturator internus. The *medial margin* of the ramus is strongly everted in the male and gives attachment to the fascia lata and to the membranous layer of the superficial fascia of the perineum.

The Ischium

The ischium is the lower, posterior part of the innominate bone. It comprises a body and a ramus. The body has upper and lower extremities, and femoral, dorsal and pelvic surfaces. The *upper extremity* of the body forms the lower and posterior part of the acetabulum, and its *lower extremity* gives off the *ramus*, which runs upwards, forwards and medially at an acute angle to fuse with the descending ramus of the pubis, so completing the obturator foramen.

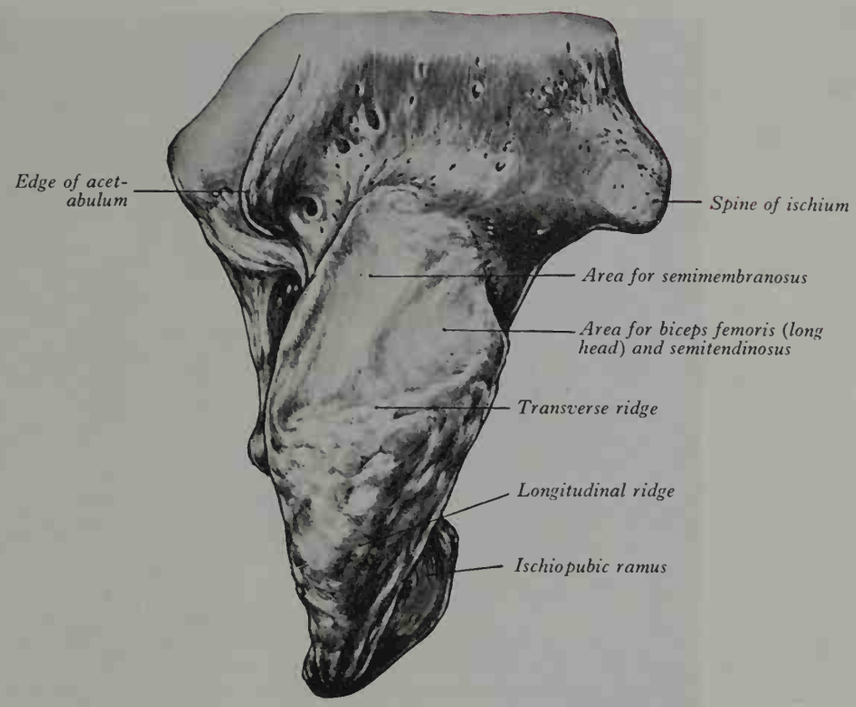
The *femoral surface* of the body faces downwards, forwards and laterally towards the thigh. It is bounded in front by the margin of the obturator foramen, and laterally by the lateral border, indistinct above but clearly defined below, where it forms the lateral border of the ischial tuberosity. The *dorsal surface* faces backwards, laterally and upwards. Above, it is continuous with the lower part of the gluteal surface of the ilium, and where the two elements meet, the bone presents a low convexity, which corresponds with the curvature of the posterior part of the acetabulum. Below, the surface is marked by the upper part of the ischial tuberosity. Above the tuberosity the bone presents a wide and shallow groove both on the lateral and on the medial side. The *ischial tuberosity* is a large, roughened impression which marks the lower part of the dorsal surface and the inferior extremity of the body of the ischium. Although obscured by the gluteus maximus when the hip joint is extended, it can be identified without difficulty when the joint is flexed. It lies 5 cm from the median plane and about the same distance above the gluteal fold (p. 600). It is an elongated area, widest near its upper end and tapering inferiorly, and provides attachment for the posterior femoral (hamstring) muscles. The dorsal surface is placed between the lateral and the posterior borders of the body. The *posterior border* is continuous above with the posterior border of the ilium and helps it to complete the lower margin of the *greater sciatic notch*. The posterior end of that margin is marked by a conspicuous projection, termed the *ischial spine*. Below the spine the border becomes rounded and indefinite, forming the floor of a rounded notch, termed the *lesser sciatic notch*, which lies between the ischial spine and the tuberosity. The *pelvic surface* is smooth and relatively featureless and is directed towards the pelvic cavity; its lower portion forms part of the lateral wall of the ischiorectal fossa in the perineum.

The ramus of the ischium presents anterior and posterior surfaces, continuous with the corresponding surfaces of the inferior pubic ramus. The *anterior surface* is directed forwards and downwards towards the thigh and is rough for the attachment of the medial femoral muscles. The *posterior surface* is smooth, and partly subdivided into a perineal and a pelvic area, like the inferior ramus of the pubis. The *upper border* helps to complete the margin of the obturator foramen; the *lower border* is roughened and free, and together with the medial border of the inferior ramus of the pubis forms the lateral boundary of the subpubic angle and part of the pubic arch.

Attached to the *femoral surface* of the **body of the ischium** below is a part of obturator externus (**3**.171B), and along the lateral border of the upper part of the ischial tuberosity the quadratus femoris. Just below the acetabulum the lateral border gives attachment to the ischiofemoral ligament.

Immediately above the ischial tuberosity the *dorsal surface* is crossed by the tendon of the obturator internus and the gemelli; the nerve to the quadratus femoris runs downwards between these structures and the bone. At a higher level, the bone is covered by the piriformis, which is partially separated from it by the sciatic nerve and the nerve to the quadratus femoris. The **ischial tuberosity** is divided by a nearly transverse ridge into an upper and a lower area (**3**.173). The upper area is associated with the hamstring muscles; it is divided by an oblique line into an upper and lateral part from which arise the semimembranosus, and a

lower and medial part from which the long head of the biceps femoris arises in common with the semitendinosus. The lower portion of the tuberosity narrows as it passes forwards on to the lower end of the ischium. It is divided by an irregular vertical ridge into a lateral and a medial area; the lateral area is the larger and affords origin to part of the adductor magnus, the medial is covered by fibro-adipose tissue, usually containing the ischial bursa of the gluteus maximus. It is the medial area on the lower part of the tuberosity which supports the body in the sitting posture. On its medial side the tuberosity is limited by a curved ridge which extends forwards on to the ramus of the ischium and to which the sacrotuberous ligament and its falciform process are attached (**3**.172B). Many of the fibres of the biceps femoris can be traced into the sacrotuberous ligament, and this intimate relationship is noteworthy, for the sacrum and the posterior part of the ilium constitute the primitive mammalian origin of the biceps femoris. The origin of the muscle from the tuberosity in man is secondary and the sacrotuberous ligament represents the remains of its primitive tendon of origin.

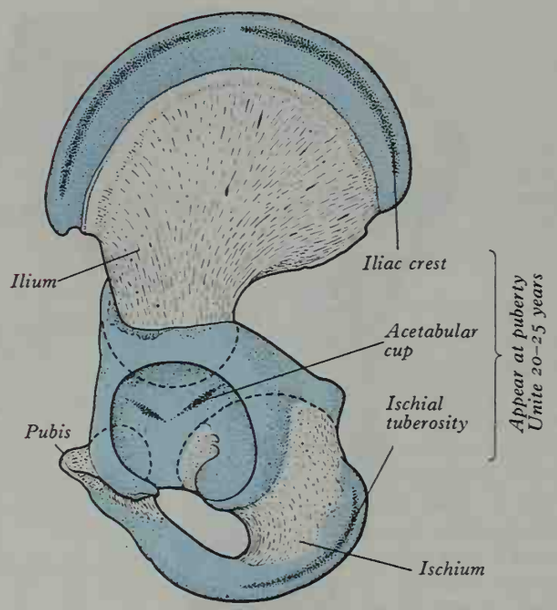


Above and medial to the tuberosity the posterior surface presents a wide, shallow groove. Here the bone is usually covered with a thin layer of hyaline cartilage and a bursa is interposed between it and the tendon of the obturator internus, which lies in the groove. To the lower margin of the groove, close to the tuberosity, the inferior gemellus is attached; the upper margin of the groove close to the ischial spine, gives origin to the superior gemellus.

The ischial spine projects downwards and slightly medially. To its margins is attached the sacrospinous ligament, which separates the greater sciatic foramen from the lesser (**4**.56). Its dorsal surface is crossed by the internal pudendal vessels and the nerve to obturator internus, as they pass through the gluteal region. The pelvic surface of the spine provides an origin for coccygeus and the most posterior fibres of levator ani. The structures passing through the greater and lesser sciatic foramina are detailed on p. 475.

The *pelvic surface* of the body of the ischium is smooth. To its upper part is attached the obturator internus, the fibres of which converge on the lesser sciatic notch and cover the remainder of this surface, with the exception of the pelvic aspect of the ischial spine. The muscle and its covering fascia separate the bone from the ischiorectal fossa.

The *anterior surface* of the *ramus of the ischium* faces the adductor region of the thigh. It gives origin to obturator externus above, the anterior fibres of the adductor magnus and, near the lower border, to the gracilis. Between the adductor magnus and the gracilis the origin of the adductor brevis may extend downwards from the inferior ramus of the pubis for a short distance. The *posterior surface* is divided into pelvic and perineal areas. The pelvic area is directed upwards and backwards and part of the obturator internus is attached to it. The perineal area is directed medially; its upper part is related to the crus of the penis or clitoris and gives origin to the sphincter urethrae; its lower part has the ischiocavernosus and the superficial transversus perinei attached to it. The inferior fascia of the urogenital diaphragm is attached to the ridge which separates the perineal from the pelvic area below, and the area for the crus from the origin of the sphincter urethrae above. The *lower border* of the ramus provides attachment for the fascia lata of the thigh and the membranous layer of the superficial fascia of the perineum.



The acetabulum (**3**.171A) is an approximately hemispherical cavity on the lateral aspect of the innominate bone about its centre, and is directed laterally, downwards and forwards. It is surrounded by an irregular projecting margin which is deficient *inferiorly*; this gap is the *acetabular notch*. The floor of the cavity is roughened and non-articular and is termed the *acetabular fossa*. The sides of the cup present an articular, *lunate surface*, which is widest superiorly; in this situation the weight of the trunk is transmitted to the femur in the erect attitude. This horseshoe-shaped strip is covered with articular cartilage and provides the surface on which the head of the femur moves within the hip joint. All three elements of the hip bone contribute to the formation of the acetabulum in man, but not in equal proportions. The pubis forms the upper and anterior fifth of the articular surface, the ischium, the floor of the acetabular fossa and rather more than the lower and posterior two-fifths of the articular surface, the ilium forms the remainder of the articular surface. A roughly linear defect occasionally crosses the acetabular surface from its *superior* border to the acetabular fossa; it does *not*, however, correspond to the junctions between ilium and ischium or ilium and pubis.

3.173 The left ischial tuberosity. Posterior aspect. The *transverse ridge* forms the lower boundary of the area for the hamstring muscles and separates it from the lower half of the tuberosity, which is divided into lateral and medial areas by the *longitudinal ridge*. To the lateral area is attached the adductor magnus; the medial area is covered with fibro-adipose tissue and supports the body in the sitting posture.

The obturator foramen is a large gap in the hip bone, below and slightly in front of the acetabulum, between the pubis and ischium. It is bounded above by the grooved obturator surface of the superior pubic ramus, medially by the body and inferior ramus of the pubis, below by the ramus of the ischium, and laterally by the anterior border of the body of the ischium, including the margin of the acetabular notch. The foramen is occupied in the recent state by a fibrous sheet, the *obturator membrane*, which is attached to its margins, except above, where a communication is left between the pelvis and the thigh. The free upper edge of the membrane is attached in front to the *anterior obturator tubercle*, which marks the anterior end of the inferior border of the superior ramus of the pubis, and behind to the *posterior obturator tubercle*, which is placed on the anterior border of the acetabular notch. These tubercles are not always easy to identify. Since the obturator groove cuts across the upper border of the foramen, the total border is in the form of a spiral. The foramen is large and oval in the male, but is smaller and nearly triangular in the female.

Structure. The thicker parts of the hip bone consist internally of cancellous bone, enclosed between two layers of compact bone; the thinner parts, at the bottom of the acetabulum and centre of the iliac fossa, are usually translucent and composed entirely of compact bone. At the upper part of the acetabulum and along the arcuate line, i.e. along the line of weight transmission from the sacrum to the head of the femur, the amount of compact bone shows a considerable increase. In this situation the underlying spongy bone displays two sets of pressure lamellae. The first arise near the upper part of the auricular surface and diverge to impinge on two stout buttresses formed by the compact bone. From there two similar sets of lamellar arches start and converge on the acetabulum (Wakeley 1929). Because of its frequent use as a site for biopsy puncture for bone marrow examination, the iliac crest,

3.174 The innominate bone at birth. More heavily stippled areas indicate the secondary centres of ossification and the Y-shaped medial extension of the cartilaginous acetabular cup is indicated by interrupted lines. The ossified part of the ischium is shown in the floor of the acetabulum.

especially in its ventral region, has been frequently studied in regard to the distribution of cortical and trabecular bone. Whitehouse (1977) has surveyed these studies; his own observations, based on scanning electron micrography, indicate that the cortical bone of the crest is peculiarly porous, being only 75 per cent bone, and as low as 35 per cent near the anterior superior iliac spine. Denser cortical bone was observed to commence at the margins of the crest, and to increase rapidly in thickness below it, on both aspects of the iliac squama.

Ossification. The hip bone is ossified from three primary centres, one each for the ilium, ischium and pubis: the centre for the ilium appears immediately above the greater sciatic notch about the eighth week of intrauterine life, the one for the ischium appears in the body in the fourth month, and that for the pubis in the superior ramus between the fourth and fifth months. At birth three parts of the hip bone are still cartilaginous; these are the whole of the iliac crest, the floor of the acetabulum and a strip along the inferior margin of the bone (**3**.174). At this stage the acetabulum is a cartilaginous cup with a triradiate stem extending medially from its deep aspect to appear on the pelvic surface as a Y-shaped epiphysial plate between the ilium, ischium and pubis (Harrison 1957). This cartilage also includes the anterior inferior iliac spine. The strip of cartilage along the inferior margin of the hip bone covers the surface of the ischial tuberosity, forms (temporarily) the full conjoined rami of the ischium and pubis and then continues to the symphysial surface of the pubis and then along the pubic crest to the pubic tubercle.

The ossifying ischium and pubis fuse to form the conjoined bony ramus at the seventh or eighth year. The secondary centres appear about puberty and join the rest of the bone between the fifteenth and twenty-fifth years. There are usually two secondary centres for the iliac crest but they fuse rapidly with one another. Ossification of the acetabular cartilage begins as two separate centres, one or other of which is often termed the *os acetabuli*, between the ilium and pubis and between the ilium and ischium; these two centres become fused as ossification spreads to include the whole stem of the cartilage. This centre forms a substantial part of the articular surface of the adult bone along the junction of the triradiate stem and cup of cartilage and around the periphery of the cup. The anterior inferior iliac spine may be ossified as an extension from this centre or from a separate centre. The cartilage around the inferior margin of the bone begins to ossify over the ischial tuberosity and ossification spreads forwards. The part which ossifies first fuses almost at once, before the more anterior parts have ossified and the fusion also extends forwards. The pubic tubercle and crest and the symphysial surfaces of the pubic bone may have separate centres.

The Skeletal Pelvis

The term *pelvis*, meaning a basin, is indiscriminately applied to the skeletal ring formed by the two innominate bones and the sacrum, the cavity of this arrangement, and also, by extension, to the entire region where trunk and lower limbs meet. It is used here in the skeletal sense, as the somewhat unsuitable name for the irregular bony girdle interposed between the femoral heads and the fifth lumbar vertebra. It is massively constructed in conformity with its primary, commonplace function of withstanding the compression and other stresses due to body weight and powerful musculature. Its mechanisms in this regard will be considered elsewhere (p. 475). Here, we shall be concerned with metrical and other characteristics, particularly in respect to sexual differences, which are of obstetric, forensic and anthropological application.

The pelvis can be regarded as separable into greater and lesser segments, sometimes called the true and false pelves, which are arbitrarily divided by an oblique plane. This passes through the sacral promontory behind and the *lineae terminales* at the sides and in front. Each linea terminalis includes the arcuate line of the ilium (p. 378) and the pecten (iliopectineal line) and crest of the pubis. The greater and lesser pelves are, however, structurally continuous, and the parts of the body cavity which they enclose are also continuous through the superior pelvic aperture, or pelvic inlet (**3**.176).

The greater pelvis consists of the flanged parts of the lilac bones above the lineae terminales on each side and the base of the sacrum posteriorly. The bone structure along this junctional zone is particularly massive, forming the main pathway on each side from the acetabular fossae to the vertebral column around the visceral cavity. The cavity of the greater pelvis is, of course, part of the abdomen; and because of the inclination of the pelvis as a whole (*vide infra*) the cavity has little anterior wall, as far as bone is concerned.

The lesser pelvis encloses a true basin when the soft tissues of the pelvic floor are in place. From the skeletal point of view it is a narrowed continuation of the greater pelvis, with irregular but more complete walls, bounding the pelvic cavity or canal. This cavity, which is naturally of the greatest obstetric importance, has an axis which is curved in the median plane. It is limited above and below by superior and inferior openings, the superior being occupied in life by viscera traversing it, the inferior being largely closed by the pelvic floor and its sphincteric mechanisms.

The superior pelvic aperture (pelvic inlet) is variable in contour, being rounded or oval, but encroached upon behind by the sacral promontory. The boundaries of the aperture, as described above, are conveniently referred to as the *pelvic brim* (**3**.176), which has particular obstetric significance (*vide infra*). It has long been subject to measurement for anthropological and obstetric reasons—as has the pelvic cavity in general—and a very considerable array of values is available, especially for the female. Naturally, the means recorded by different observers show some variation, being founded on groups differing greatly in racial and economic background. The figures cited here are merely approximate samples of the values to be expected in Europeans (Martin 1928). The following three dimensions have become conventional.

A. The *anteroposterior diameter* (true conjugate) is measured between the midpoints of the sacral promontory and the upper border of the symphysis pubis (male 100 mm, female 112 mm).
B. The *transverse diameter* is the maximum distance that can be found between similar points (as far as they can be assessed by eye) on opposite sides of the pelvic brim (male 125 mm, female 131 mm).
C. The *oblique diameter* is measured from one iliopubic

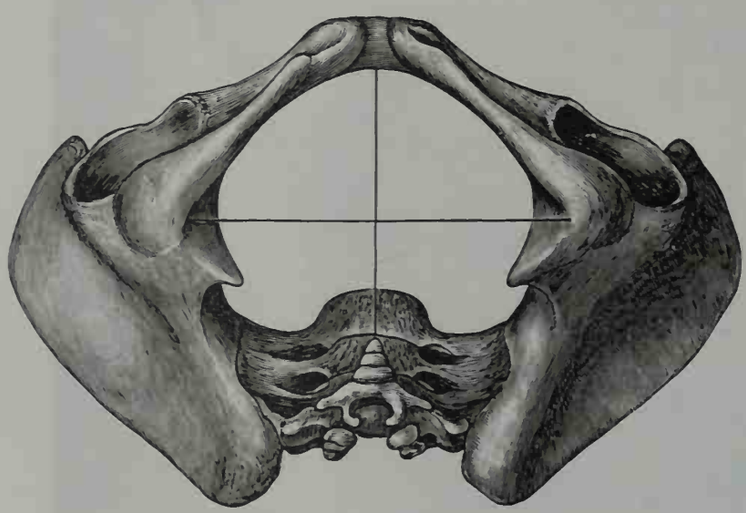
eminence to the opposite sacroiliac joint (male 120 mm, female 125 mm).

The cavity of the lesser pelvis is short and curved, being markedly longer in its posterior wall than in its anterior. In front and below, it is bounded by the body of the pubis and its rami and symphysis, limited behind by the concave anterior surface of the sacrum and by the coccyx, and on each side is a smooth quadrangular area formed by the pelvic aspect of the fused ilium and ischium. The region thus enclosed is the pelvic cavity proper, through which pass, in all land vertebrates, the end of the alimentary canal and the urogenital ducts. It thus contains, in human beings, the rectum, bladder and parts of the reproductive organs. The rectum is most posterior, the bladder anterior, and the uterus intermediate in position.



The diameters of the pelvic cavity are also sometimes estimated, and while this could be done theoretically at a large number of levels, the measurements are usually carried out at approximately mid-level.

A. The *anteroposterior diameter* is measured between the midpoints of the third sacral segment and the posterior surface of the symphysis pubis (male 105 mm, female 130 mm).
B. The *transverse diameter* is the widest transverse distance that can be found between the bony side walls of the cavity. It is in fact often the greatest transverse dimension in the whole extent of the cavity (male 120 mm, female 125 mm).
C. The *oblique diameter* is defined as the distance from the lowest point of one sacroiliac joint to the midpoint of the opposite obturator membrane (male 110 mm, female 131 mm).

The inferior pelvic aperture (pelvic outlet) (**3**.177) is much less simple in outline than the superior aperture, being indented behind by the coccyx and sacrum and on each side by the ischial tuberosities. The perimeter of the opening thus consists of three wide notches, or arcs, the anterior being the *pubic arch*, between the converging ischiopubic rami. Between the sacrum and coccyx

3.176 The diameters of the superior aperture of the lesser pelvis (female). A = sacroiliac joint; B = iliopubic eminence; C and D = middle of pelvic brim; E = sacral promontory; F = pubic symphysis.

3.177 The diameters of the inferior aperture of the lesser pelvis (female). (The oblique diameter is not shown.)

behind and the ischial tuberosities at the sides, are two large *sciatic notches*, divided by the sacrotuberous and sacrospinous ligaments into the *greater* and *lesser sciatic foramina* (p. 475). Taking into account these ligaments, the inferior aperture is rhomboidal or diamond-shaped, its anterior limbs being the ischiopubic rami (joined together by the inferior pubic ligament in the midline), the posterior sides being the sacrotuberous ligaments, with the coccyx in the midline. The pelvic outlet is thus not entirely rigid in its posterior half, being limited only by the ligaments and the coccyx, which is mobile on the sacrum. Even when the sacrum is taken as the posterior midline limit of the aperture, as is more satisfactory for measurement, it is to be remembered that the sacrum also is slightly mobile at the sacroiliac joints. It is also to be noted that the plane of the inferior aperture is theoretical rather than real. The anterior, ischiopubic part of the opening has a plane which inclines downwards and backwards to a transverse line joining the lower limits of the ischial tuberosities. The posterior half of the aperture has a plane corresponding roughly to the sacrotuberous ligaments and sloping downwards and forwards to the same transverse line. The dimensions of the inferior aperture are measured as follows:

A. The *anteroposterior diameter* is usually measured from the apex of the coccyx, despite the bone's mobility, to the midpoint of the lower rim of the symphysis. Sometimes the lowest part of the sacrum is used for the posterior point (male 80 mm, female 125 mm).
B. The *transverse diameter* is measured between the ischial tuberosities, from the lower border of their medial surfaces. It is consequently termed the *bi-tuberous diameter* (male 85 mm, female 118 mm).
C. The *oblique diameter* extends from the midpoint of the sacrotuberous ligament on one side to the junction of the ischial and pubic rami on the other (male 100 mm, female 118 mm).

Apart from these three pelvic planes of measurement, which by agreement form the basis of pelvic osteometry, certain other planes and measurements are also used, especially in obstetric practice. The *plane of greatest pelvic dimensions* is an obstetrical concept, representing the level in the pelvic cavity where it is most capacious. It is between the pelvic brim and the midlevel plane, corresponding with the latter in its anterior level (middle of the symphysis) but inclining slightly above it to reach the sacrum between its second and third segments. The *plane of least pelvic dimensions* is said to be at about the midlevel of the cavity, but its transverse diameter is the shortest distance between the apices of the ischial spines. It is at this level that most difficulty with labour is encountered. The *posterior median diameter* is a useful concept in obstetric application. It corresponds to the part of any anteroposterior diameter behind its intersection with the transverse diameter at that level. It can thus be considered at any of the conventional levels or planes, and is an indicator of the capacity of the posterior segment of the pelvic cavity. Because of the impossibility of direct measurement of the osseous dimensions of the pelvic cavity in living patients, except by radiological methods, some indirect measurements have long been practised.

The *diagonal* (or *oblique*) *conjugate* is the distance between the sacral promontory and the lower border of the symphysis, measured *per vaginam*, and is taken as a guide to the 'true' conjugate. The latter, and, of course, all the diameters usually described anatomically in the pelvic cavity, disregard the existence of soft tissues. The *intercristal* and *interspinous diameters*, which are respectively the greatest widths between the iliac crests and the anterior superior iliac spines, are sometimes estimated and compared in females. Average values are 250 mm and 275 mm, the difference between them being regarded as an indication of the width of the pelvic cavity, on the generalization that the iliac crests do not turn medially at their anterior ends to the same extent in the female as they do in the male. The value of this method is dubious, because correlation between sexual characteristics in the pelvis is still the subject of controversy.

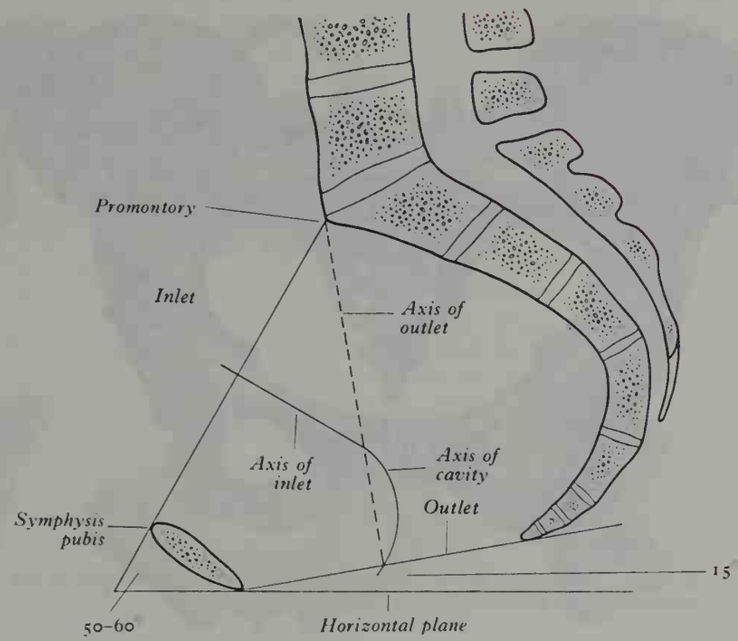
Morphological Classification of the Pelvis

The importance of the dimensions detailed above is mainly obstetric, but also, less frequently, forensic. All diameters and other measurements of the pelvis display, as elsewhere in the skeleton, considerable variation in individuals, and the figures quoted are merely means taken from limited surveys. Naturally, sexual differences also occur, and there are differing racial ranges in values. The range in any group, both for males and females, is found to be wide wherever it has been adequately assessed. Measurements have necessarily been carried out on series of skeletonized pelves in the most extensive studies; the data from these are not only of anthropological interest but have also formed the basis of attempts to classify variant forms of pelvis which could be clinically identified, without resorting to the full range of basic measurements. These cannot all be measured in the living, but radiological pelvimetry has become a highly refined technique (Borell and Fernström 1960), although radiation risks impose a limiting factor. In the female patient it is obviously her individual measurements which are significant, and not available average values, and it is the comparison between these dimensions and those of the particular fetal head involved which is of principal concern. These are all dimensions which can only be satisfactorily measured by radiographic techniques, and hence modern pelvimetry and fetal cephalometry have, to a considerable extent, displaced older caliper measurement in obstetric practice,

whenever the requisite expertise is available (Clyne 1963; Lewis 1964).

The basic pelvic measurements, however obtained, have been analysed by a succession of anatomists, anthropologists, obstetricians and radiologists in an attempt to classify the human pelvis, more especially in the female. The *pelvic brim index*—(ant.-post./trans. diameters) × 100—was one of the earliest attempts to characterize the shape of the pelvic cavity (Turner 1886). Like the cephalic index (p. 348) its range is divided into steps, on which basis pelves are described as *platypellic* (transversely flattened), *mesatipellic* (intermediate form) and *dolichopellic* (long anteroposteriorly). This classification has been carried further, on anatomical and radiological data, to add a *brachypellic* form, also known as *android* and responsible for most cases of severe difficulty in childbirth (Greulich and Thoms 1938, 1939; Thoms 1940). It should be emphasized that these methods of classification depend upon exact measurements and are equally applicable to males and females. For example, in one large series, children and males were found to be predominantly dolichopellic, females mostly mesati- and brachy-pellic.

Platypellic pelves are comparatively rare in all series. Another method of classification depends jointly upon basic anatomical data and analyses of radiological data, the latter including inspectional as well as metrical observations (Caldwell and Moloy 1933; Caldwell *et al.* 1940). This approach to the problem involves dividing the superior pelvic aperture by its transverse diameter into an anterior segment, the *forepelvis* and a posterior *hindpelvis*, the latter being more variable in shape and capacity. The slope of the pelvic walls, whether straight, convergent, or divergent (as seen in radiographs), the pelvic depth and the shape and size of the greater sciatic notch (lateral radiographs), and the shape of the subpubic arch are all taken into consideration. This study led to the wide acceptance of the classification into four basic pelvic types shown in illustration **3**.181. It should be emphasized that the classification depends fundamentally upon measurement of skeletal material, though it is frequently applied in practice in a somewhat subjective manner. Though the existence of intermediate forms of pelvis is not denied, the classification is claimed to embrace all but a very small percentage. The basic skeletal data of the original study were as follows:



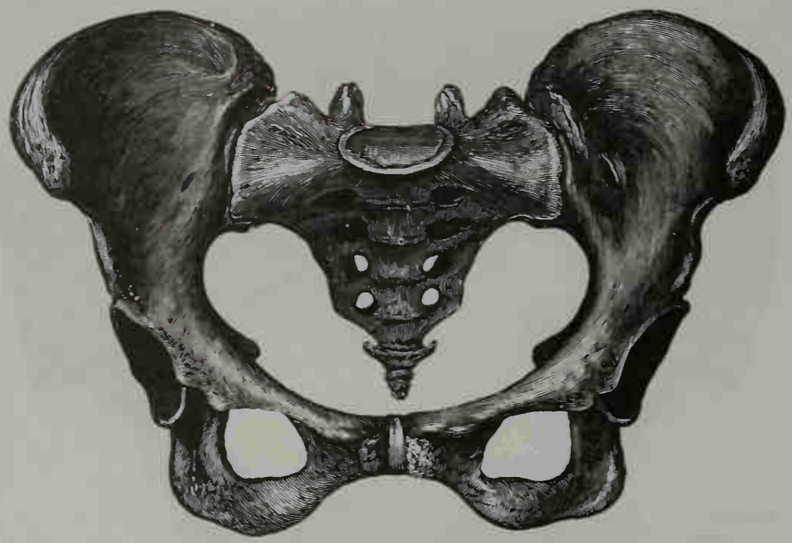
PELVIC TYPE	CONJUGATE DIA. (mm)	TRANSVERSE DIA. (mm)	WHITE FEMALES (%)	NEGRO FEMALES (%)
Gynaecoid (=mesatipellic)	108·5	137·6	41·4	42·1
Android (=brachypellic)	105·9	135·6	32·5	15·7
Anthropoid (=dolichopellic)	117·5	129·4	23·5	40·5
Platypelloid (=platypellic)	85·5	144·5	2·6	1·7

Apart from racial differences (e.g. the high rate of anthropoid pelves in Negro women), these observations emphasize the low incidence of the highly 'flattened' platypelloid form. It is interesting to note that children (under 9 years) and adult males also show a high incidence of dolichopelly; perhaps this is a paedomorphic trait in the male. The platypelloid pelvis has been described as 'ultra-human'.

Correlation of pelvic type with general bodily physique is still a matter of controversy (Smout *et al.* 1969). It has been claimed, for example, that women with the dangerous android form of pelvis are thick-set, short-necked, and broad-shouldered (Kenny 1944), but such views have been regarded as unreliable by other observers (Ince and Young 1940).

Pelvic Axes and Inclination

The axes of the superior pelvic aperture passes through the centre of and at right angles to the opening's plane. It is directed downwards and backwards, and if prolonged it passes through the umbilicus and the middle of the coccyx. The axis is similarly established for the inferior aperture, and when projected upwards it impinges on the sacral promontory. An axis could be likewise constructed for any intermediate plane, and an axis for the whole cavity can be regarded as the concatenation of an infinite series of such lines. It follows the curvature of the cavity, indicated by the profile of the sacrum and coccyx in lateral views (**3**.178). The form of the *pelvic axis* and the disparity in depth between the anterior and posterior contours of the cavity are both important factors in the mechanism of passage of the fetus through the pelvic canal.



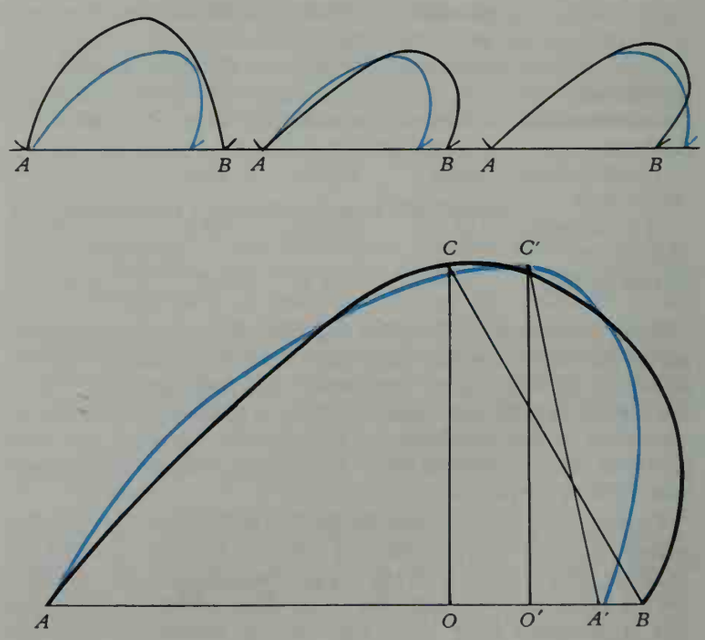
3.178 A median sagittal section through the female pelvis to show the planes of inlet and outlet and their relation to each other and the horizontal plane. The curved axis of the pelvic cavity is also shown. It should be observed that, as depicted in this section, the curve of the sacrum affects the lower part of the third and the upper part of the fourth sacral vertebrae. In many cases the curve is restricted to the fourth vertebra only.

In the standing position the pelvic canal curves obliquely backwards relative to the trunk and the abdominal cavity (**3**.178). The whole pelvis is tilted forwards so that the plane of the pelvic brim makes an angle of 50 to 60° with the horizontal. The plane of the inferior aperture is tilted in the same sense to about 15°, the dorsal parts of the perimeters of both planes being above the ventral. Strictly speaking, the pelvic outlet has two planes, an anterior passing backwards from the symphysis and a posterior passing forwards from the apex of the coccyx, the two sloping down to meet at the intertuberous line. With the pelvis orientated as in standing, the pelvic aspect of the symphysis pubis faces as much upwards as backwards, and the concavity of the sacrum is directed antero-inferiorly. The front of the symphysis and the anterior superior iliac spines are in the same vertical plane. In the sitting position the body weight is transmitted through the inferomedial parts of the ischial tuberosities, a variable amount of soft tissues intervening. In this posture the same spines are in a vertical plane through the centres of the acetabular fossae. Thus the whole pelvis is tilted backwards, and the lumbosacral angle is somewhat diminished at the promontory.

Sex Differences in the Pelvis

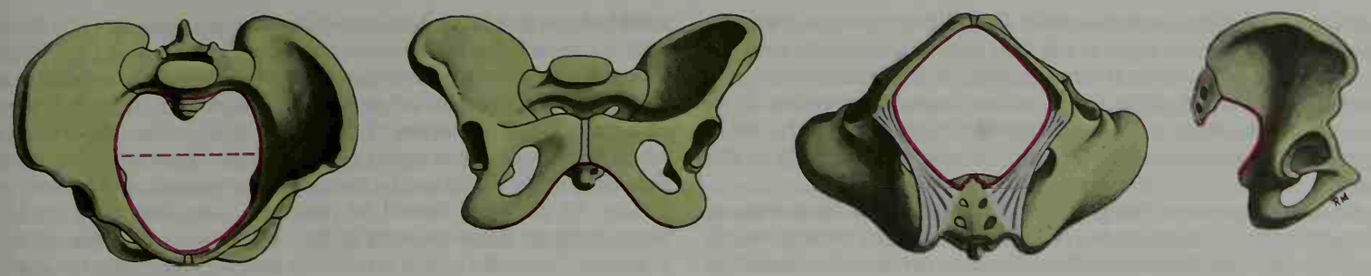
As is to be expected, the pelvis provides the most marked and typical skeletal differences between the male and female (**3**.179, 180, 181). Perhaps less to be expected is the distinction that can be made between the sexes in this respect even during fetal life, particularly in the subpubic angle or arch (Boucher 1957). Radiographic studies of the pelvis in American children during the first postnatal year have shown that in general male infants exceed females in dimensions of the whole pelvis, whereas the females exceed males in measurements of the pelvic cavity (Reynolds 1945). In the prepubertal period of 2 to 9 years similar tendencies are apparent; but the maximal difference is said to

3.179A The female pelvis. Anterior aspect. (From a specimen in the museum of the Royal College of Surgeons of England).



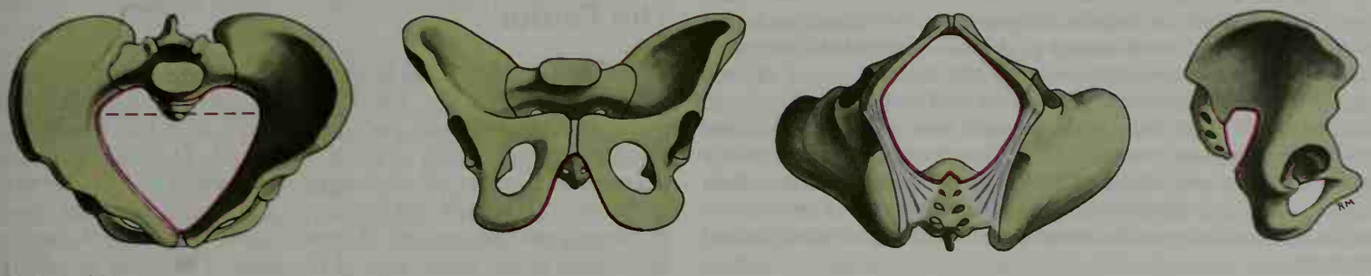
3.179B The male pelvis. Anterior aspect.

occur at 22 months, the sexual divergence decreasing in the later years of childhood (Reynolds 1947).

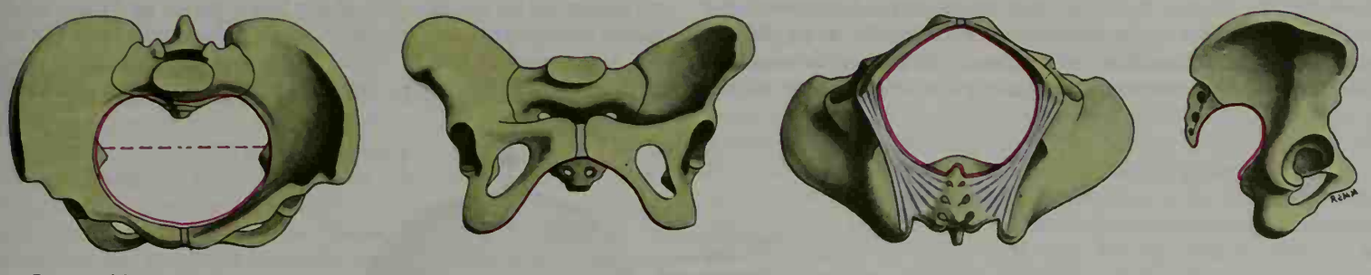


Sexual differences in the adult pelvis have been studied and measured extensively (Genovese 1959). They can be divided into metrical and non-metrical characteristics, the range of most showing some overlap between the sexes.

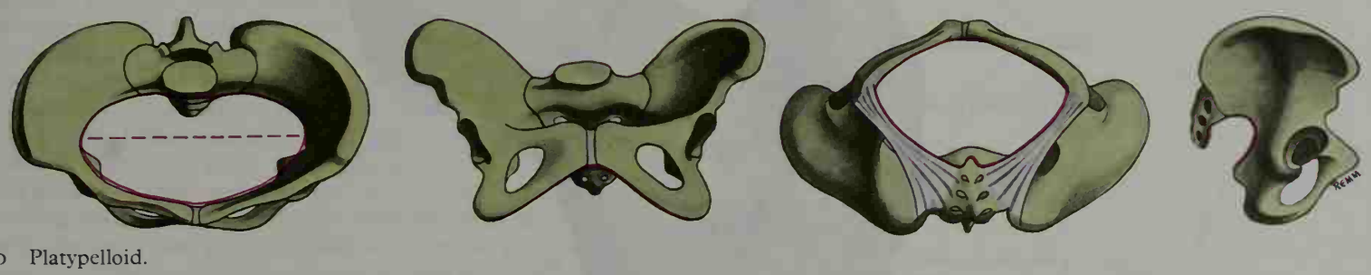
The differences are inevitably associated with function, and while the primary function of the pelvis in *both* sexes is locomotor, it is specially adapted to the needs of childbirth in the female. This reproductive adaptation affects particularly the lesser pelvis; but the changes in this affect the proportions and dimensions of the greater pelvis to a variable degree in the female. Since the male is distinctly more muscular, and therefore more heavily built, the overall dimensions of the pelvis, such as intercristal measurement, are greater in males, markings for muscles and ligaments are more pronounced, and the general architecture is relatively stouter. The iliac crest is more rugged and curves medially at its anterior end more acutely than in the female, whose crests are less curved in every particular. The iliac blades are more vertical in the female, but do not extend so far upwards; the iliac fossae are therefore shallower, and the iliopectineal line, or pecten pubis, is more vertical. These iliac peculiarities probably account for the greater prominence of hip in the female.



The male is relatively and absolutely more heavily built above the pelvis than the female, and this produces characteristic differences at the lumbosacral and hip joints. The articular facet on the base of the sacrum for the fifth lumbar vertebra and intervening disc occupies distinctly more than a third of the width of the base, but less than a third in the female, whose sacrum is also relatively broader, accentuating this difference. Similarly at the hip joint, the acetabulum is absolutely larger in the male, and its diameter is about equal to the distance of its anterior rim from the symphysis pubis. In the female, however, the acetabular diameter is usually distinctly less than this distance, not only because it is absolutely smaller than in the male, but also because the whole of the anterolateral wall of the pelvic cavity is comparatively wider in the female. The symphysis and the adjoining parts of the pubis and ischium, forming the anterior pelvic wall, are also absolutely less in height than in the male, and this is commonly associated with a somewhat triangular shape in the obturator foramen, which is more ovoid in males. The different mode of growth in the pubic region in the sexes is also expressed in the subpubic arch or angle, situated below the symphysis and between the inferior pubic rami. It is more angular in the male, being of the order of 50 to 60°. In the female it is less easy to measure because of the rounded nature of the angle, but it is usually 80 to 85°. Also associated with the pubic width of the female is greater separation between the pubic tubercles. The ischiopubic rami display some differences. They are much more lightly built in the female and are narrowed near the symphysis. In the male they bear a distinctly roughened and everted area for the attachment of the crus penis, the corresponding attachment for the clitoris being poorly developed. The ischial spines are closer together in the male, being characteristically inturned. The greater sciatic notch is usually much wider in the female; comparisons have been made of its width and angle, mean angular values for males and females being 50·4° and 74·4° (Hanna and Washburn 1953). The greater value of this angle in the female, and the greater width of the notch, are associated with the increased backward tilt of the sacrum, and generally greater anteroposterior diameter of the female pelvic cavity, especially at lower levels. For a method of comparing the *depth* of the notch in the sexes, consult Jovanović and Živanović (1965). More recently,



3.180 *Above*: three common profiles of the greater sciatic notch in males (blue) and females (black). *Below*: points, axes and angles utilized in mensuration of the greater sciatic notch. AB equals *maximal width*, i.e. distance between the tip of the ischial spine and a tubercle marking attachment of the piriformis muscle. OC equals *maximal depth* (perpendicular to AB). OB equals *posterior segment* of width. Index I = OC × 100/AB. Index II = OB × 100/AB. ACB = *total angle*. BCO = *posterior angle*. (Modified, with kind permission, from Singh and Potturi 1978).



A Anthropoid.

B Android.

D Platypelloid.

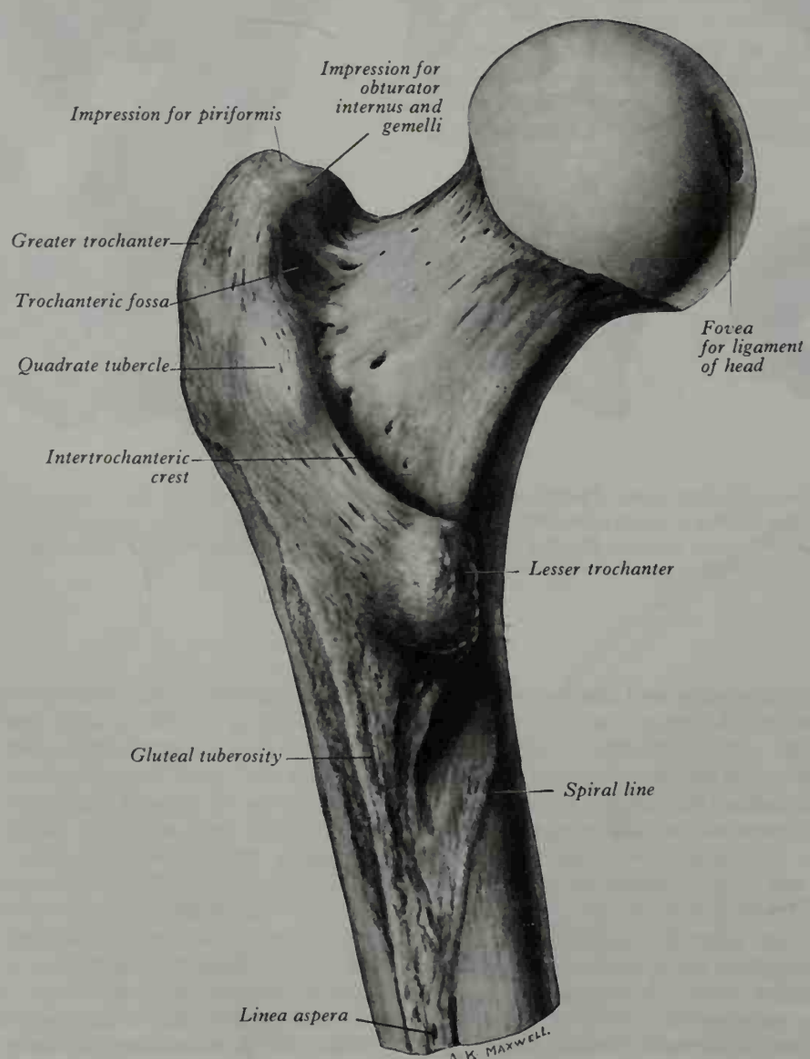
3.181 The major differences between the four types of pelvis in the most widely accepted classification. Types shown in A and B are commonest in males, B and C in females, while D is rare, even in females. Note the variations in superior and inferior apertures, greater sciatic notch, and subpubic arch. Note varying proportion between fore- and hind-pelvis, anterior and posterior to transverse diameter of the inlet. (Caldwell and Moloy's Classification, after Clyne 1963.)

a detailed analysis of various dimensions and derived indices in relation to sex determination and the greater sciatic notch has appeared (Singh and Potturi 1978). Having reviewed the literature, the latter studied 200 adult hip bones (120 males and 80 females) of known sex. Using defined demarking points (Jit and Singh 1966) they measured maximal width, maximal depth, posterior segment of width, total angle, posterior angle, and indices I and II—*see* **3**.180 and original paper for details. The width and depth of the notch *per se* were found to be valueless as criteria for determining sex: the posterior angle was the best single parameter, whilst the length of the posterior segment and index II were also highly effective, especially in females.

The sacrum presents a considerable number of sexual differences, in addition to the differences in orientation just mentioned. The female sacrum is less curved, its curvature being most marked between the first and second segments and between the third and fifth, with an intervening flattened region. The male sacrum is more evenly curved, relatively long and narrow, and more often consists of over five segments (due to the addition of a lumbar or coccygeal vertebra). A *sacral index* can be assessed by comparing sacral breadth (measured between the most anterior points of the two auricular surfaces) with length (measured between the midpoints on the anterior margins of the promontory and apex); average values for male and female are 105 and 115 per cent. The auricular surfaces differ in some respects, being relatively smaller and more obliquely set in the female; contrary to a commonly made statement, they extend on to the upper three sacral vertebrae in *both* sexes. The concavity of the dorsal border of the auricular surface is more marked in females (Weisl 1954).

Many of these differences have been summarized in the generalization that the pelvic cavity is longer and more conical in the male, shorter and more cylindrical in the female, though in

both the axis of the canal is curved. The differences are greater at the inferior aperture than at the pelvic brim, where in absolute measurements the male is not as different from the female as is sometimes implied. The shape of the superior aperture is, of course, more likely to be anthropoid or android in the male, gynaecoid or android in the female, the sexes overlapping to this extent.



In forensic practice the problem of identifying human remains frequently involves diagnosis of sex, which can be most certainly established from the pelvis. Even parts of this may be useful for this purpose, though some doubt must always remain. A number of detailed studies of the metrical characteristics of various parts of the pelvis have been carried out, involving various indices. The ilium has received particular attention. For example, an index has been devised which essentially compares the pelvic and sacroiliac parts of the bone (Derry 1923/24). A line is extended backwards from the iliopectineal eminence to the nearest point on the anterior margin of the auricular surface and then to the iliac crest. The auricular point divides this *chilotic line*, as it is called, into anterior (pelvic) and posterior (sacral) segments, each of which is expressed as a percentage of the other. These *chilotic indices* display reciprocal values in the sexes, the pelvic part of the chilotic line being relatively predominant in the female, the sacral part in the male.

The most detailed metrical study of the ilium, involving a number of indices, leads to the conclusion that its characteristics are of limited reliability in sexing the pelvis (Straus 1927). However, the higher incidence and more marked nature of the preauricular sulcus in the female was confirmed (*see* p. 380). A *pubo-ischial index*, based on the maximum lengths of the ischium and pubis, as measured from their point of junction in the acetabulum, produces values such as 83·7 per cent and 100·0 per cent for American males and females (Washburn 1949). When this index was correlated with the angle of the sciatic notch it was claimed that the sex of 98 per cent of pelves could be correctly deduced. The correlation of such data is to be emphasized, for when a considerable range of pelvic data are considered together, especially where they can be metrically expressed, an accuracy of at least 95 per cent should be possible. Complete accuracy has been claimed when the rest of the individual's skeleton is also available. Nevertheless, it is unlikely that the assessment of sex in isolated and restricted human remains, a not unusual forensic problem, can always be absolutely certain.

The Femur

The femur or thigh bone is, of course, the longest and strongest bone (**3**.182–189). Its length is associated, naturally, with mankind's striding gait and its strength with the weight and muscular forces which it must withstand. Its shaft is almost cylindrical in most of its length and bowed with a forward convexity. Its upper extremity is a rounded articular head, projecting medially on a short neck of bone, formed by the medial inclination of the upper part of the shaft. The distal or inferior extremity is more massive, being in the form of a double 'knuckle' or condyle, articulating with the tibia.

In the erect posture the femora are oblique (**3**.1). Their heads are separated by the breadth of the lesser pelvis and their shafts incline downwards and medially, so that the medial sides of the two knees almost touch. Since the bones of the legs descend vertically from the knees, the obliquity of the femoral shafts

390 **3**.182 The proximal part of the left femur. Posterior aspect.

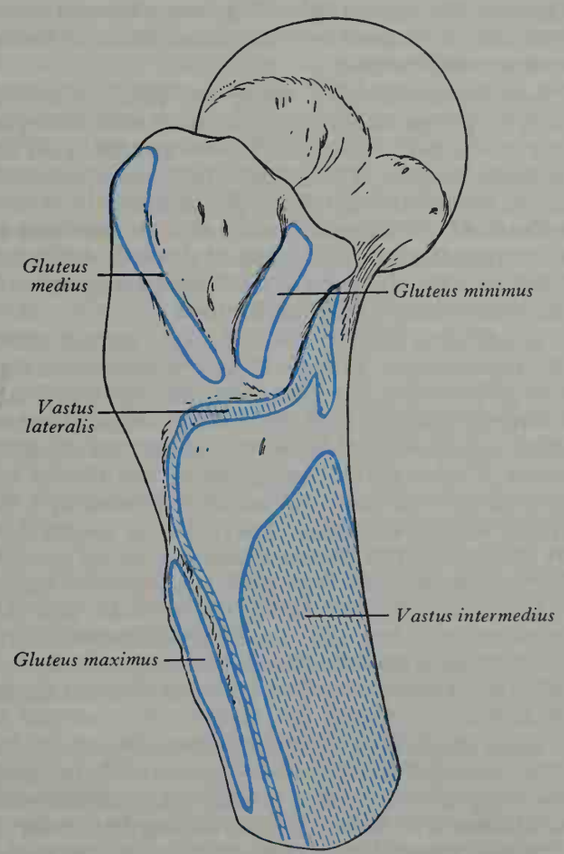
results in the approximation of the feet in the erect attitude, bringing them directly under the line of body weight. The narrowness of the base detracts from the stability of the body but greatly facilitates forward movement and increases the speed and smoothness with which it can be executed. The degree of obliquity of the shafts varies in different individuals, but is greater in women on account of the greater breadth of the pelvis and relative shortness of the femora.

The upper end of the femur (**3**.182) comprises a head, a neck, a greater and a lesser trochanter.

The head of the femur is rather more than half a 'sphere' (*see* pp. 477, 432); it is directed upwards, medially and slightly forwards, to articulate with the acetabulum. Its surface is smooth, but a little below and behind its centre is a small roughened pit or *fovea*.

The neck of the femur, which is about 5 cm long, connects the head and the shaft, with which it forms an angle of about 125°. This arrangement facilitates the movement of the hip joint and enables the lower limb to swing clear of the pelvis. The neck is narrowest at its middle and is wider at its lateral than at its medial end. Its two borders are rounded. The upper border is roughly horizontal and is gently concave upwards. The lower border is straighter but oblique, and directed downwards, laterally and backwards to meet the shaft near the lesser trochanter. The anterior surface of the neck is flattened and its junction with the shaft is marked by a prominent rough ridge, termed the *intertrochanteric line*. The posterior surface is convex backwards and upwards in its transverse axis, and concave in its long axis, and its junction with the shaft is marked by a rounded ridge, termed the *intertrochanteric crest*.

The greater trochanter is a large, quadrangular projection at the upper part of the junction of the neck with the shaft. Its posterosuperior portion projects upwards and medially (**3**.185) so as to overhang the adjoining part of the posterior surface of the neck; in this situation its medial surface presents a roughened, depressed area, the *trochanteric fossa*. The upper border of the trochanter lies one hand's breadth below the tubercle on the iliac crest, and is on a level with the centre of the head of the femur. The anterior surface of the trochanter bears a roughened impression; its lateral surface is divided into two areas by an oblique, flattened strip, wider above than below, which runs downwards and forwards across it. The lateral surface of the trochanter can be palpated in the living (**3**.183), and, when the adjoining muscles are relaxed, the trochanter can be gripped. The trochanteric fossa occasionally presents a tubercle or exostosis, which has been regarded as a useful non-metrical racial characteristic (*see* p. 238).



The lesser trochanter (**3**.182) is a conical eminence, which projects medially and backwards from the shaft at its junction with the lower and posterior part of the neck. Its summit and anterior surface are roughened, but its posterior surface, which lies at the lower end of the intertrochanteric crest, is smooth. It is placed too deeply to be felt in the living.

The intertrochanteric line marks the junction of the anterior surface of the neck with the shaft of the femur (**3**.184). It is a prominent roughened ridge, which commences in a tubercle at the upper and medial part of the anterior surface of the greater trochanter and runs downwards and medially. It reaches the lower border of the neck on a level with the lesser trochanter, but in front of it. It often presents a second tubercle near its lower end. Below, it is continuous with the *spiral line* (p. 392).

The intertrochanteric crest (**3**.182) marks the junction of the posterior surface of the neck with the shaft of the femur. It is a smooth rounded ridge, which commences at the posterosuperior angle of the greater trochanter and runs downwards and medially to terminate at the lesser trochanter. A little above its middle it presents a low rounded elevation, the *quadrate tubercle*.

The head of the femur is entirely intracapsular and is encircled immediately lateral to its greatest diameter by the acetabular labrum. Its circumference is sharply defined, except anteriorly, where the cartilage-covered surface extends on to the front of the neck. The fovea which marks the head below and behind its centre (**3**.182) affords attachment to the ligament of the head of the femur. The inferomedial part of the anterior surface of the head is related to the femoral artery, from which it is separated by the tendon of the psoas major and the articular capsule. The blood supply of the head is of surgical importance. Around the neck, at the attachment of the fibrous capsule of the hip joint, there is a vascular ring supplied by branches of the medial and lateral circumflex arteries. From this arteries arise which pierce the capsule and pass under the zona orbicularis (p. 477) to ascend along the neck beneath the reflection of synovial membrane. These arteries divide into metaphysial branches which enter the neck and epiphysial branches which pass into the peripheral non-articular portion of the head to supply the epiphysis. During growth the territories of the two groups of branches are separated by the epiphysial plate; after osseous union of the head with the neck they anastomose freely. A small supply to the head of the femur is carried by the vessels in the ligament of the head (pp. 397 and 728) which are acetabular branches of the obturator and medial femoral circumflex arteries; these anastomose with the epiphysial vessels (Crock 1965). Observations on the developmental patterns of this blood supply in late fetal and early post-natal periods do not entirely corroborate the above description (Ogden 1974). Although the medial and lateral circumflex arteries contribute equally to the vascular network initially, the final pattern consists of two major branches of the medial circumflex, both related to the posterior aspect of the femoral neck. The supply from the lateral circumflex diminishes and the arterial 'ring' becomes incomplete. As the femoral neck elongates, the extracapsular ring becomes more and more distant from the epiphysial head of the femur.

The neck of the femur is marked by numerous vascular foramina, especially on its anterior surface and on the upper part of its posterior surface. The angle which it makes with the shaft is widest at birth and diminishes steadily until the adult condition is reached. It is less in the female than in the male, owing to the increased breadth of the lesser pelvis and the greater obliquity of the shaft of the femur. The *anterior surface* of the neck is entirely intracapsular and on this surface the capsular ligament extends laterally to the intertrochanteric line. Facets, often covered by an extension of the articular cartilage of the head, and various imprints frequently occur on the anterior surface of the neck. Although attributed to squatting habits, they are also seen in non-

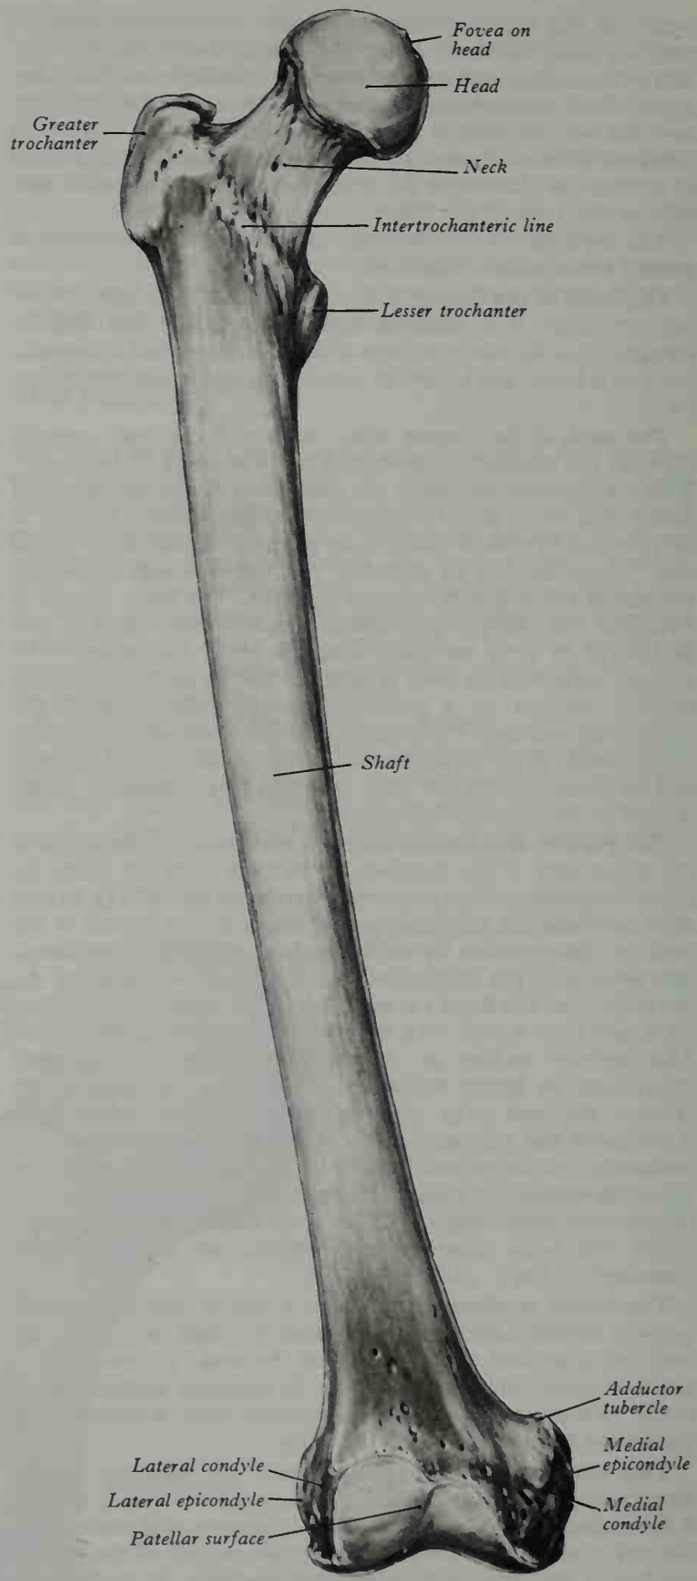
3.183 The proximal part of the right femur. Lateral aspect.

squatters and there is no agreement about their causation (Kostick 1963; Kate 1963). One such feature, the *cervical fossa* (of Allen) may be of racial significance (*see* p. 238). On the *posterior surface* the capsular ligament does not reach the intertrochanteric crest (**3**.182), and only a little more than the medial half of the neck lies within the capsule. The part of the anterior surface adjoining the head covered with cartilage is related to the iliofemoral ligament in the erect posture. A faint groove crosses the posterior surface in an upward and lateral direction; it is produced by the obturator externus tendon as it passes to the trochanteric fossa. The neck of the femur does not lie in the same plane as the shaft, but is carried forwards as it passes upwards and medially. On this account the transverse axis of the head of the femur makes an angle with the transverse axis of the lower end of the bone, and this angle is known as the *angle of femoral torsion* (approximately 15°).

The greater trochanter (**3**.183) provides insertion for most of the muscles of the gluteal region. The gluteus minimus is inserted into the rough impression on its anterior surface. The gluteus medius is inserted into the oblique, flattened strip, which runs downwards and forwards across its lateral surface. The area in front of this insertion is separated from the tendon by the trochanteric bursa of the gluteus medius; the area behind the insertion is covered by the deep fibres of the gluteus maximus, and part of the trochanteric bursa of that muscle may be interposed. The upper border of the trochanter gives insertion to the piriformis, and its medial surface to the common tendon of the obturator internus and the two gemelli. At their insertions these two tendons are frequently blended with each other to a variable extent. The trochanteric fossa receives the insertion of the obturator externus.

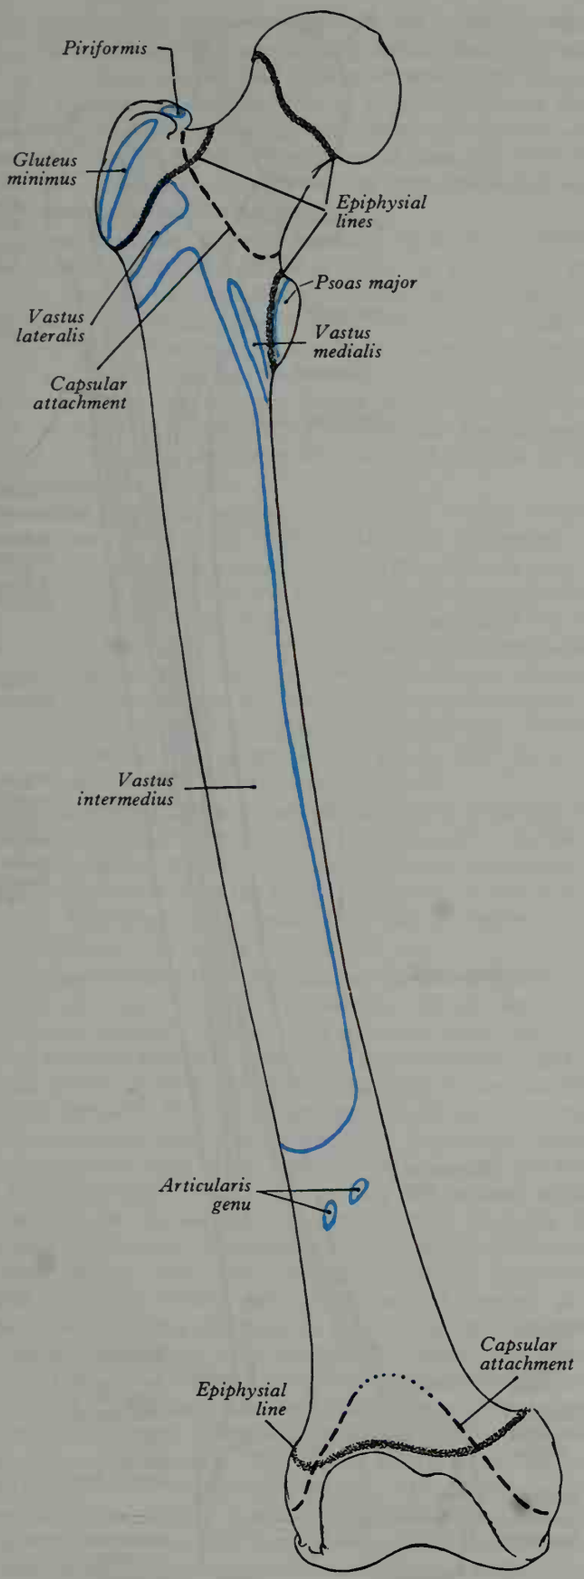
The lesser trochanter has attached to it psoas major on its summit and on the medial part of its anterior surface. The base of the trochanter is expanded and its medial or anterior surface has the iliacus attached to it extending downwards for a short distance behind the spiral line. The upper fibres of the adductor magnus play over the posterior surface of the lesser trochanter and a bursa is sometimes interposed between them.

The *intertrochanteric line* marks the lateral limit of the capsular ligament of the hip joint. Its upper part, including the tubercle already noticed, receives the attachment of the upper band of the iliofemoral ligament; its lower part receives the lower band of the same ligament. The highest fibres of the vastus lateralis arise from the upper end of the line, and the highest fibres of the vastus medialis from its lower end.



The *intertrochanteric crest*, above the *quadrate tubercle*, is covered by the gluteus maximus; below the tubercle it is separated from that muscle by the quadratus femoris and the upper border of the adductor magnus. The tubercle itself, and a portion of the bone below, receive the insertion of the quadratus (**3**.185B).

The shaft of the femur (**3**.184, 185) is narrowest in its middle: it expands a little as it is traced upwards, but it widens appreciably near the lower end of the bone. Its long axis inclines about 10° from the vertical axis of the tibia.



In its *middle third* the shaft possesses three surfaces and three borders. The extensive *anterior surface*, is smooth and gently convex in all directions. It is placed between the lateral and the medial borders, which are both rounded and somewhat arbitrary. The *lateral surface* is directed more backwards than laterally, and is bounded in front by the lateral border and behind by the posterior border. The posterior border is formed by a broad, rough ridge, termed **the linea aspera**, which usually forms a crestlike projection, with distinct lateral and medial lips. In this situation the compact bone of the shaft is increased in amount to withstand the compression forces concentrated here by its anterior curvature. The *medial surface* is directed medially and slightly backwards; smooth, like the two other surfaces, it is bounded in front by the indistinct medial border and behind by the linea aspera.

In its *upper third* the shaft presents a fourth surface, which is directed backwards. This *posterior surface* is bounded medially by a narrow, roughened line, often termed the *spiral line*, which is continuous above with the lower end of the intertrochanteric line, and below with the medial lip of the linea aspera. On the lateral side the surface is bounded by a broad, roughened vertical ridge termed the *gluteal tuberosity*, which extends upwards and laterally to the root of the greater trochanter and is continuous below with the lateral lip of the linea aspera. This posterior surface is therefore triangular.

In its *lower third* the shaft also possesses a fourth, *posterior surface*. This is placed between the *medial* and *lateral supracondylar lines*, which are continuous above with the corresponding lips of the linea aspera. These lines form definite but not conspicuous ridges, of which the lateral is the more distinct. Near

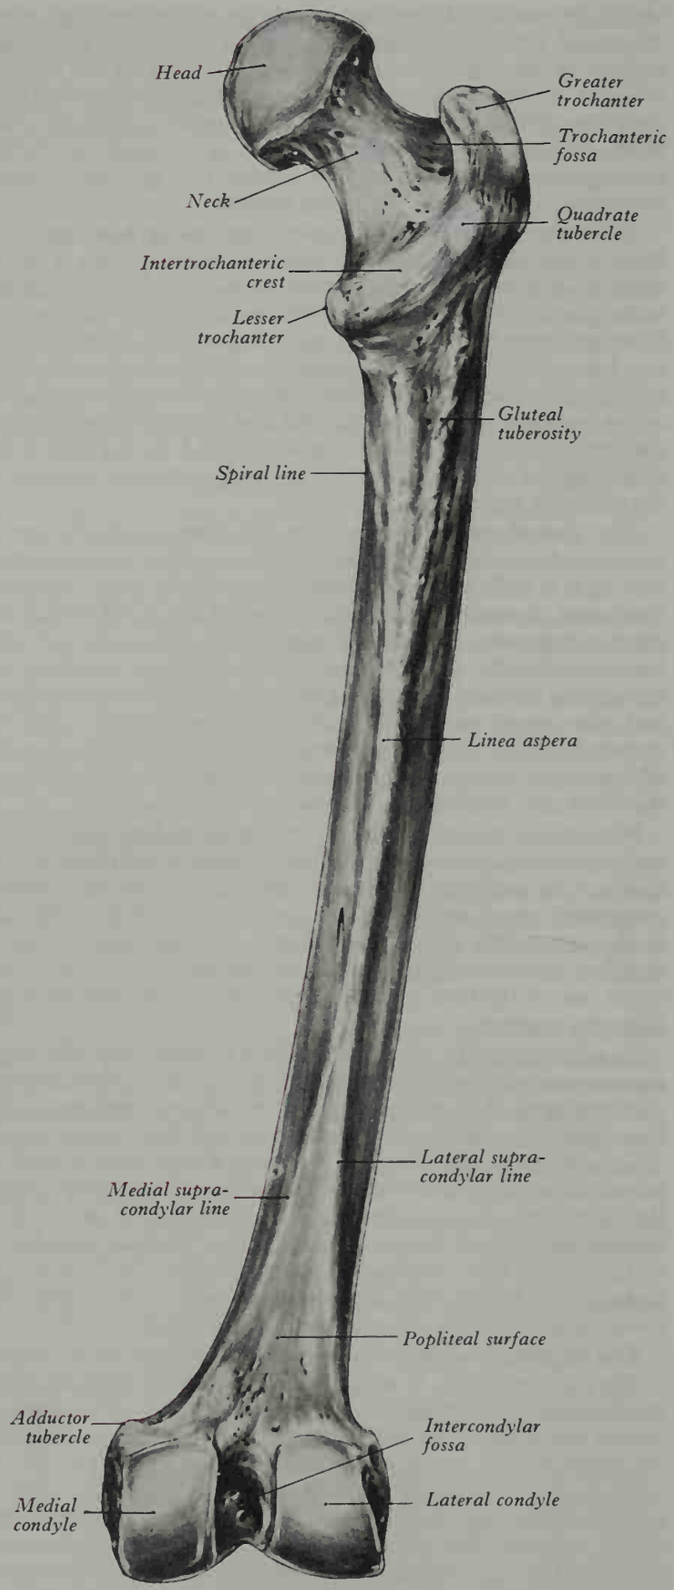
3.184A The right femur. Anterior aspect. Compare with Key, **3**.184B.

3.184B Key to 3.184A. The epiphysial lines are stippled. The interrupted lines correspond to the attachments of the capsular ligaments. The dotted part of the lower line indicates the site of communication between the cavity of the knee joint and the suprapatellar synovial bursa.

its upper end the medial supracondylar line is in part obliterated; here the femoral artery lies in close relation with the bone as it passes from the thigh to the popliteal fossa. The posterior surface of the lower third is a flattened, triangular area, the *popliteal surface* of the femur (3.185); in its lower and medial part it presents a rough and slightly elevated area.

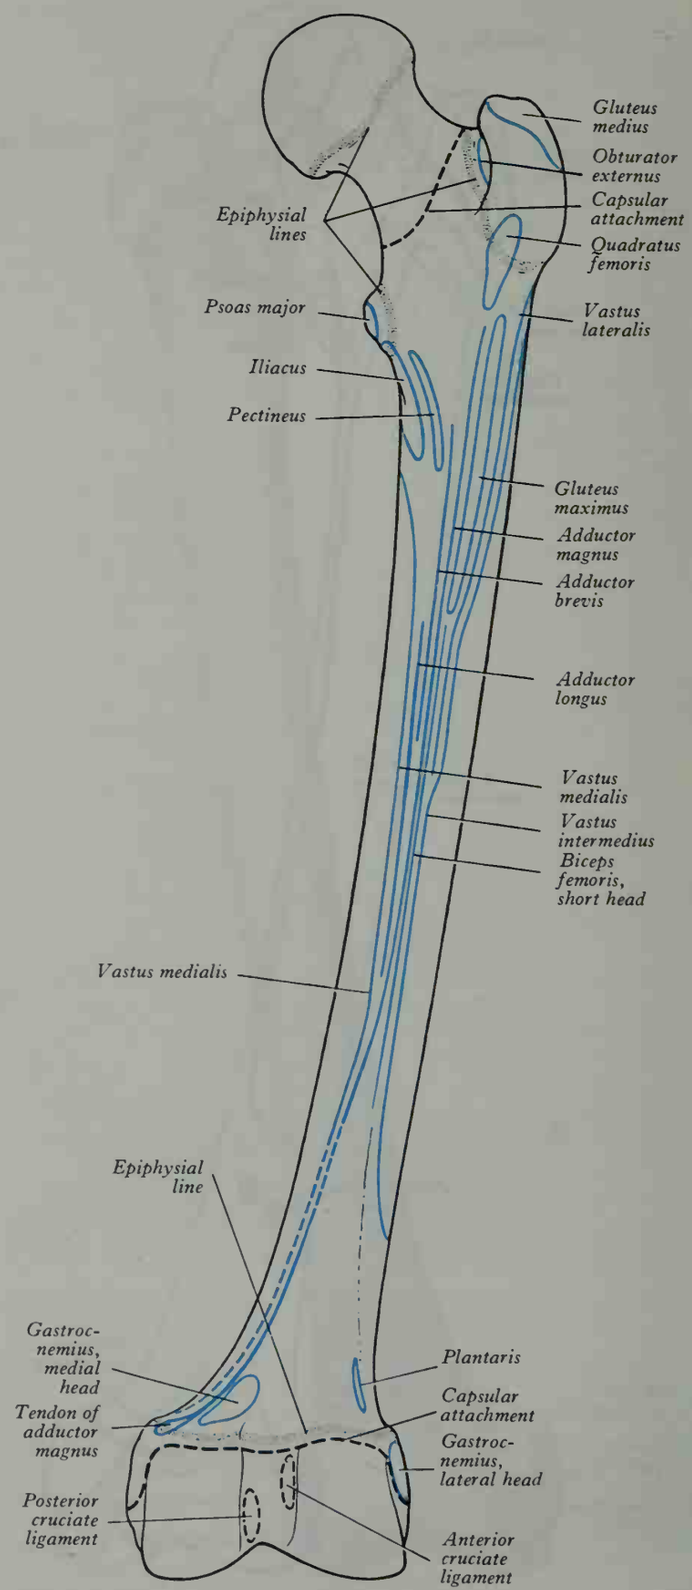
The shaft (3.184B, 185B) is thickly surrounded with muscles and cannot be felt through the skin. Its *anterior* and *lateral surfaces* provide attachment in their upper three-fourths for the vastus intermedius; below that muscle the articularis genu arises by several small slips from the front of the bone. The lower portion of the anterior surface for 5 or 6 cm above the patellar articular surface is covered by the suprapatellar bursa, which intervenes between the bone and the muscles mentioned. The lower portion of the lateral surface is covered by vastus intermedius. The *medial surface* is devoid of muscular attachments and is covered by the vastus medialis.

The vastus lateralis has a linear origin which commences in front at the root of the greater trochanter and follows it to the upper end of the gluteal tuberosity. It then descends along the lateral margin of the tuberosity to the lateral lip of the linea aspera, from the upper half of which it takes origin. The vastus medialis also has a linear origin. It commences at the lower end of the intertrochanteric line and follows the spiral line to the medial lip of the linea aspera. At the lower end of the linea aspera it follows the upper part of the medial supracondylar line; below this the origin may be partly or wholly from the aponeurotic insertion of the adductor magnus.



The *gluteal tuberosity* may take the form of an elongated, roughened depression or it may project as a ridge. Occasionally a part of it is sufficiently prominent to merit the name of a *third trochanter*. It receives the deeper fibres of the lower half of the gluteus maximus. The medial edge of the tuberosity provides insertion for the pubic fibres of the adductor magnus; the succeeding fibres of that muscle are inserted into the linea aspera and the upper part of the medial supracondylar line; the remaining fibres form a stout tendon which is inserted into the adductor tubercle (p. 395) and sends a membranous expansion to the lower part of the medial supracondylar line.

Between the gluteal tuberosity and the spiral line the posterior surface receives the insertions of the pectineus and the adductor brevis. The pectineus is inserted into a line, sometimes slightly roughened, which descends from the root of the lesser trochanter to the upper end of the linea aspera. The adductor brevis is attached lateral to the pectineus and extends downwards to the upper part of the linea aspera, where it is attached medial to the adductor magnus.



In addition to the attachments already described, the **linea aspera** receives the adductor longus, the intermuscular septa and the short head of biceps femoris. The structures connected to the linea aspera are inseparably blended at their bony attachments. The perforating arteries cross the linea aspera from medial to lateral sides, under tendinous arches in the adductor magnus and the short head of biceps femoris. The foramina for the nutrient arteries are situated close to the linea aspera. They vary in number and position. One is usually near the upper end of the linea aspera, and a second, which is not always present, near its lower end. The foramina are directed upwards through the compact bone.

The popliteal surface of the shaft is the floor of the upper part of the popliteal fossa. It is covered by a variable amount of fat, which separates the popliteal artery from the bone. The superior medial genicular artery arises from the popliteal artery as it lies in the intercondylar notch. It arches medially above the medial condyle, but is separated from the bone by the medial head of gastrocnemius, attached to the rough elevation a little above the medial condyle. Below this there may be a smooth facet which underlies the bursa under the medial head of the gastrocnemius. More medially, above the articular surface, there is often an imprint which, in acute flexion, receives the rough tubercle on the medial tibial condyle for the attachment of semimembranosus (Kostick 1963). The superior lateral genicular artery arches upwards and laterally above the lateral condyle, but is separated from the bone by the attachment of plantaris to the lower part of the lateral supracondylar line.

The lateral supracondylar line is most distinct in its upper two-thirds, to which the short head of the biceps femoris and the lateral intermuscular septum are attached. Its lower part is marked by a small roughened area which gives origin to the plantaris and often encroaches on to the popliteal surface. The **medial supracondylar line** is feebly marked in its upper two-thirds, where it gives origin to the vastus medialis. Near its upper end it is crossed by the femoral vessels as they enter the fossa from the adductor canal. It is often sharp and prominent for 3 or 4 cm

3.185A The right femur. Posterior aspect. Compare with Key, **3**.185B.

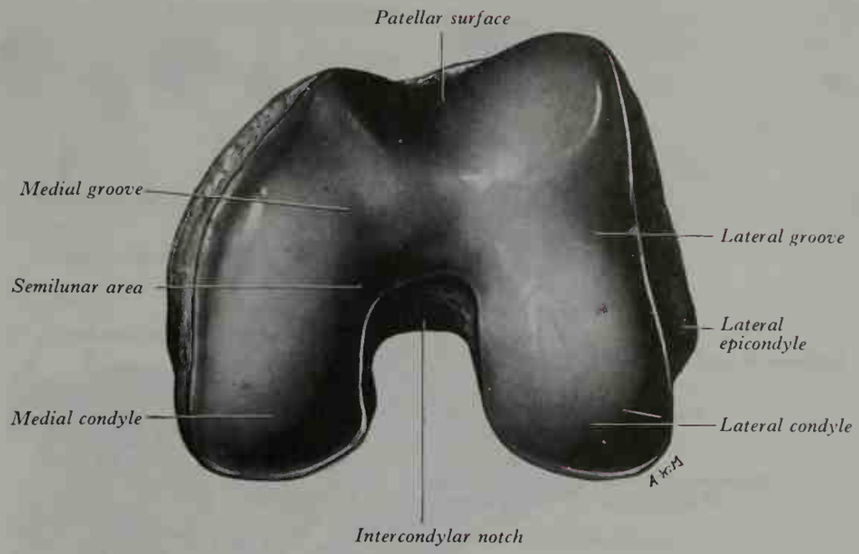
above the adductor tubercle and in this situation it gives attachment to a membranous expansion from the tendon of the adductor magnus.

The lower end of the femur is widely expanded and thus provides a good bearing surface for the transmission of the weight of the body to the top of the tibia. It consists of two prominent masses of bone, the *condyles*, which are partially covered by a large *articular surface*. Anteriorly the two condyles are united and are continuous with the front of the shaft; posteriorly they are separated by a deep gap, the *intercondylar fossa* (intercondylar notch), and they project backwards considerably beyond the plane of the popliteal surface.

The *articular surface* forms a broad ∩-shaped area for articulation with the patella above and tibia below (**3**.186). The *patellar surface* extends over the anterior surfaces of both condyles, but much the larger part of it is on the lateral condyle. It is concave from side to side, being grooved proximo-distally to accommodate the posterior surface of the patella. The *tibial surface* is divided into medial and lateral parts by the intercondylar fossa, but anteriorly each part is directly continuous with the patellar surface. The medial part forms a broad strip which covers the convex inferior and posterior surfaces of the

medial condyle, and is gently curved with the convexity of the curve directed medially. The lateral tibial surface covers the same aspects of the lateral condyle but is broader and passes straight backwards. Heiple and Lovejoy (1971) suggested that a deep patellar groove is a hominid feature, concerned with bipedal gait. Wanner (1978) has studied its variations and disagrees with this view. The role of the groove, in preventing lateral subluxation of the patella therefore remains *sub judice*.

The lateral condyle (**3**.187) is flattened on its lateral surface and is not so prominent as the medial condyle, but it is stouter and stronger, for it is placed more directly in line with the shaft and probably takes a greater share in the transmission of the weight to the tibia. The most prominent point on its lateral aspect is termed the *lateral epicondyle*, and the whole of this surface can be felt through the skin. A short groove, deeper in front than behind, separates the lateral epicondyle from the articular margin below and behind. The medial surface of the condyle forms the lateral wall of the intercondylar fossa.

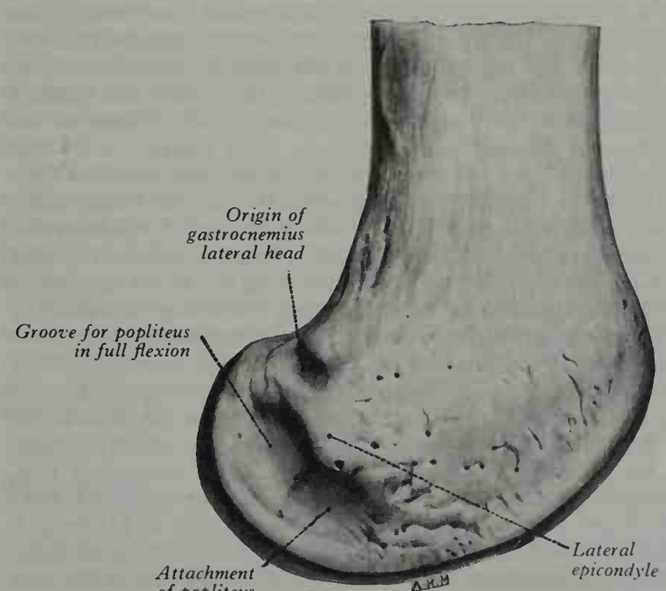


The medial condyle possesses a bulging, convex medial aspect, which can be palpated without difficulty. Its uppermost part is marked by a small projection, termed the *adductor tubercle* (**3**.185A) because it gives insertion to the tendon of the adductor magnus. The tubercle is an important bony landmark for the surgeon, and can be identified most readily when it is approached from above. It is, however, often a facet, rather than a tubercle. The most prominent point on the medial surface of the condyle is below and a little in front of the adductor tubercle and is termed the *medial epicondyle*. The lateral surface of the condyle is the roughened medial wall of the intercondylar fossa.

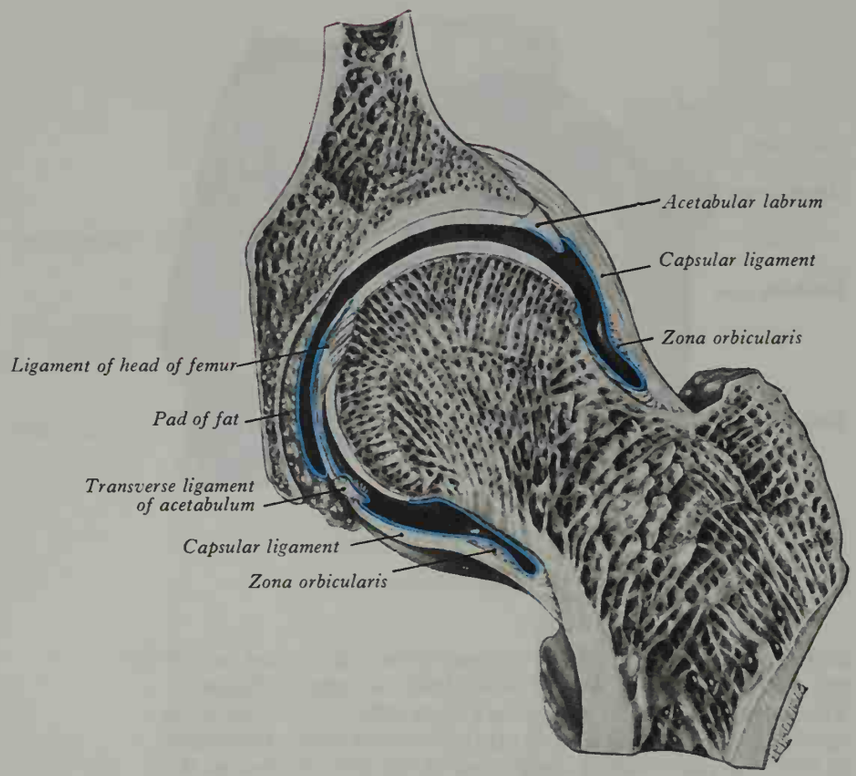
The intercondylar fossa (intercondylar notch) separates the two condyles below and behind. In front it is limited by the lower border of the patellar surface, and behind by the *intercondylar line*, which separates it from the popliteal surface. It lies within the capsular ligament of the knee joint, but is covered with synovial membrane only over a very limited area.

The patellar surface extends higher on the lateral than on the medial side; its upper border therefore is oblique and runs downwards and medially (**3**.186). It is separated from the tibial surfaces by two faint grooves; which cross the condyles obliquely. The lateral groove is the better marked (**3**.186); it runs laterally and slightly forwards from the front part of the intercondylar fossa and expands to form a faint triangular depression, which rests on the anterior edge of the lateral meniscus when the knee joint is fully extended. The medial groove is restricted to the medial part of the medial condyle and likewise rests on the anterior edge of the medial meniscus in full extension of the knee. Where this groove ceases the patellar surface is continued backwards on to the lateral part of the medial condyle as a semilunar area adjoining the anterior part of the intercondylar fossa. This area articulates with the medial vertical facet of the patella in full flexion of the knee joint; it is not distinctly outlined in most femora. In habitual squatters the articular cartilage may extend on to the lateral aspect of the lateral condyle where it underlies the vastus lateralis. **The tibial surfaces** are convex from side to side and from before backwards. The anteroposterior curvature of the two surfaces is not uniform, being much sharper in both posteriorly than it is in front. The medial tibial surface is longer than the lateral anteroposteriorly, and shows a slight curve, which is concave to the lateral side; these differences are important determinants of the rotatory (spin) movements, both adjunct and conjunct (p. 436), which are possible at the knee joint (p. 488).

The medial condyle projects medially and downwards to such an extent that, despite the obliquity of the shaft, the lower surface of the lower end of the bone is practically horizontal. A curved strip, about 1 cm wide, adjoining the medial margin of the articular surface, is covered with synovial membrane and lies within the capsule of the knee joint. The medial epicondyle, which lies above this area, gives attachment to the tibial collateral ligament of the knee joint.



The lateral condyle is less prominent and its lateral surface projects but little beyond the lateral surface of the shaft. The lateral epicondyle has attached to it the fibular collateral ligament of the knee joint, and above and behind it the bone bears an



3.186 The distal end of the left femur. Inferior aspect.

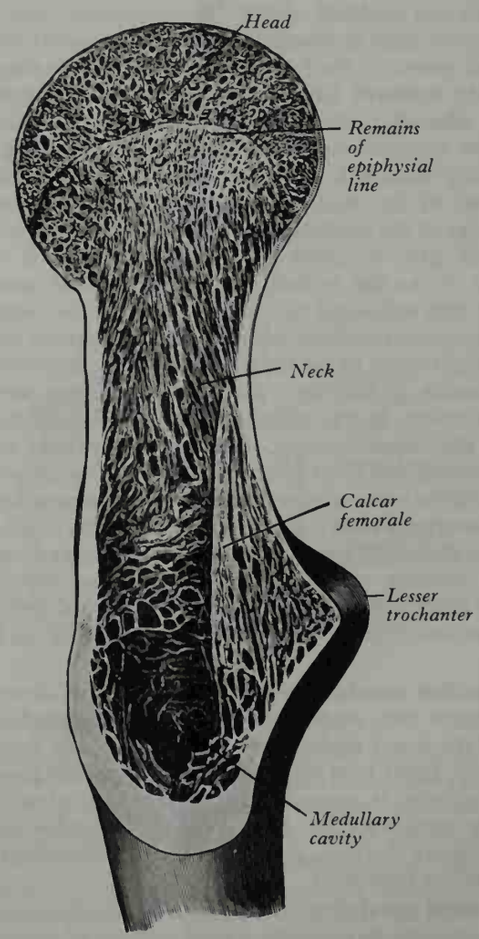
impression which is the origin of those fibres of the lateral head of the gastrocnemius that do not arise from the capsular ligament. The deepened, anterior end of the groove which lies between the epicondyle and the articular margin is the attachment of popliteus (**3**.187); the posterior (or upper) end of the groove contains the tendon of the muscle only in full flexion of the knee. In extension the tendon passes across the margin of the articular surface below, and sometimes grooves it. Immediately adjoining the articular margin a strip of the lateral condyle, 1 cm broad, is intracapsular, and is covered with synovial membrane, with the exception of the attachment of popliteus.

The intercondylar fossa separates the projecting portions of the two condyles, and is intracapsular but, to a large extent, extrasynovial. Its lateral wall, formed by the medial surface of the lateral condyle, bears a flattened impression which occupies its upper and posterior part and extends on to the floor of the fossa close to the intercondylar line. This is for the attachment of the upper end of the anterior cruciate ligament. The medial wall of the fossa, formed by the lateral surface of the medial condyle, bears a similar but rather larger impression for the upper end of the posterior cruciate ligament; it is placed anteriorly and extends on to the anterior part of the floor of the fossa. These two impressions look relatively smooth, being largely devoid of vascular foramina, like most impressions for tendons or ligaments; but the rest of the fossa is rough and pitted by vascular

3.187 The distal end of the right femur. Lateral aspect.

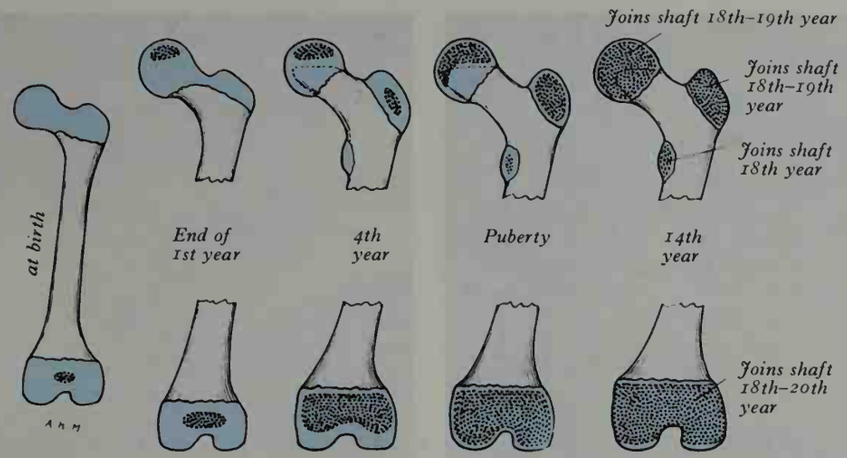
3.188 A section through the hip joint.

foramina, although occasionally the bursal recess between the two ligaments extends upwards to reach it. The *intercondylar line* gives attachment to the capsular ligament and, laterally, to the oblique popliteal ligament of the knee joint. To the anterior border of the fossa the infrapatellar synovial fold is attached (p. 485).



Structure. The shaft of the femur is a cylinder of compact bone, with a large medullary cavity. The wall of the cylinder is thick in the middle third of the shaft, where the bone is narrowest and the medullary cavity most capacious; but above and below this the wall becomes thinner, while the medullary cavity is gradually filled up with trabecular bone; the upper and lower ends of the shaft—and the articular extremities more especially—consist of trabecular bone, invested by a thin compact layer.

The trabeculae in the ends of the femur are approximately disposed along the lines of greatest compression and stress (p. 478). In the upper end (**3**.188, 189) the chief trabeculae are arranged as a series of bony plates at right angles to the articular surface of the head which converge to a central dense wedge; this wedge is supported by strong trabeculae which extend to the sides of the neck and are specially marked along its upper and lower borders. Any force therefore applied to the head of the femur is transmitted directly to the central wedge and thence to the junction of the neck with the shaft. This junction is in turn strengthened by a series of dense trabeculae which extend from the lesser trochanter to the lateral end of the superior border of the neck; this arrangement will obviously offer considerable resistance to either tensile or shearing forces applied to the neck through the head. A smaller bar stretching across the junction of the greater trochanter with the neck and shaft resists the shearing force of the muscles attached to this prominence. These two bars—one at the junction of shaft and neck, the other at the junction of shaft and greater trochanter—form the upper layers of a series of arches which extend across between the sides of the shaft and transmit to it forces applied to the upper end of the bone. A thin vertical plate of bone, named the *calcar femorale* (**3**.189), springs from the compact wall of the shaft in the region of the linea aspera and extends into the spongy bone of the neck. Medially, it joins the inner surface of the posterior wall of the neck of the bone; laterally, it continues the plane of the posterior wall of the neck into the greater trochanter, where it shades off into the general spongy bone. It is thus situated in a plane anterior to the trochanteric crest and to the base of the lesser trochanter. Intensive study of the proximal end of the femur by scanning electron microscopy, admittedly on a small series of specimens, had largely confirmed the above views (Whitehouse and Dyson 1974). A surprisingly wide variation in the metrical parameters of the trabecular pattern in different regions of the femoral head and neck was nevertheless observed.



Tensile and pressure tests of 40 human femora also indicated that the axial trabecular tissue of the femoral head withstands such stresses at much higher levels than peripheral trabeculae (Kaessmann *et al.* 1972).

In the lower end, the trabeculae spring on all sides from the inner surface of the cylinder, and descend in a direction perpendicular to the articular surface—the trabeculae above the condyles being the strongest and having a more accurately perpendicular course. In addition to this, there are horizontal planes of spongy bone, arranged like crossed girders forming a series of cubical compartments.

Ossification (**3**.184B, 185B, 190). The femur is ossified from five centres; one each for the shaft, head, greater trochanter, lesser trochanter and lower end. Except for the clavicle, it is the first long bone to show traces of ossification. Ossification begins in the middle of the shaft in the seventh week of intrauterine life, and extends upwards and downwards so that the miniature shaft is largely ossified at birth. The secondary centres appear as follows: in the lower end, during the ninth month of intrauterine life (from this centre the condyles and epicondyles are formed); in the head during the first six months after birth; in the greater trochanter during the fourth year: and in the lesser trochanter between the twelfth and fourteenth years. The manner in which the epiphysis for the head develops is noteworthy. The ossific centre appears in the upper part of the cartilaginous head and until the age of 10 is restricted to that part of the bone, so that the epiphysial line, as seen in X-ray photographs (**3**.175), is horizontal and the lower and medial part of the articular surface is borne on the neck (**3**.190).

3.189 An oblique section through the proximal end of the left femur showing the *calcar femorale*. Compare with **3**.1C and **3**.188.

3.190 Stages in the ossification of the femur. Note how the neck, which is ossified as an extension from the shaft, invades the cartilaginous head.

Thereafter the medial margin of the epiphysis grows over the lower and medial part of the articular surface and covers it completely. As a result, when fully developed, the epiphysis forms a gently hollowed-out cup on the summit of the neck. The epiphysial line at the upper end follows the articular margin except superiorly where it is separated from the articular surface by a non-articular area through which blood vessels enter the head (Trueta 1957; Smith 1962). The epiphyses fuse independently with the shaft, the lesser trochanter soon after puberty, then the greater trochanter, then the head at the fourteenth year in females and seventeenth in males and finally the lower end at the sixteenth year in females and eighteenth in males. It should be noted that the lower epiphysial plate passes through the adductor tubercle (**3**.184B).

Applied Anatomy. The distal extremity of the femur is the only epiphysis in which ossification constantly starts just before birth. The presence of this centre of ossification is always relied upon in medico-legal investigations as proof that a newborn child found dead was viable. The position of the epiphysial plate should be carefully noted. It is on a level with the adductor tubercle, and the epiphysis does not, therefore, form the whole of the synovial covered portion of the lower end of the bone. It is essential to bear this point in mind when operations are performed on the lower end of the femur, since growth in length of the bones takes place chiefly from the lower epiphysial cartilage, and any interference with it in a young child may involve marked shortening of the limb.

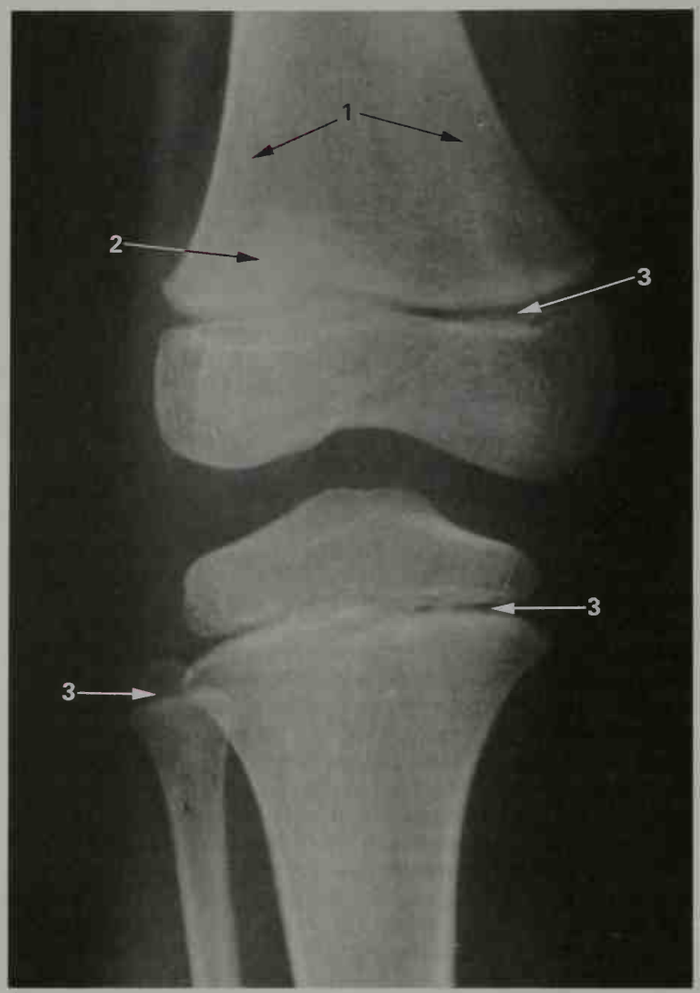
Fractures of the neck of the femur are due to indirect violence and usually occur through tripping over some minor obstruction. The trunk continues to move forwards and, overbalancing, falls to the same side, imposing full medial rotation on the thigh and leg. Below the age of 16 the usual injury suffered from such an accident is a spiral fracture of the shaft of the femur. In contrast between the ages of 16 and 40 the result is often a 'bucket-handle' tear of the medial meniscus of the knee joint. In older patients, between 40 and 60, a common result is a Potts' fracture of the leg, but, in patients over 60, a fracture of the neck of the femur is commonplace owing to the senile osteoporotic changes which have occurred in the bone. Women are more liable to this injury than men, for their bones are more lightly built in the first instance.

In the normal, when the lower limb is aligned with the trunk, the tip of the greater trochanter is on the line joining the anterior superior iliac spine and the most prominent part of the ischial tuberosity (Nelaton's line). In displacements due to fracture of the neck and other conditions the tip of the greater trochanter may lie above this line.

The Patella

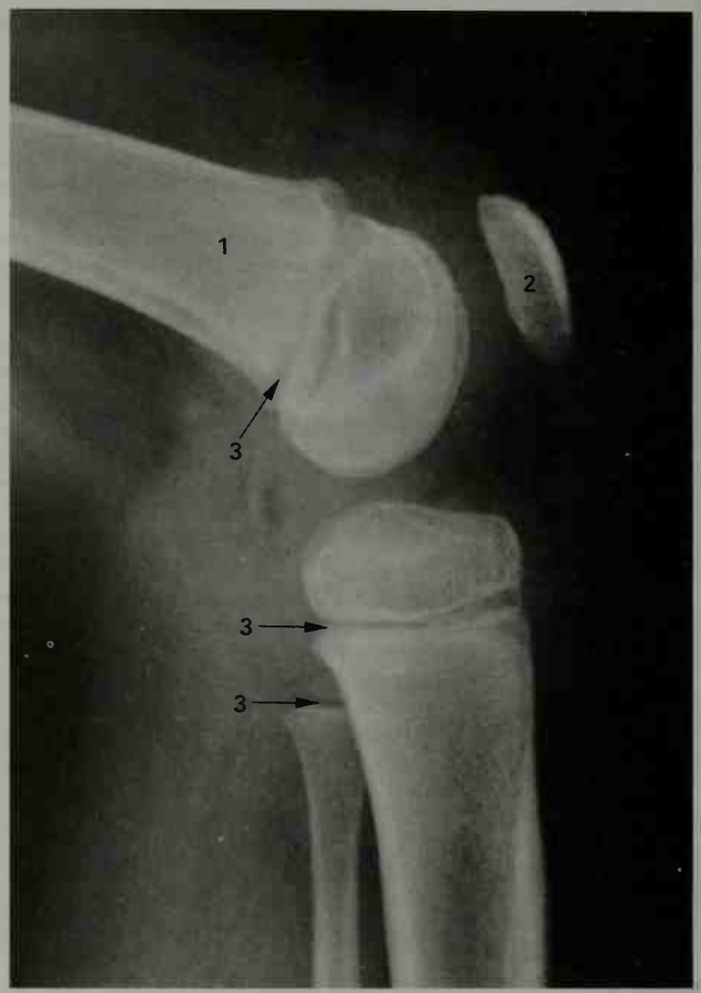
The patella (**3**.193), the largest of the sesamoid bones, is in the front of the knee joint embedded in the back of the tendon of the quadriceps femoris. It is flattened, triangular below, curved above, and has anterior and posterior surfaces, three borders, and an apex. In the living subject in the erect attitude, its lower limit lies more than 1 cm above the line of the knee joint.

The *anterior surface*, readily palpable, is convex, perforated by nutrient vessels, and marked by numerous rough, longitudinal striae. It is separated from the skin by a bursa and covered by an expansion from the tendon of the quadriceps femoris; this expansion is continuous below with the superficial fibres of the so-called patellar *ligament*, which is, of course, the *tendon* of the quadriceps. The *posterior surface* presents in its upper part a smooth, oval, articular area, divided into two facets by a smooth vertical ridge, which corresponds to the groove on the patellar surface of the femur, and the facets to the medial and lateral parts of the same surface; the lateral facet is the broader and deeper. The ridge is also covered by articular cartilage, and there is hence no true division of the articular surface, which really consists of two regions angulated with respect to each other by the 'ridge'. A narrow strip, broader above than below and often inconspicuous in the macerated specimen, is marked off from the medial part of the medial facet. This strip comes into contact with the medial condyle of the femur in extreme flexion of the knee joint. Below the articular surface the *apex*, which points downwards, is roughened in its lower part for the attachment of the ligamentum patellae; its upper part is covered by the infrapatellar pad of fat.



The *superior border* is thick, and slopes from behind, downwards and forwards: except near its posterior margin, it has attached to it the part of the quadriceps femoris which is derived from the rectus femoris and vastus intermedius. The *medial* and *lateral borders* are thinner and they converge below: they give attachment to those portions of the quadriceps femoris which are derived from the vasti medialis et lateralis. Near the junction of the base and lateral border there is a small, shallow, circular depression into which a part of the tendon of the vastus lateralis is inserted.

Structure. The patella consists of a nearly uniform dense cancellous bone, covered by a thin compact lamina. The trabeculae immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the articular surface towards the other parts of the bone.



Ossification. The patella begins to ossify from several centres which appear in the third to sixth years and quickly coalesce. Accessory marginal centres appear later and fuse with the central mass (Hellmer 1935). (See also Prakash *et al.* 1979, for bibliography.)

The Tibia

The tibia (**3**.195, 196) is the medial and much the stronger of the two bones of the leg; excepting the femur it is the longest bone of the skeleton. It is prismoid in section in its shaft and has expanded extremities. Its lower end is smaller than the upper, and on its

medial side a stout process, termed the medial malleolus, projects downwards beyond the rest of the bone. The anterior border of the shaft is a conspicuous, sharp crest, which curves medially at the lower end towards the medial malleolus; it is the most prominent of the three borders.

The upper end of the tibia is expanded, especially in its transverse axis, providing an adequate bearing surface for the body weight transmitted through the lower end of the femur. It comprises two prominent masses, the *medial* and *lateral condyles*, and a smaller projection, the *tuberosity of the tibia*. The condyles project backwards a little, so as to overhang the upper part of the posterior surface of the shaft. Superiorly each is covered with an articular surface, the two being separated by an irregularly roughened *intercondylar area*. They form visible and palpable landmarks at the sides of the ligamentum patellae, the lateral condyle being the more prominent. When the knee is flexed passively, the anterior margins of the tibial condyles can be felt readily, and each forms the lower border of a depression at each side of the patellar ligament.

The medial condyle is the larger but does not overhang so much as the lateral condyle. Its upper articular surface (**3**.194A), oval in outline, is concave in all diameters, and its lateral border projects upwards, deepening the concavity and covering an elevation, the *medial intercondylar tubercle*. The posterior surface of the condyle is marked, immediately below the articular margin, by a horizontal, roughened groove. Its medial and anterior surfaces form a rough strip, separated from the medial surface of the shaft by an inconspicuous ridge.

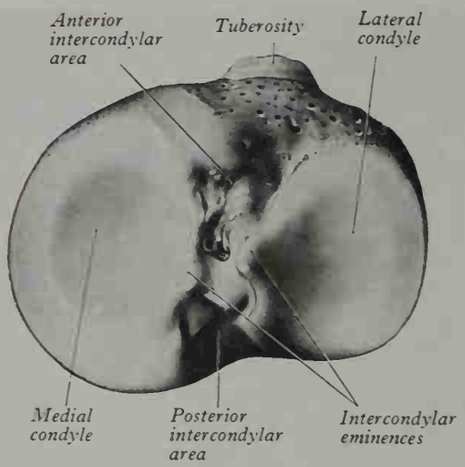
The lateral condyle overhangs the shaft, especially at its posterolateral part, which bears on its inferior surface a small circular facet for articulation with the upper end of the fibula. The upper surface (**3**.194A) is covered with an articular surface for the lateral condyle of the femur. Nearly circular in outline, it is slightly hollowed in its central part, and its medial border extends upwards to cover an elevation, termed the *lateral intercondylar tubercle*. The posterior, lateral and anterior surfaces of the condyle are rough.

The anterior surfaces of the two condyles became continuous in front with a large triangular area, the apex of which is directed downwards and is formed by the tuberosity of the tibia. The lateral edge of this area forms a sharp ridge which separates the lateral condyle from the lateral surface of the shaft.

The intercondylar area (**3**.194A) is a roughened area on the superior surface, which intervenes between the articular surfaces of the two condyles. It is narrowest at its middle, where it is elevated into the *intercondylar eminence*. The lateral and medial parts of the eminence project slightly upwards, and constitute the *lateral* and *medial intercondylar tubercles*. Both behind and in front of the eminence the intercondylar area becomes wider, as the curved margins of the articular surfaces recede from each other.

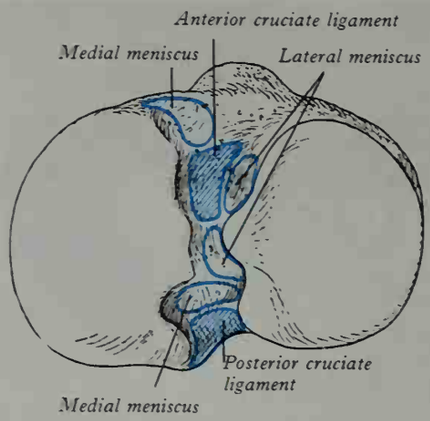
The tuberosity of the tibia is at the upper end of the anterior border of the shaft, and is the truncated apex of the triangular area on the front of the bone where the anterior surfaces of the two condyles become continuous. It is a low eminence, divided into a lower roughened and an upper smooth region. The lower can be felt through the skin, from which it is separated only by a bursa, the subcutaneous infrapatellar bursa; to the upper part is attached the ligamentum patellae.

The upper surface is tilted backwards relative to the long axis of the shaft. The tilt is maximal in the newborn and decreases with age; it is also more marked in habitual squatters (Kate and Robert 1965). The *articular surface of the medial condyle* is oval in shape, with its long axis anteroposterior and is perceptibly the longer of the two, in conformity with the differences which exist between the tibial surfaces of the two femoral condyles (p. 482). It is related around its anterior, medial and posterior margins to the medial meniscus, and the area of contact is flattened. The imprint of the cartilage, which is widest behind and narrower at the medial side and in front, can often be recognized on the bone. The rest of the surface is concave, and its raised lateral margin covers the medial intercondylar tubercle. The *articular surface of the lateral condyle* is more nearly circular in shape. Like the medial articular surface it is related to the corresponding meniscus, and bears its flattened imprint. Elsewhere the surface is very slightly concave to adapt it to the surface of the corresponding femoral condyle, and its raised medial margin is continued on the lateral intercondylar tubercle. The edges of the two articular surfaces are sharp except at the posterior part of the lateral surface, where the margin is smooth and rounded; in this situation the tendon of the popliteus is intimately related to the bone.



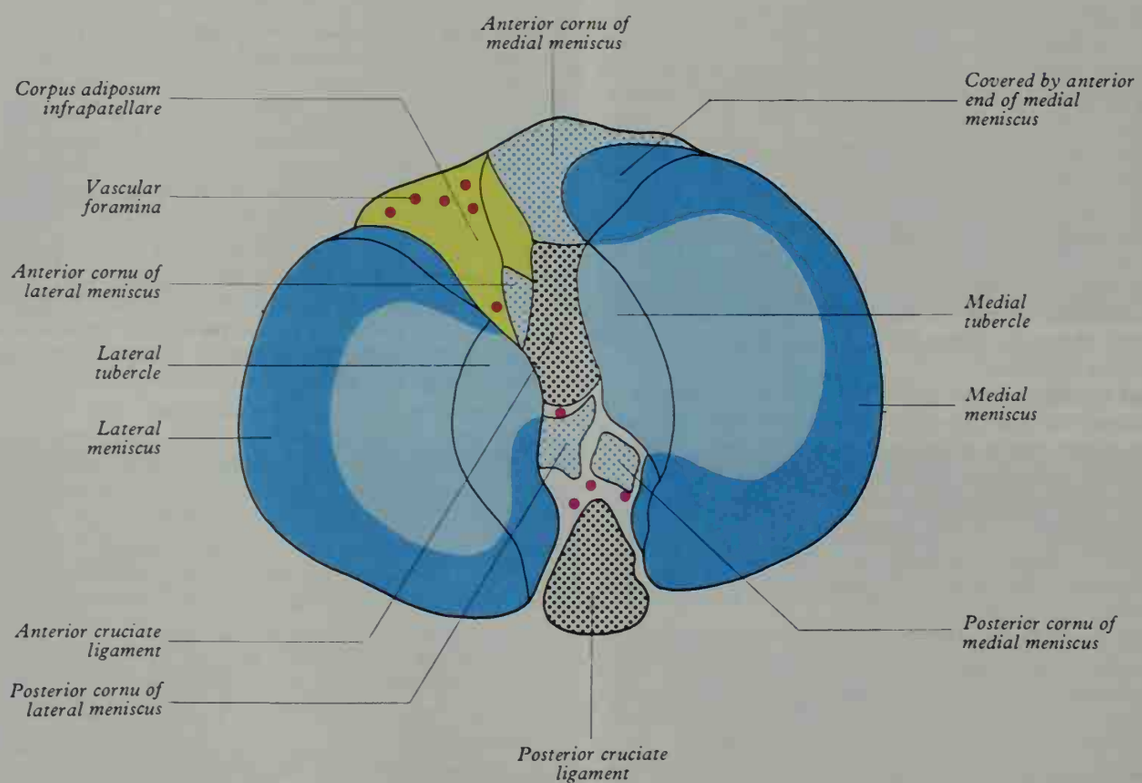
The anterior intercondylar area (**3**.194B) is widest anteriorly. In its anteromedial part, just in front of the medial articular surface, it bears a slight depression to which is attached the anterior horn of the medial meniscus. Behind that depression a relatively smooth area affords attachment to the lower end of the anterior cruciate ligament. The anterior horn of the lateral meniscus is attached in front of the intercondylar eminence and lies lateral to the anterior cruciate ligament. The *intercondylar eminence* with its medial and lateral tubercles, occupies the narrow, middle part of the area. The posterior slope of the eminence gives attachment to the posterior horn of the lateral meniscus, and behind that the **posterior intercondylar area** inclines downwards and backwards. A depression behind the base of the medial intercondylar tubercle gives attachment to the posterior horn of the medial meniscus. The rest of the area is smooth and affords attachment to the lower end of the posterior cruciate ligament, as far back as the ridge to which the capsular ligament is attached.

To the superior lip of the groove on the posterior surface, the capsular ligament and the posterior part of the tibial collateral ligament of the knee joint are attached; its inferior lip receives the insertion of semimembranosus. At the lateral limit of the groove is a rough tubercle which provides the principal attachment of the semimembranosus tendon (Cave and Porteous 1958). The medial and anterior surfaces of the condyle, which are marked by numerous vascular foramina, give attachment to the medial patellar retinaculum.



In a recent study of 13 healthy knee joints, which were used for measurements (together with observations on 75 macerated specimens), a more detailed plan of ligamentous and other attachments was evolved (*see* Jacobsen 1974; and **3**.194C). Considerable variation in the areas of these attachments was noted. Dense fibrous attachments produced facets, separated by areas of a more porous appearance (p. 400).

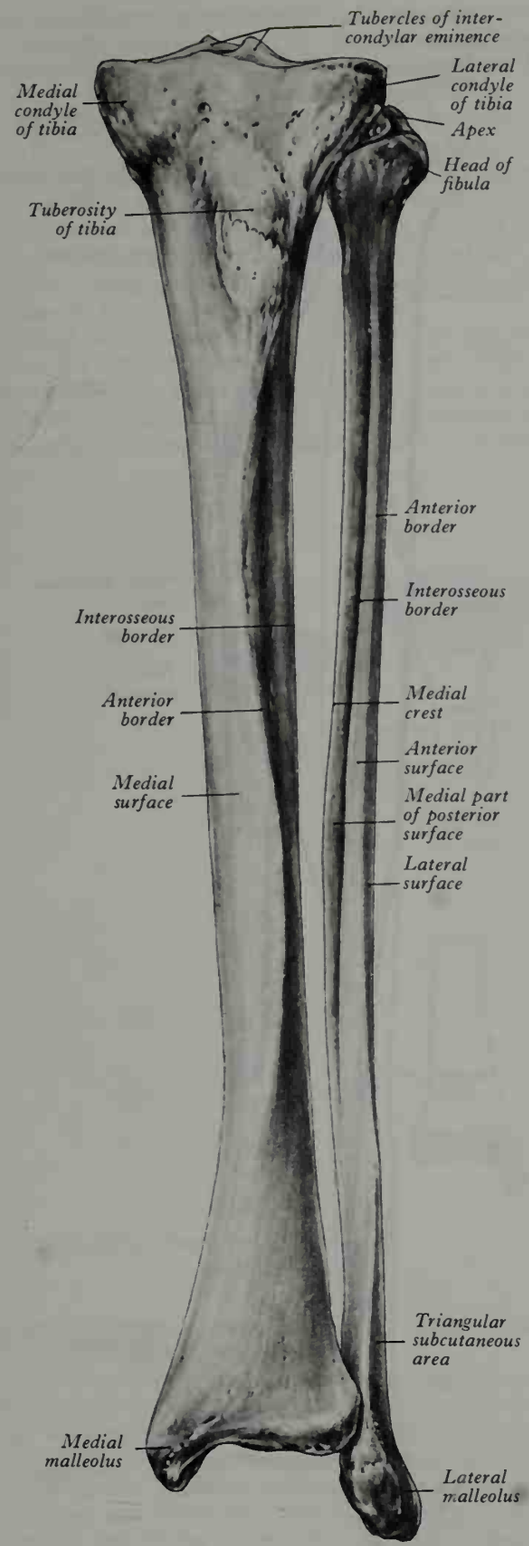
The tibia has been investigated extensively by Ljungren (1976) using stereometric techniques; analysis has shown functional adaptation of the curvatures and inclinations of the tibial condylar facets and the tibial tuberosity, particularly in regard to habits of locomotion in different racial groups.



The fibular facet on the *lateral condyle* is directed downwards and slightly backwards and laterally. Above and to its medial side the posterior surface of the condyle is grooved by the tendon of the popliteus, but a synovial recess intervenes between the tendon and the bone. The lateral and anterior surfaces of the condyle are separated from the lateral surface of the shaft by a sharp margin which gives attachment to the deep fascia of the leg. An impression on the anterior surface, often well marked though flattened, affords attachment for the iliotibial tract. Small slips from the tendon of the biceps femoris are inserted above and in

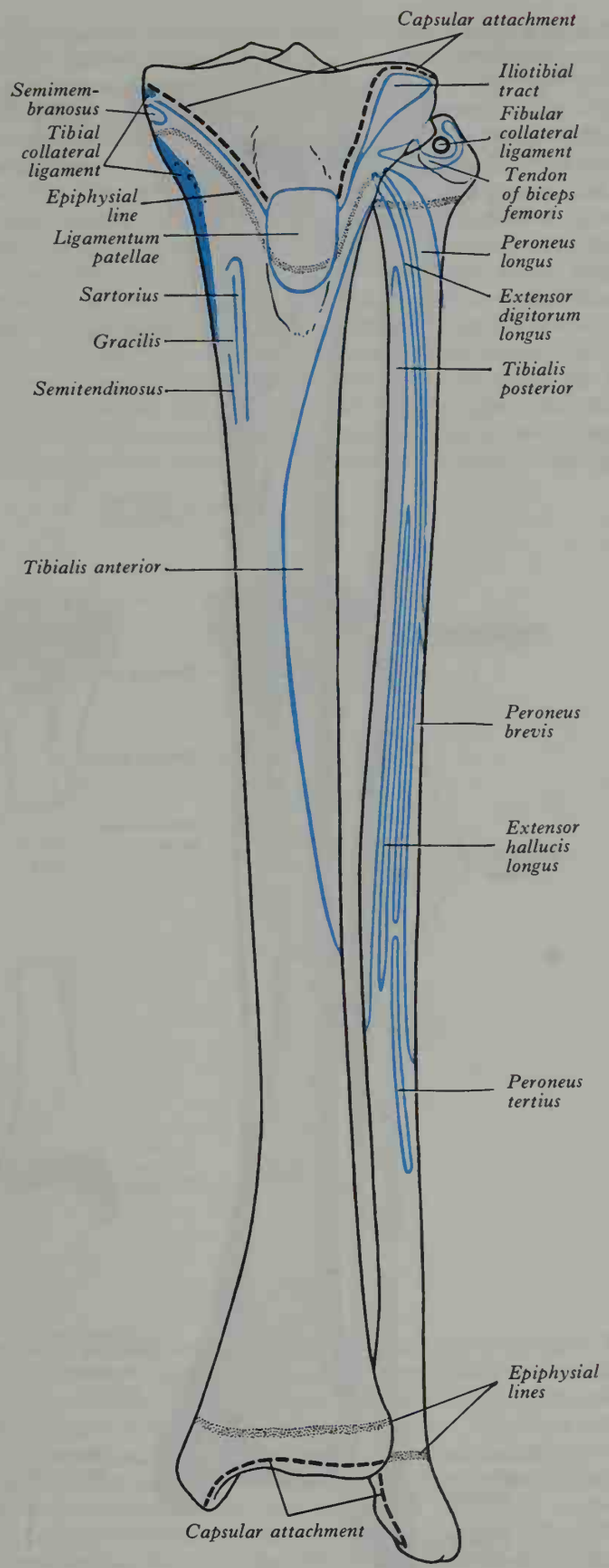
3.194A The proximal articular surface of the right tibia. The imprints of the menisci were very conspicuous in this specimen.

3.194B An outline of A showing the attachments of the menisci and cruciate ligaments.



3.194C A detailed analysis of the surface features of the proximal aspect of the human tibia (left). The condylar areas are shown in full blue, the parts in contact with the menisci being in deep blue, while the remaining condylar regions are in light blue. The attachments of the meniscal cornua are in blue stipple, and those of the cruciate ligaments are in black stipple. The yellow area indicates the extent of contact with the corpus adiposum, and the red dots signify vascular foramina. (Adapted by kind permission of Dr. Klaus Jacobsen, Department of Orthopaedic Surgery, The Gentofte Hospital, Copenhagen, *Journal of Anatomy* and Cambridge University Press.)

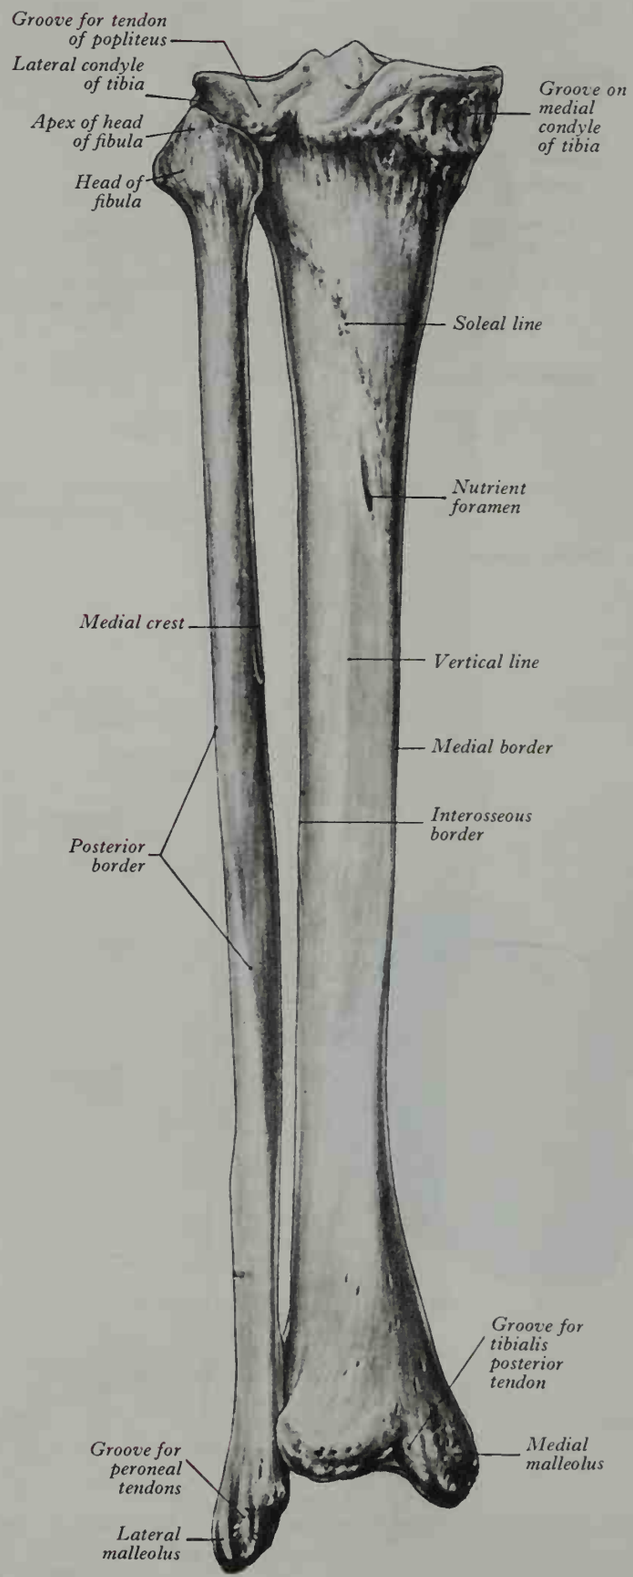
front of the fibular facet; below these the uppermost fibres of the extensor digitorum longus and occasionally those of the peroneus longus arise from the lateral surface.



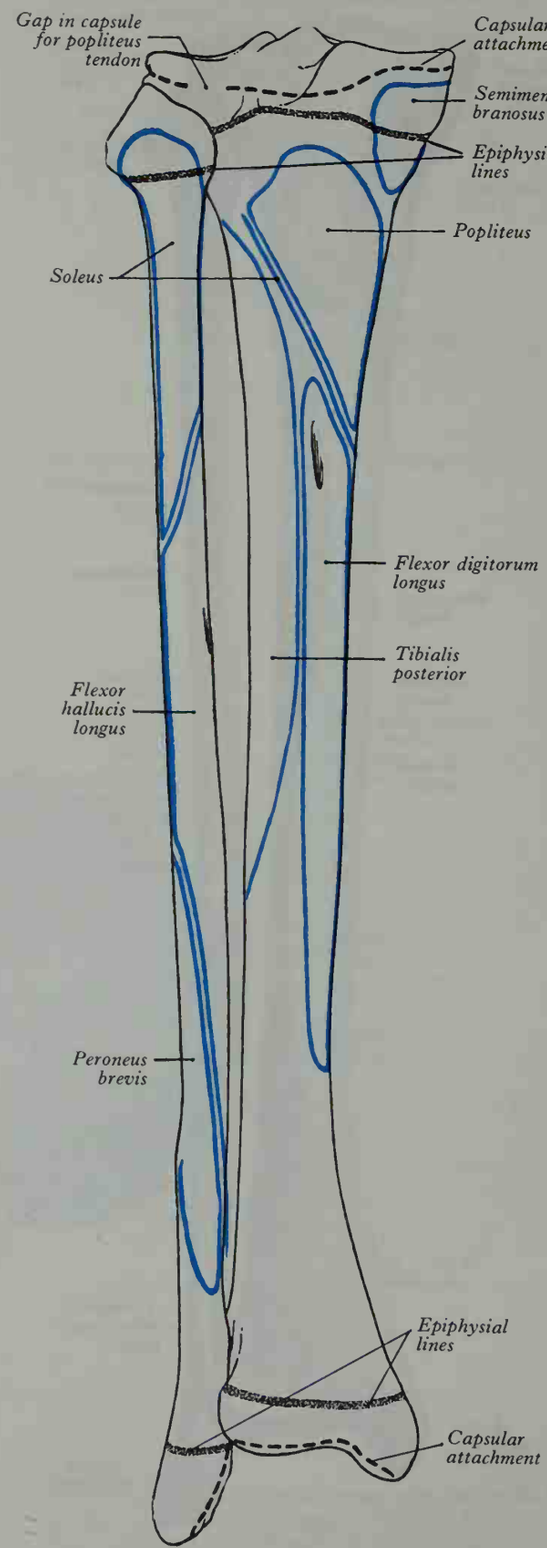
The line which divides the **tibial tuberosity** into upper and lower part marks the position of the epiphysial line between the upper epiphysis and shaft (p. 404). The ligamentum patellae is attached to the smooth portion; its superficial fibres may extend to the crest and lower rough portion where the lower limits of the attachment may be marked by a slight ridge (Lewis 1958). The lower part of the tuberosity is subcutaneous. Above the tuberosity the bone is related to the deep surface of the ligament, but the deep infrapatellar bursa and fibro-adipose tissue intervene. In habitual squatters there is usually a vertical groove on the front of the lateral condyle, which is occupied by the margin of the ligamentum patellae in flexion.

The shaft of the tibia (3.195, 196), being triangular in section, possesses medial, lateral and posterior surfaces, separated by anterior, interosseous and medial borders. It is thinnest at the junction of its middle and lower thirds, but expands considerably towards its upper and lower ends.

The *anterior border* commences at the tuberosity of the tibia and runs downwards to the medial malleolus. It is subcutaneous throughout its length, and, except in its lower fourth, where it is rounded and indistinct, forms a sharp crest (the 'shin'). It is



3.195A Left tibia and fibula. Anterior aspect. Compare with key, shown in 3.195B.



3.195B Key to 3.195A. The epiphysial lines are stippled; the interrupted lines correspond to the attachments of the capsular ligaments.

slightly sinuous and its lower fourth diverges towards the medial side. The *interosseous border* commences below and a little in front of the fibular facet on the lateral condyle and descends to reach the anterior border of the fibular notch, which marks the lateral aspect of the lower end of the tibia. In nearly the whole of its length it affords attachment to the interosseous membrane which connects the tibia to the fibula. As a rule it is poorly defined at its upper end, but is obvious below this. The *medial border* commences below the anterior end of the groove on the medial condyle and runs downwards to the posterior margin of the medial malleolus. Its upper and lower fourths are rounded and ill-defined, but its middle region is sharp and distinct.

The *medial surface* is bounded in front by the anterior border, and behind by the medial border. It is broad and smooth, and is subcutaneous throughout practically its whole extent. The *lateral surface*, also broad and smooth, is placed between the anterior and the interosseous borders. In its upper three-fourths it is directed laterally and is slightly concave from before backwards. Its lower fourth is carried round on to the front of the bone, owing to the deviation of the anterior border to the medial side and the forward inclination of the lower part of the interosseous border. This part of the surface is somewhat convex forwards. The *posterior surface* is bounded by the interosseous and the medial borders, and is widest at its upper end, where it is crossed from above downwards

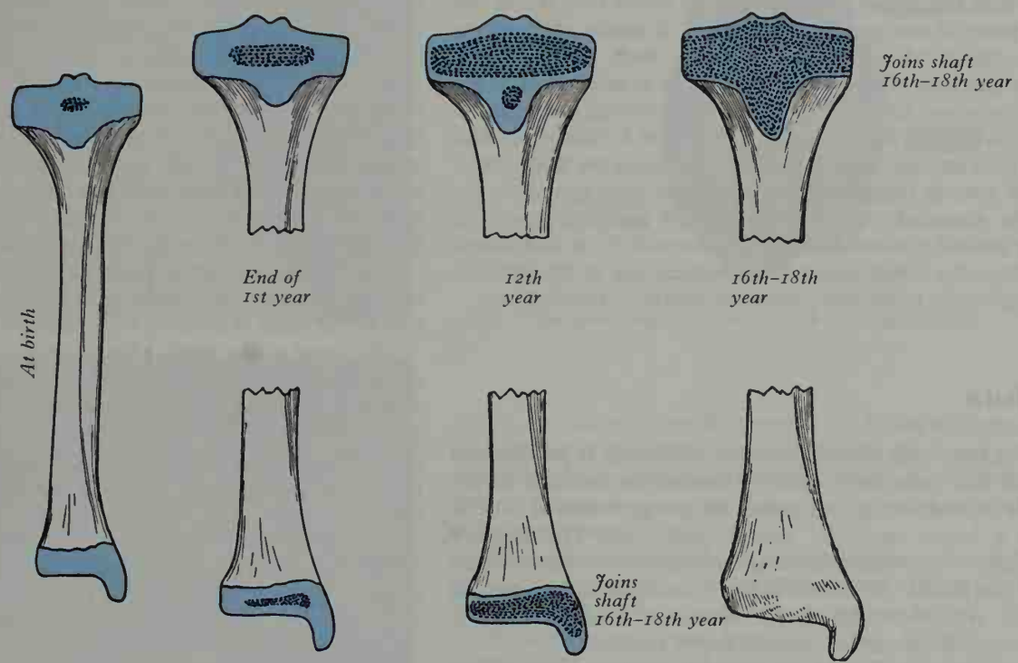
3.196A Left tibia and fibula. Posterior aspect. Compare with Key, shown in **3**.196B.

3.196B Key to **3**.196A. The epiphysial lines are stippled; the interrupted lines correspond to the attachments of the capsular ligaments.

and medially by an oblique, roughened ridge, termed the *soleal line*. The area below this line is subdivided by a faint *vertical line*, which begins at or just below the middle of the soleal line and soon fades away. A prominent vascular groove marks the bone near the upper end of the vertical line and descends to a large nutrient foramen; it may be situated lateral or medial to the vertical line.

The *anterior border* provides attachment for the deep fascia of the leg. A little above the medial malleolus it receives the medial end of the superior extensor retinaculum. Above the soleal line the *medial border* gives attachment to the fascia covering the popliteus, to the posterior fibres of the tibial collateral ligament of the knee joint and to slips of the semimembranosus; below the soleal line it gives origin for a short distance to fibres of the soleus and attachment to the fascia which covers the deep muscles of the leg. At its lower end it becomes continuous with the medial border of the groove which lodges the tendon of the tibialis posterior. The *interosseous border* gives attachment to the interosseous membrane of the leg, except at its upper and lower ends. Its upper end is scarcely recognizable, and in this situation there is a large gap in the interosseous membrane for the passage of the anterior tibial vessels. Its lower end forms the anterior boundary of the fibular notch and gives attachment to the anterior tibiofibular ligament.

The *medial surface* is usually rough, close to the upper part of



the medial border over an area nearly 5 cm long and 1 cm wide, for attachment of the anterior part of the tibial collateral ligament of the knee joint and behind this to the semimembranosus. In front of this roughened area the surface provides insertion for the tendons of sartorius, gracilis and semitendinosus, which rarely mark the bone. The gracilis, above, and semitendinosus, below and behind, are inserted immediately in front of the ligamentous area; the sartorius has a linear attachment which commences above and descends in front of the other two (**3**.195 B). The rest of the surface is covered only by superficial fascia and skin, but its lower part is crossed obliquely by the great saphenous vein as it ascends from in front of the medial malleolus.

The *lateral surface* in its upper two-thirds or less, provides attachment for tibialis anterior. Its lower part is devoid of muscular attachments, but is crossed by the tendon of the tibialis anterior (which lies along the lateral side of the anterior border), the extensor hallucis longus, the anterior tibial vessels and nerve, the extensor digitorum longus and peroneus tertius, in that order from the medial to the lateral side.

The *posterior surface* gives insertion to the popliteus over the triangular area above the soleal line, with the exception of the area adjoining the fibular facet. To the *soleal line* are attached the strong fascia which covers the popliteus, and the soleus, its covering fascia, and the fascia covering the deep muscles of the leg. The upper end of the line does not reach the interosseous border and is marked by a tubercle, to which is attached the medial end of the tendinous arch in the soleus. Lateral to the tubercle the posterior tibial vessels and nerve descend on the surface of the tibialis posterior. Below the soleal line, the *vertical line* separates the attachments of flexor digitorum longus on the medial side from that of tibialis posterior (**3**.196 B). The lower quarter, or more, of the posterior surface is devoid of muscular attachments, but is intimately related to the tendon of the tibialis posterior as it runs downwards and medially to reach the groove on the back of the medial malleolus. The flexor digitorum longus lies on the posterior surface of the tibialis posterior crossing it obliquely from the medial to the lateral side, but the posterior tibial vessels and nerve and the flexor hallucis longus come into contact only with the lateral part of this surface for a short distance inferiorly.

The lower end of the tibia is slightly expanded, and projects medially and downwards as the medial malleolus. It possesses anterior, medial, posterior, lateral and inferior surfaces.

The *anterior surface* is smooth and bulges forwards beyond the inferior surface, from which it is separated by a narrow groove. It is continuous above with the lateral surface of the shaft (p. 401). The *medial surface* also is smooth and is continuous above with the medial surface of the shaft and below with the medial surface of the malleolus. It is subcutaneous and can be seen and felt through the skin. The *posterior surface* is crossed at its medial end by a groove, usually conspicuous, which can be traced down on to the posterior surface of the medial malleolus. Elsewhere this surface of the lower end is smooth and is continuous above with the posterior surface of the shaft. The *lateral surface* is the triangular *fibular notch*, which is bound by ligaments to the lower end of the fibula. The anterior and posterior borders of the notch project and converge to meet above on the interosseous border of the bone. The floor of the notch is roughened in its upper part for the attachment of an interosseous ligament. Its lower part is smooth and is sometimes covered with articular cartilage. The *inferior surface* is smooth for articulation with the body of the talus. Wider in front than behind, it is concave from before backwards and slightly convex from side to side. Medially it is continuous with the articular surface of the medial malleolus. The tibial articular surface may extend into the narrow groove (*vide supra*) which separates this surface from the anterior aspect of the tibial shaft. Such extensions, which may be medial or lateral or both in situation, are described as *squatting facets*, and they articulate with corresponding facets on the neck of the talus (p. 407), when the foot is in extreme dorsi-flexion. Such features have been used in racial evaluation (p. 238).

3.197 Stages in the ossification of the tibia.

The medial malleolus is a short but stout process. Its lateral surface is smooth and occupied by a comma-shaped articular facet, which articulates with the medial side of the talus. Its anterior surface is rough, and its posterior surface bears the lower end of the groove that marks the posterior surface of the lower end of the shaft. The lower border of the malleolus is pointed anteriorly and depressed posteriorly.

The *anterior surface* of the lower end is related to the tendons, vessels and nerve which lie on the lower part of the lateral surface of the shaft and have already been enumerated (p. 402). To the narrow groove adjoining the anterior border of the inferior surface is bound the anterior part of the articular capsule of the ankle joint. The groove on the *posterior surface* is adapted to the tendon of tibialis posterior, which at that level usually separates the tendon of the flexor digitorum longus from the bone. More

laterally the posterior tibial vessels and nerve and the flexor hallucis longus tendon are in contact with this surface. The anterior and posterior borders of the *fibular notch* give attachment respectively to the anterior and posterior tibiofibular ligaments. The *medial malleolus* ends at a higher level than the lateral, which also lies on a more posterior plane. Its anterior surface has attached to it the anterior part of the articular capsule of the ankle joint. The groove for the posterior tibial muscle's tendon, on the posterior surface, has a prominent medial border, to which the flexor retinaculum is attached. The upper end of the deltoid ligament is attached to the lower border of the malleolus, both to the pointed anterior part and to the depression behind it.

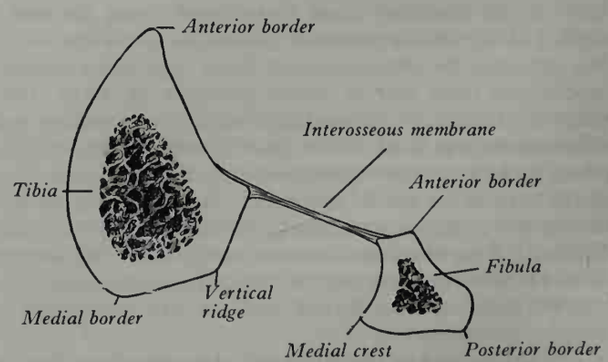
Ossification. The tibia is ossified from three centres (**3**.195B, 196B, 197): one for the shaft and one for each end. Ossification begins in the middle of the shaft about the seventh week of intrauterine life. The centre for the upper end is usually present at birth; from it, at about 10 years of age, a thin tongue-shaped process extends downwards in front to form the smooth part of the tuberosity (**3**.197). An additional centre for the tongue-shaped process is not uncommon; it appears about the twelfth year and soon fuses with the upper epiphysis. In its lower two-thirds the epiphysial plate of the upper end consists of dense collagenous tissue, the fibres of which are aligned with those of the ligamentum patellae. This peculiar structure is attributed to the large tensile stresses to which this part is subjected through the ligament (Lewis 1958; Smith 1962). The centre for the lower end appears early in the first year. The lower end joins the shaft about the fifteenth year in females and seventeenth year in males, the upper in the sixteenth year in females and eighteenth year in males. The medial malleolus is usually formed by a downward extension from the lower epiphysis, commencing in the seventh year; it occasionally possesses a separate centre of ossification.

The Fibula

The fibula (**3**.195, 196), the lateral bone of the leg, is much more slender than the tibia, for it is not called upon to share in the transmission of body weight. It possesses an upper end or head, a shaft, and a lower end, the lateral malleolus. The slightly constricted part of the shaft adjoining the head is sometimes called the neck of the fibula. The shaft shows considerable variation in its form, for it is moulded by the muscles to which it gives attachment; and these variations may prove confusing.

The head of the fibula is slightly expanded in all its diameters, and projects beyond the shaft in front, behind and on the lateral side. On its upper surface is a nearly circular facet, which articulates with the inferior surface of the lateral condyle of the tibia; it faces upwards, and slightly forwards and medially. A blunt elevation, the *apex of the head* (*styloid process*), projects upwards from the lateral part of its posterior surface. The head of the fibula can be felt through the skin on the posterolateral aspect of the knee, nearly 2 cm below the level of the knee joint. Immediately below the head the common peroneal nerve crosses the posterolateral aspect of the neck and can be rolled against the bone in the living subject. If sufficient pressure is exerted, tingling sensations will be experienced on the dorsum of the foot, radiating to the toes, and especially to the medial side of the big toe.

The lower end or lateral malleolus projects downwards to a lower level than the tibia and lies on a more posterior plane. Its *lateral aspect* is subcutaneous and easily felt; its *posterior aspect* carries a broad groove with a prominent lateral border. Its *anterior aspect* is rough and rounded and is continuous below with the inferior border. The *medial surface* presents a triangular articular facet, with its apex pointing downwards (**3**.200). It articulates with the lateral surface of the talus in the ankle joint, and is convex from above downwards. Behind the articular facet the bone is marked by a roughened depression, the *malleolar fossa*, which readily admits the tip of a finger.



The shaft of the fibula (**3**.195, 196) possesses three borders and three surfaces, each of which is associated with a particular group of muscles. The borders are anterior, posterior and interosseous. At its lower end the *anterior border* commences at the apex of an elongated, triangular area which is continuous below with the lateral surface of the lateral malleolus. Traced upwards, it ascends to reach the anterior aspect of the head. The *posterior border* is continuous with the medial margin of the groove on the back of the lateral malleolus. Usually sharp and distinct in its lower part, it is often rounded in the upper half of its extent. The *interosseous border* lies to the medial side of the anterior border and as a rule is on a more posterior plane (**3**.198), but in the upper two-thirds of the bone these two borders are very close to each other, and the intervening surface may be reduced to 1 mm or less in width.

The *lateral surface* is bounded by the anterior and posterior borders. It is associated with the peroneal muscles, and is directed laterally in its upper three-fourths. Its lower quarter inclines backwards and becomes continuous with the groove on the back of the lateral malleolus. The *medial surface* is bounded by the anterior and the interosseous borders. It is usually directed forwards and medially, but frequently faces directly forwards. Wider below, it becomes very narrow in its upper half, and may be reduced to little more than a rounded ridge. It is associated with the extensor muscles of the leg. The *posterior surface* is the largest of the three and is placed between the interosseous and the posterior borders. It is associated with the flexor muscles of the leg. In its upper two-thirds it is divided into two areas by a longitudinal ridge, termed the *medial crest*, which is separated from the interosseous border by a grooved surface, directed medially. The rest of the posterior surface faces backwards in its upper half or more, but its lower part curves round on to the medial aspect and faces medially. The lower part of this area fits into the fibular notch on the tibia and is roughened for the attachment of the interosseous tibiofibular ligament.

The elongated, triangular area immediately above the lateral surface of the lateral malleolus (**3**.195A) is subcutaneous, but the rest of the shaft is covered with muscles and cannot be palpated.

The *head of the fibula* affords origin to fibres of the extensor digitorum longus in front, peroneus longus anterolaterally, and soleus behind. The fibular collateral ligament of the knee joint is attached just in front of the apex and is embraced by the principal insertion of the biceps femoris. The margins of the articular facet provide attachment for the capsular ligament of the tibiofibular articulation.

The *anterior border* of the fibula divides inferiorly into two ridges which enclose between them a subcutaneous triangular surface (**3**.195A). The anterior intermuscular septum of the leg is attached to its upper three-fourths, and the lateral extremity of the superior extensor retinaculum to the lower part of the anterior border of the triangular area. The lower part of the posterior margin of the triangular area gives attachment to the lateral extremity of the superior peroneal retinaculum. The *interosseous border* terminates below at the upper extremity of the roughened area for the interosseous ligament. It provides attachment for the interosseous membrane and does not reach the head of the bone, on account of the gap in the upper part of the membrane for the transmission of the anterior tibial vessels. The *posterior border* is not always recognizable at its upper end; except at its lower end it gives attachment to the posterior intermuscular septum of the leg. The *medial crest* of the bone is intimately related to the peroneal

artery, and the nutrient foramen of the fibula is situated either on the crest or in its immediate vicinity near the middle of the shaft. A layer of the deep fascia of the leg is attached, which separates the tibialis posterior from the flexor hallucis longus and the flexor digitorum longus.

The *medial surface* of the fibula is often termed the *extensor surface*, for attached to it are the extensor digitorum longus, the extensor hallucis longus and the peroneus tertius. The extensor digitorum longus arises from the whole breadth of the upper fourth of the surface and from the anterior part of the succeeding two-fourths; the extensor hallucis longus arises from its middle two-fourths behind the extensor digitorum longus; the peroneus tertius from its lower fourth or more, being directly continuous with the lower part of the extensor digitorum longus. The *lateral* or *peroneal surface* gives origin to the peroneus longus and the peroneus brevis. The peroneus longus arises from the whole

3.201 Stages in the ossification of the fibula.

extent of the upper third of the surface and from the posterior part of the middle third. The peroneus brevis arises in front of the lower half of the peroneus longus and extends downwards beyond it almost to the lower end of the bone. On account of the relative attachments of their fleshy bellies the tendon of the peroneus brevis is closely applied to the bone below and separates it from the tendon of the peroneus longus. The *posterior surface*, which is divided longitudinally into two parts by the medial crest, is often termed the *flexor surface*. The region which lies between the crest and the interosseous border is slightly hollowed out and gives origin to the tibialis posterior; it is often crossed by an oblique ridge which gives attachment to an intramuscular tendon. This part of the surface is usually confined to the upper three-fourths of the shaft, and at its lower end the medial crest becomes confluent with the interosseous border. The portion of the posterior surface which lies between the medial crest and the posterior border gives origin in its upper fourth to the soleus, which extends upwards on to the posterior aspect of the head; near the upper end of the medial part of this origin a roughened tubercle marks the lateral end of the tendinous arch which crosses the posterior tibial vessels and nerve as part of the attachment of soleus. Below the origin of the soleus the remainder of this surface gives origin to the flexor hallucis longus, almost to the lower end of the bone. A little above its middle, this surface is pierced by the nutrient foramen, which directed downwards and transmits a branch from the peroneal artery.

The anterior surface of the *lateral malleolus* gives attachment to the anterior talofibular ligament. The lower border is marked in front by a slight notch and behind by a small projection which constitutes the apex of the malleolus. It is to the notch that the calcaneofibular ligament is attached. The tendons of the peroneus brevis and peroneus longus groove the posterior aspect; the latter is the more superficial and is closely covered by the superior peroneal retinaculum. The *malleolar fossa* (**3**.200) is pitted by numerous small vascular foramina; to its upper part the posterior tibiofibular ligament is attached, to its lower part the posterior talofibular ligament.

Ossification. The fibula is ossified from three centres (**3**.201): one for the shaft, and one for each end. Ossification begins in the shaft about the eighth week of intrauterine life, in the lower end in the first year, and in the upper about the third year in females and fourth year in males. The lower epiphysis—the first to ossify—unites with the shaft about the fifteenth year in females and seventeenth year in males, whereas the upper epiphysis, which does not begin to ossify until later, does not unite with the shaft until about the seventeenth year in females and nineteenth year in males. In this respect the fibula contrasts with the ossification pattern of other long bones.

THE SKELETON OF THE FOOT

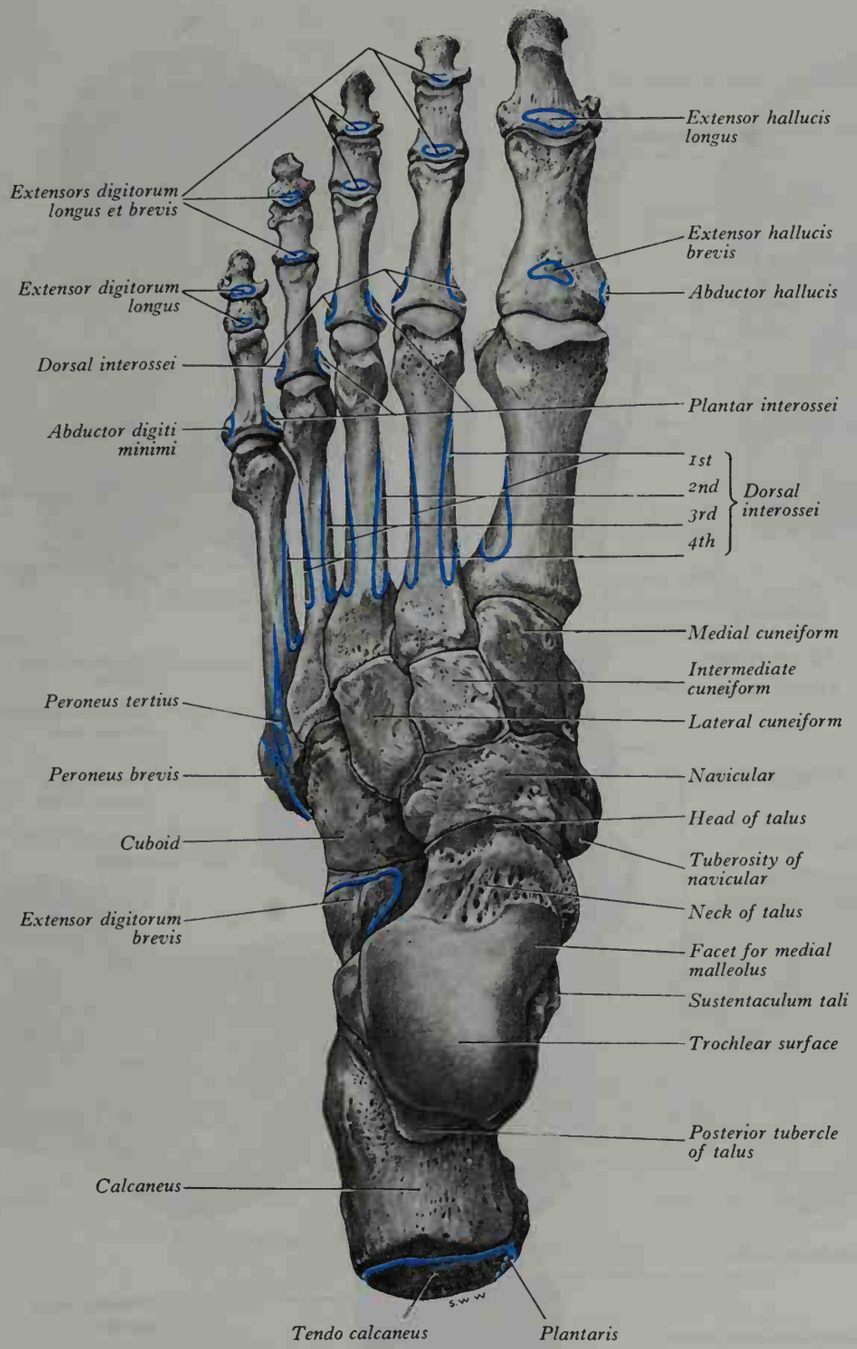
Functionally the skeleton of the foot may be divided into segments: the tarsus, the metatarsus, and the phalanges or digital bones. In the description which follows use will be made of the terms *plantar* and *dorsal*, which are self-explanatory, and this will obviate, almost entirely, the employment of the terms anterior and posterior, which are not entirely apposite in the foot. The terms proximal and distal will also be employed, wherever reasonable, with the same significance with which they were used in the hand. Reference to the rotation which occurs in the early stages of the development of the limbs (p. 153) will explain how it comes about that, whereas the thumb is the most lateral of the digits in the hand (when in the 'anatomical position' but not, of course, in the much more 'functional position' of medial rotation of the shoulder joint combined with some degree of flexion at the elbow joint and a mid-prone position of the forearm bones and hand), the great toe is the most medial in the foot. (See also p. 350.)

The Tarsus

The seven bones of the tarsus make up the skeleton of the posterior half of the foot (**3**.202, 203). The tarsus is homologous with the carpus, but its constituent elements are larger and stronger, on account of the part they play in supporting and distributing the weight of the body. As in the carpus the tarsal bones are arranged in proximal and distal rows, but an additional element is interposed between the two rows on the medial side. The proximal row comprises the *talus* and the *calcaneus*. These do not lie side by side; the talus is above the calcaneus, but its long axis is directed forwards, medially and downwards, and its anterior end or head is medial to the calcaneus, though at a higher level. The distal row contains, from medial to lateral side, the *medial cuneiform*, *intermediate cuneiform*, *lateral cuneiform* and the *cuboid*. These lie side by side and together contribute to the formation of a transverse arch, convex dorsally. On the medial side the *navicular bone* is interposed between the head of the talus and the three cuneiforms. Laterally the calcaneus articulates directly with the cuboid.

The foot is set at right angles to the leg in standing, and the tarsus and metatarsus are arranged in such a way as to form intersecting longitudinal and transverse arches. As a result thrust and weight are not transmitted to the ground from the tibia directly through the tarsus, but are distributed through the tarsal and is metatarsal bones to the extremities of the arches (*see* p. 617). Each of the tarsal bones is roughly cuboidal in form and hence presents six surfaces.

The Individual Tarsal Bones



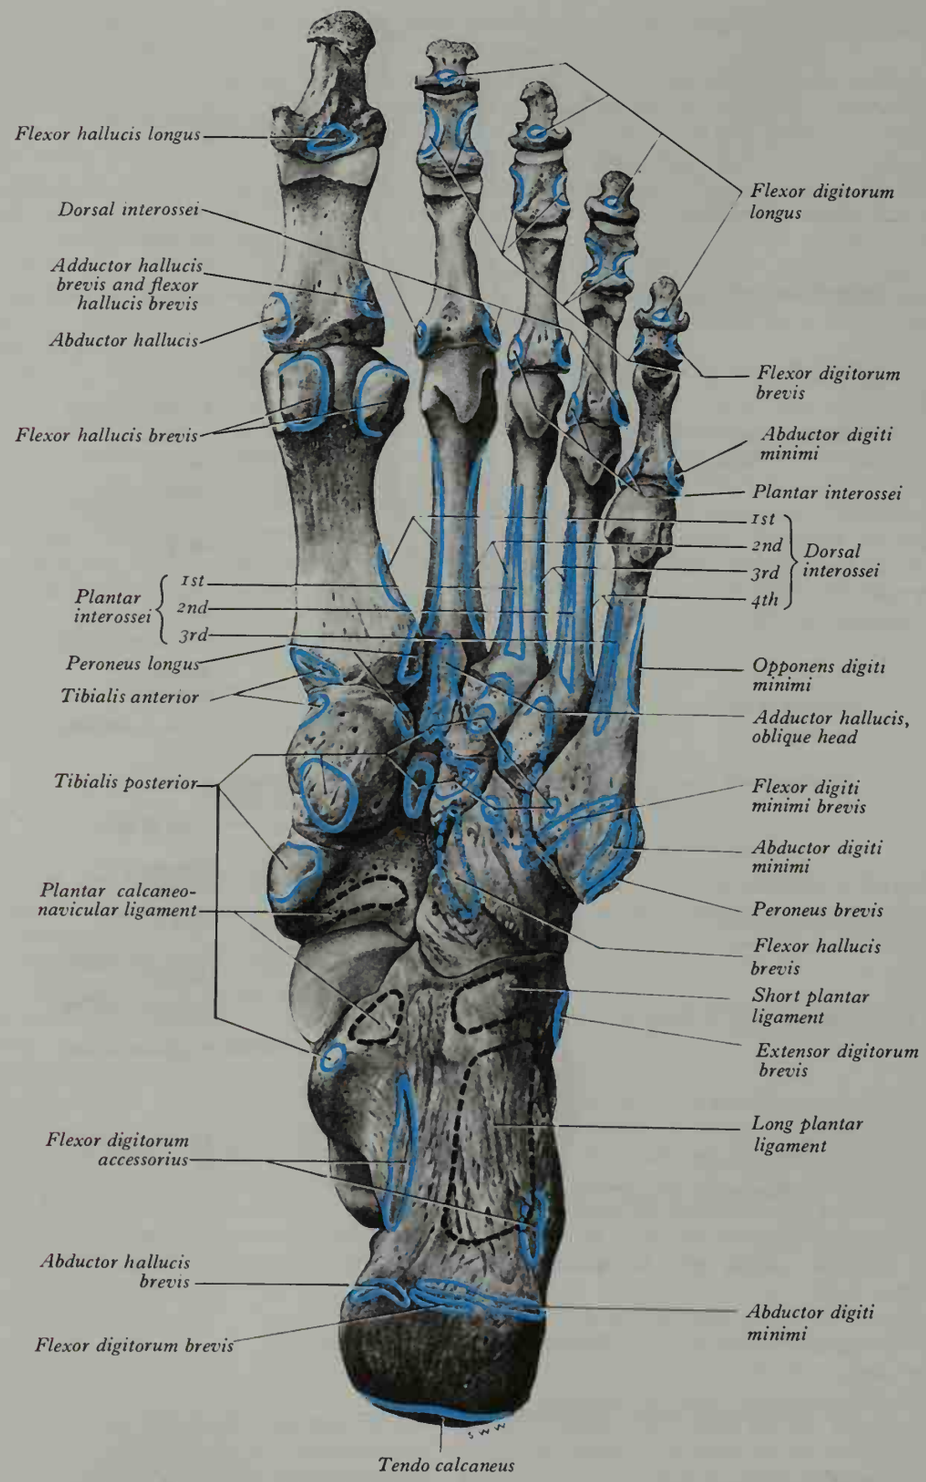
The Talus

The talus (**3**.204 A–D) is the connecting link between the rest of the foot and the bones of the leg, through its part in the formation of the ankle joint. The rounded head at the distal end of the bone, the trochlear surface for the tibia on the dorsal surface, the large triangular facet for the lateral malleolus on the lateral surface, the neck, and the body are the main features of the bone.

The head of the talus, directed distally and slightly downwards and medially, has a *distal surface*, which is oval and convex, with its long axis also directed downwards and medially to articulate with the proximal surface of the navicular bone. Its *plantar surface* has three articular areas, separated by indistinct ridges. Of these the most posterior is largest; oval in outline, it is slightly convex and rests on the upper surface of a shelf-like projection from the medial side of the calcaneus, the *sustentaculum tali*. Anterior and lateral to this area, and usually continuous with it, a flattened articular facet rests on the anteromedial part of the upper surface of the calcaneus; it is continuous in front with the navicular surface. Medial to the two calcanean facets a part of the head of the talus is covered with articular cartilage and is continuous on the one hand with the calcanean areas and on the other with the navicular area (**3**.204 B). It is in contact with the *plantar calcaneonavicular ligament* (p. 497). When the foot is inverted passively, the dorsal and lateral part of the head can be both seen and felt; it lies 3 cm in front of the lower end of the tibia and becomes obscured by the extensor tendons when the toes are dorsiflexed.

The neck of the talus is the slightly constricted part which connects the head to the body. It is set very obliquely on the body and inclines medially. Its roughened surfaces give attachment to ligaments, and the medial part of its plantar surface exhibits a deep groove, the *sulcus tali*. When the talus and calcaneus are articulated together this groove forms the roof of a bony canal, the *sinus tarsi*, which is occupied by the interosseous talocalcanean and cervical ligaments.

The body of the talus is cuboidal in shape. Its dorsal surface



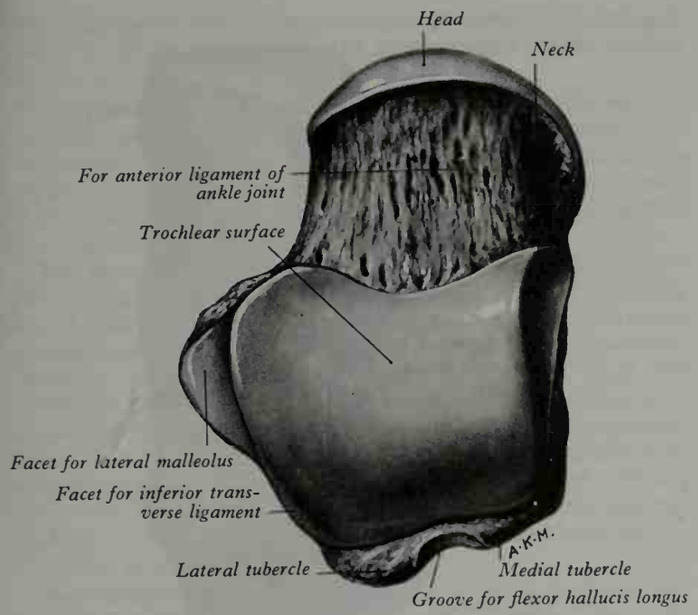
3.202 The skeleton of the left foot. Dorsal aspect. Attachments of extrinsic and intrinsic muscles.

is covered by a *trochlear* articular surface, which articulates with the lower end of the tibia in the ankle joint. It is convex from before backwards and gently concave from side to side, and it is widest anteriorly. The *lateral surface*, triangular in outline, is smooth for articulation with the lateral malleolus, and is concave from above downwards. Superiorly it is continuous with the trochlea; inferiorly its apex forms the *lateral process* of the talus. The *medial surface* is covered in its upper part by a comma-shaped articular facet which is deeper in front than behind and articulates with the medial malleolus. Below this facet the surface is rough and is pitted by numerous vascular foramina. The *posterior surface* is rough, small in extent and projects to form the *posterior process* of the bone. It is marked by an oblique groove placed between two tubercles. The *lateral tubercle*, usually the larger, is on the lateral side of the groove; the *medial tubercle* is less prominent and lies immediately behind the sustentaculum tali of the calcaneus (**3**.203). The *plantar surface* rests on the dorsal surface of the calcaneus and is covered with an oval concave facet, the long axis of which runs distally and laterally at an angle of about 45° with the median plane.

The talus is devoid of any muscular attachments, but it provides attachment for numerous ligaments (**4**.86, 87), for it takes part in the formation of the talocrural, subtalar and talocalcaneonavicular joints.

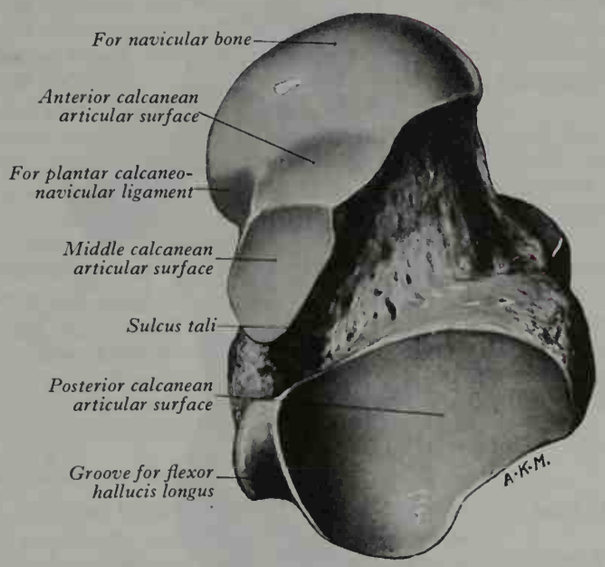
The long axis of the neck is inclined downwards, distally and medially, making an angle of about 150° with the long axis of the body. This angle is smaller (130°–140°) in the newly born (**3**.205), and helps to account for the inverted position of the foot in young children. The dorsal surface of the neck gives attachment distally to the dorsal talonavicular ligament and the articular capsule of the ankle joint; the proximal part of this surface therefore lies within the capsular ligament of the ankle joint. The medial articular facet and, less frequently, part of the trochlear articular surface may extend forwards on to the neck, especially in the child (**3**.205). A *squatting facet* is commonly found on the upper and lateral part of the neck in Indians but seldom in adult Europeans.

3.203 The skeleton of the left foot. Plantar aspect. The attachments of the tibialis posterior to the metatarsals vary; those to the third and fifth may be absent. The adductor hallucis (oblique head) and the flexor hallucis brevis arise in large part from the ligaments and tendinous extensions in the sole of the foot and not directly from bone; these attachments are shown by interrupted lines.



It articulates with the anterior margin of the tibia in extreme dorsiflexion (Barnett 1954; Singh 1959). The facet may be double, forming *medial* and *lateral talar facets*. The lateral part of the neck gives attachment to the anterior talofibular ligament, which extends downwards along the neighbouring anterior border of the lateral surface. The inferior surface of the neck gives attachment to the interosseous talocalcanean and cervical ligaments (p. 495).

The medial border of the *trochlear articular surface* is straight but its *lateral border* inclines medially at its posterior part, which is often broadened and flattened to form a small elongated triangular area. It is this part of the bone which comes into contact with the posterior tibiofibular ligament in dorsiflexion of the ankle joint.



The *posterior process* receives the attachment of the posterior talofibular ligament, which extends upwards to the groove, or depression, between the process and the posterior border of the trochlea. Its plantar border gives attachment to the posterior talocalcanean ligament. The *groove* between the two tubercles of the process contains the tendon of the flexor hallucis longus and is continuous below and in front with the groove on the plantar surface of the sustentaculum tali. The *medial tubercle* gives attachment on its medial aspect to the medial talocalcanean ligament below, and to the most posterior of the superficial fibres of the deltoid ligament above.

To the roughened area below the comma-shaped articular facet on the medial surface the deep fibres of the deltoid ligament are attached.

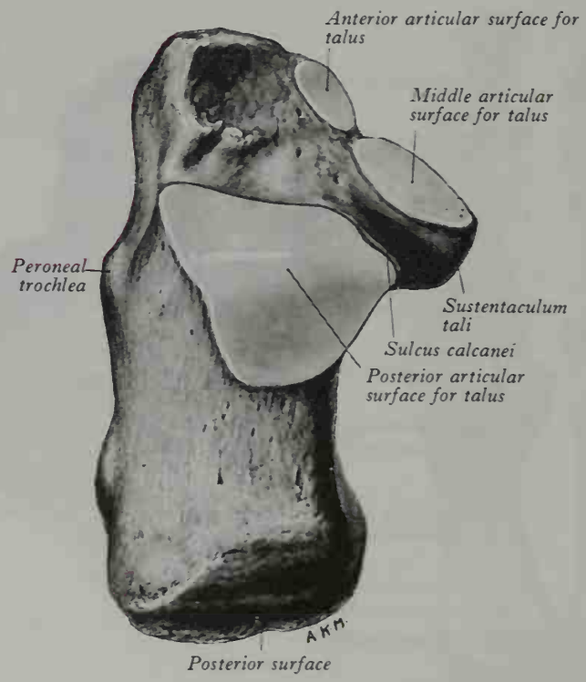
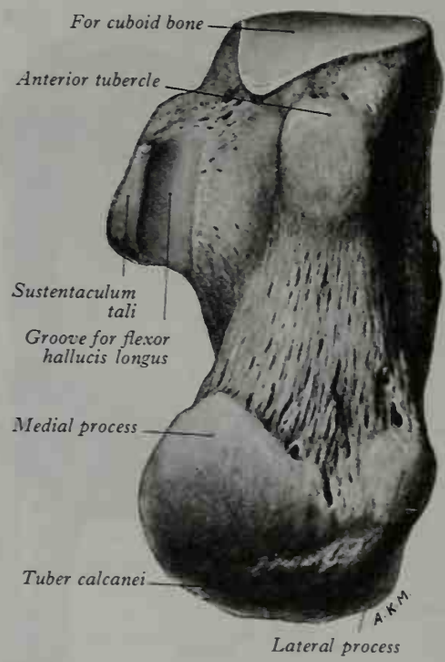
recorded (Singh and Singh 1975); the ranges in adult Indian males and females were 15·1 to 36·8 and 6·0 to 20·5 gm; the respective means being 23·50 and 15·32 gm. Estimation of sex on dimensional data has been claimed by Steele (1976).



The Calcaneus

The calcaneus (**3**.206A–D) is the largest of the tarsal bones; it projects backwards beyond the bones of the leg so as to provide a short lever for the muscles of the calf, which are inserted into its posterior surface. It is irregularly cuboidal in shape, and its long axis is directed forwards, upwards and somewhat laterally. The small articular anterior end contrasts with the larger, roughened, posterior end. The dorsal surface bears a large, articular facet about its middle which distinguishes it from the rough plantar surface. Finally the lateral surface is flattened, whereas the medial surface is hollowed out from above downwards and backwards.



The dorsal or superior surface is divisible into three areas. The posterior third is roughened, convex from side to side and concave from behind forwards; it supports a mass of fibro-adipose

3.206A–D THE LEFT CALCANEUS

tissue located between the tendo calcaneus and the back of the ankle joint. The middle third carries the *posterior facet for the talus*, which is oval in outline and convex anteroposteriorly. The anterior third is partly articular and partly non-articular. In front of the posterior articular facet there is a rough depression, which becomes narrower and takes the form of a groove on the medial side. This is termed the *sulcus calcanei*; it corresponds to the sulcus tali and helps it to complete the sinus tarsi in the articulated foot. In front of and medial to this groove an elongated articular area covers the dorsal surface of the sustentaculum tali, and extends forwards and laterally on to the body of the bone. This area is often divided into two by a narrow non-articular interval which marks the anterior limit of the sustentaculum tali, the *middle* and *anterior facets for the talus*. The incidence of this division varies with sex and race. Rarely, all three facets on the upper surface of the talus are fused into one large irregular area (Bunning and Barnett 1963, 1965). Recently, a detailed analysis of the patterns of the *anterior* facets for articulation with the head of the talus has been made on a series of 401 normal Indian calcanei: four types were described. Type I (67 per cent) showed one continuous facet on the sustentaculum which extended to the anteromedial corner of the distal calcaneal end; Type II (26 per cent) presented two facets, one sustentacular and one distal calcaneal; Type III (5 per cent) possessed only a single sustentacular facet; and Type IV (2 per cent) was similar to Type I, but was also confluent with the posterior talar facet of the calcaneus.

The anterior surface is the smallest of the six surfaces, and is entirely covered by an obliquely set concavoconvex facet which articulates with the cuboid bone.

The posterior surface is divided into three areas. The uppermost is smooth and separated from the tendo calcaneus by a bursa and some fatty tissue. The middle area is the largest and is limited above by a groove and below by a rough ridge; it is for the

tendo calcaneus. The lowest area slopes downwards and forwards and is vertically striated; it is the subcutaneous weight-bearing surface.

The plantar surface is rough, especially posteriorly, where it bears the *calcanean tuberosity*. The *lateral* and *medial processes* of the tuberosity extend distally for a short distance, separated by a notch. The medial process is the broader of the two (**3**.206B). More distally a tubercle marks the distal limit of the attachment of the long plantar ligament.

The lateral surface is almost flat and is deeper behind than in front; it can be palpated on the lateral aspect of the heel and can be traced forwards below the lateral malleolus. In its anterior part it presents a small elevation, termed the *peroneal trochlea (tubercle)* (**3**.206C), which is exceedingly variable in size and, when well developed, can be felt in the living subject 2 cm below the tip of the lateral malleolus. It exhibits an oblique groove on its postero-inferior aspect, for the peroneus longus tendon, and a shallower anterosuperior groove, for the peroneus brevis tendon. About 1 cm or more behind the peroneal trochlea a second elevation may mark the bone; it is for attachment of the calcaneofibular part of the lateral ligament of the ankle joint.

The medial surface is concave from above, downwards and backwards, and its concavity is accentuated by a shelf-like process, the *sustentaculum tali*, which projects medially from the anterior part of its upper border (**3**.206D). The superior surface of this process bears the middle facets for the talus, and its inferior surface is marked by a groove which is continuous with the groove on the posterior surface of the talus and is adapted to the flexor hallucis longus tendon (**3**.206B). The medial surface of the sustentaculum tali can be felt indistinctly through the skin immediately below the tip of the medial malleolus; occasionally it presents a groove for the flexor digitorum longus tendon.

The *sulcus of the calcaneus* gives attachment to the interosseous talocalcanean and cervical ligaments (p. 495) and to the medial root of the inferior extensor retinaculum. In addition, the non-articular area in front of the posterior facet for the talus is part of the attachment of extensor digitorum brevis and the attachment of the principal band of the inferior extensor retinaculum and the stem of the bifurcated ligament.

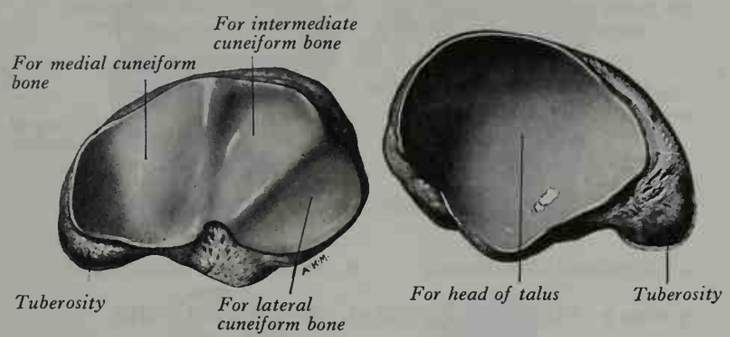
The *medial process of the tuberosity* affords attachment by its prominent medial margin to abductor hallucis and the superficial part of the flexor retinaculum, and in front to the plantar aponeurosis and the flexor digitorum brevis. To the *lateral process* is attached abductor digiti minimi, which also extends medially to the front of the medial process. The roughened region between the two processes, proximally, and the tubercle, distally, gives attachment to the long plantar ligament, while the short plantar ligament springs from the tubercle and the narrow rough area distal to it. The lateral tendinous head of the flexor digitorum accessorius arises in front of the lateral process close to the lateral margin of the long plantar ligament.

The *posterior surface* is wider below than above. Close to the medial side of the attachment of the tendo calcaneus the muscle plantaris terminates.

The anterior part of the *lateral surface* is crossed by the peroneal tendons, but in most of its extent is covered only by the skin and superficial fascia. The peroneus brevis tendon, after passing behind the lateral malleolus, runs forwards and slightly downwards above and in front of the *peroneal trochlea*; the peroneus longus tendon passes downwards and forwards below and behind the trochlea, which gives attachment to a slip from the inferior peroneal retinaculum (p. 611). The calcaneofibular ligament is attached to the bone about 1 cm behind the peroneal trochlea, and the site is usually indicated by a low rounded elevation.

The *sustentaculum tali* assists, by its dorsal surface, in the formation of the talocalcaneonavicular joint; its plantar surface is grooved by the flexor hallucis longus tendon, and the margins of the groove give attachment to the deep part of the flexor retinaculum. The medial margin of the process is narrow, roughened, and convex from before backwards. Anteriorly the plantar calcaneonavicular ligament is attached to it (p. 497), behind that a slip from the tibialis posterior tendon and some of the superficial fibres of the deltoid ligament, and posteriorly the medial talocalcanean ligament. Below the attachment of the deltoid ligament the tendon of the flexor digitorum longus is related to this aspect of the process and sometimes its position is indicated by a groove. Below the groove for the flexor hallucis longus the medial surface gives origin to the large, fleshy, medial head of the flexor accessorius.

Singh and Singh (1975) have studied variations in the dry weight of the calcaneus in both sexes in an adult Indian population. The male range was 23·3 to 56·8 gm (mean = 36·64), and 13·0 to 33·0 gm (mean = 24·75) in females. Steele (1976) has advocated sex estimation on dimensional data.



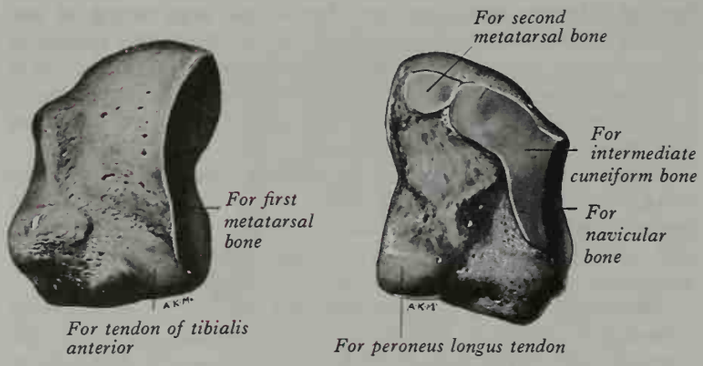
The calcaneus has been the subject of an interesting comparison between the right and left bones (Webber and Garnett 1976); comparisons in 52 adults showed a significantly greater density of the calcaneus corresponding to the side of hand preference. It was concluded that the concordance between upper limb dominance and the increased density of the ipsilateral os calcis had been determined during fetal life.

The Navicular Bone

The navicular bone (**3**.207) is interposed between the head of the talus proximally and the cuneiform bones distally.

The *distal surface* is convex from side to side and is divided into three facets (of which the most medial is the largest) for articulation with the three cuneiform bones. The *proximal surface*, oval and concave, articulates with the head of the talus. The *dorsal surface* is roughened and convex from side to side. The *medial surface* also is rough and is continued downwards to form a prominent projection termed the *tuberosity*. It can be felt through the skin about 2·5 cm below and in front of the medial malleolus. The *plantar surface*, also rough, is concave, and separated from the tuberosity on the medial side by a groove. The *lateral surface* is rough and irregular, but frequently presents a facet for articulation with the cuboid.

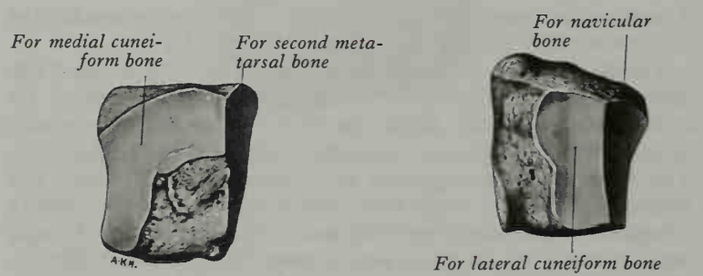
The facet for the medial cuneiform is triangular, with its rounded apex on the medial side. The facets for the intermediate



A Distal aspect. B Proximal aspect.

3.207A, B THE LEFT NAVICULAR BONE

and lateral cuneiform bones are also triangular, but their apices point towards the sole. To the dorsal surface are attached the dorsal talonavicular, cuneonavicular and cubonavicular ligaments. The **tuberosity** of the navicular bone provides the principal attachment for the tibialis posterior tendon, and the groove which lies on its lateral side transmits the part of this tendon which runs forward to reach the cuneiform bones and the bases of the middle three metatarsal bones. A slight projection marks the plantar surface of the bone on the lateral side of the groove. Together with the proximal part of this surface it provides attachment to the plantar calcaneonavicular ligament. To the roughened part of the lateral surface is attached the calcaneonavicular part of the bifurcated ligament.



The Cuneiform Bones

The three cuneiform bones (**3**.208, 209, 210) are wedge-shaped and articulate with the navicular bone proximally and the bases of

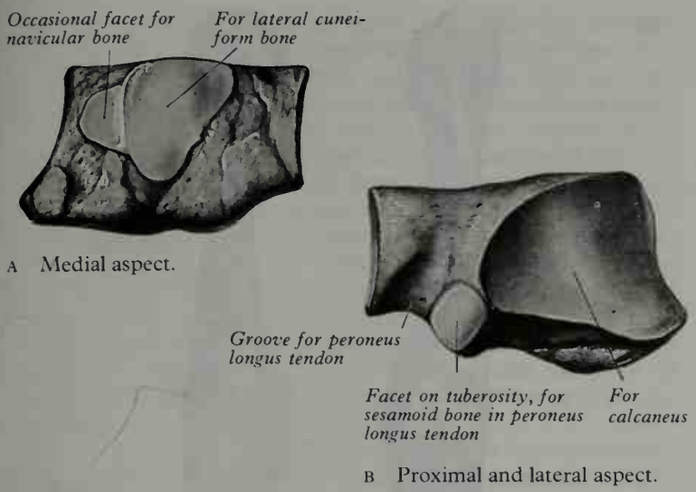
3.210A, B THE LEFT LATERAL CUNEIFORM BONE

the first, second and third metatarsal bones distally. The medial cuneiform is the largest, the intermediate the smallest. In the intermediate and in the lateral cuneiform bones the dorsal surface is the base of the wedge and the plantar surface represents the edge, but in the medial cuneiform the wedge is reversed so that its edge is represented by the narrow, dorsal surface of the bone. This arrangement is an important factor in the construction of the transverse arch of the foot. The proximal surfaces of the three cuneiform bones form a slight concavity for the navicular, but the distal parts of the medial and lateral cuneiforms project distally beyond the intermediate cuneiform, and bound a deep recess into which the base of the second metatarsal bone projects.

The medial cuneiform bone (**3**.208) articulates with the navicular proximally and with the base of the first metatarsal distally. The *dorsal surface* is rough and narrow. The *plantar surface* receives a substantial slip from the tendon of tibialis posterior. The *distal surface* bears a large reniform facet for articulation with the base of the first metatarsal bone, the little notch representing the hilum being on its lateral margin. The *proximal surface* bears a piriform facet, which articulates with the navicular bone. Concave in its vertical axis, it is narrower dorsally. The *medial surface* is rough and subcutaneous; it is slightly convex in its vertical axis and its distal-plantar angle is marked by a large, flattened impression for most of the fibres of the tibialis anterior tendon (**3**.208A). The *lateral surface* is partly articular and partly non-articular. Along its proximal and dorsal margins it is covered with a smooth ⌜-shaped strip which articulates with the intermediate cuneiform bone. The dorsal and distal part of this strip is separated by a vertical ridge from a small, almost square, facet which articulates with the dorsal part of the medial surface of the base of the second metatarsal bone. Below this facet the medial cuneiform is attached to the medial side of the base of the second metatarsal bone by a strong interosseous ligament, and proximally the interosseous intercuneiform ligament connects it to the medial side of the intermediate cuneiform. The distal and plantar part of the lateral surface is roughened where it receives the insertion of part of the peroneus longus tendon (**3**.208B).



The intermediate cuneiform bone (**3**.209) articulates distally with the base of the second metatarsal and proximally with the navicular bone. It is of regular wedge-like form, the base of the wedge forming the roughened, *dorsal surface*, and the edge the narrow, *plantar surface*, which receives a slip from the tibialis posterior tendon. The *distal* and *proximal surfaces* are each covered with a triangular articular facet, for the base of the second metatarsal and the navicular bone respectively. The *medial surface* is partly articular and partly non-articular. Along its proximal and dorsal margins it bears a smooth, ⌜-shaped strip, occasionally divided into two, articulating with the medial cuneiform. The *lateral surface* also is partly articular and partly non-articular. Along its proximal margin is a vertical strip, usually indented at its middle, for articulation with the lateral cuneiform. Strong interosseous ligaments connect the non-articular parts of the lateral and medial surfaces to the lateral and medial cuneiform bones, respectively.

The lateral cuneiform bone (**3**.210) is placed between the intermediate cuneiform and the cuboid. Distally it articulates with the base of the third metatarsal and proximally with the navicular bone. Like the intermediate cuneiform, its *dorsal surface*, rough and almost rectangular, represents the base of the wedge, and its *plantar surface*, narrow and rough, the edge. The latter receives a slip from the tibialis posterior tendon and may share in the origin of flexor hallucis brevis. The *distal surface* is completely covered with a triangular articular facet for the base of the third metatarsal bone. The *proximal surface* is rough in its plantar part but is smooth and articular in its dorsal two-thirds, which articulate with the navicular by means of a triangular facet. The *medial surface* is partly articular, partly non-articular. Along its proximal margin is a vertical strip, indented at its middle, for the intermediate cuneiform, and along its distal margin a narrower strip, often divided into two small facets, serves for articulation with the lateral aspect of the base of the second metatarsal bone. The *lateral surface* also is partly articular and partly non-articular. A large triangular or oval facet is situated proximally for articulation with the cuboid; a small facet, semi-oval in shape, is placed at the dorsal part of its distal margin for articulation with the dorsal part of the medial side of the base of the fourth metatarsal bone. The non-articular portions of the medial and lateral surfaces provide attachment for strong intercuneiform and cuneocuboid ligaments, which play an important part in maintaining the transverse arch of the foot.

The Cuboid Bone

The cuboid bone (**3**.211) is the most lateral one in the distal row of the tarsus, and is situated between the calcaneus proximally and the fourth and fifth metatarsal bones distally.

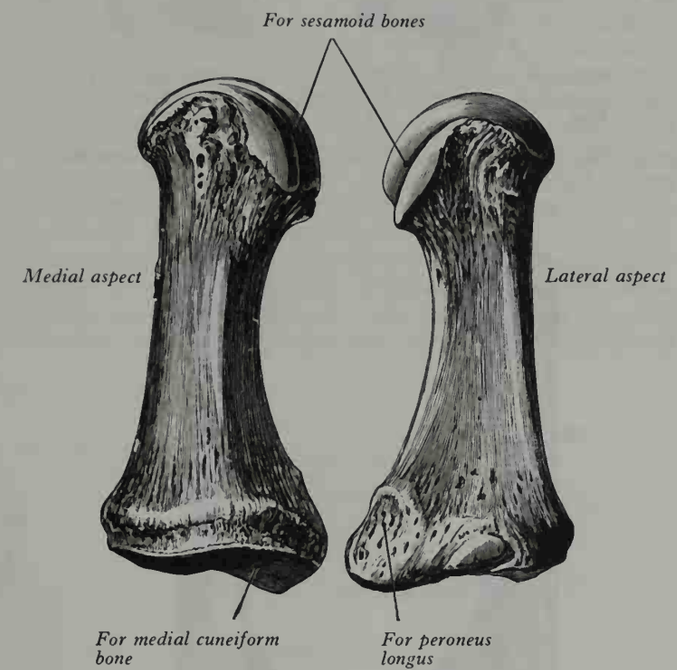
The *dorsal surface*, directed laterally as well as dorsally, is rough for ligamentous attachments. The distal part of the *plantar surface* is crossed by an oblique *groove for the peroneus longus tendon*, bounded proximally by a prominent ridge. This ridge ends laterally in an enlargement, the *tuberosity of the cuboid bone*. The lateral aspect of the tuberosity is faceted for the sesamoid bone or cartilage which is frequently found in the peroneus longus tendon. Proximal to the ridge of the plantar surface is rough and, owing to the obliquity of the calcaneocuboid joint, extends

A Medial aspect.

B Proximal and lateral aspect.

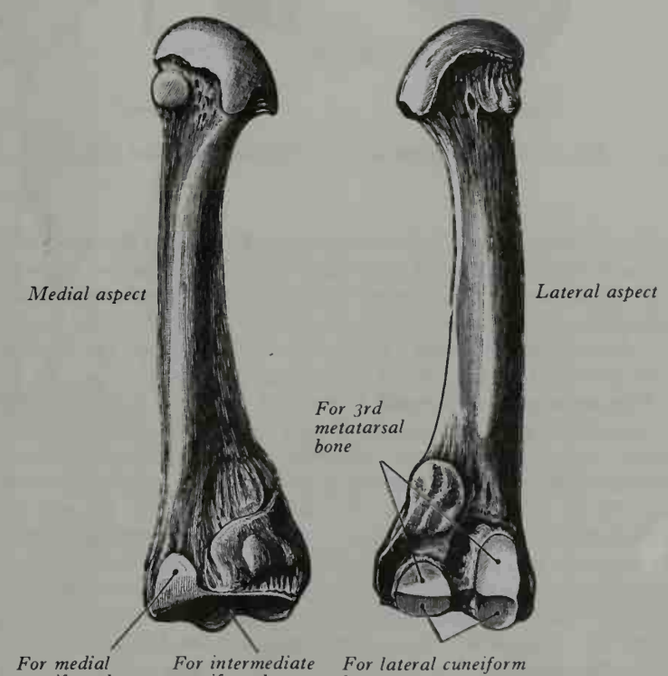
3.211 A, B THE LEFT CUBOID BONE

proximally and medially so that the medial border of this surface is much longer than the lateral border. The *lateral surface* is rough and exhibits a deep notch on its plantar edge which marks the commencement of the groove for the peroneus longus tendon. The *medial surface* is much more extensive and is partly articular and partly non-articular. It is marked near its middle by a smooth oval facet for articulation with the lateral cuneiform bone; proximal to this a small facet for the navicular bone is sometimes present. The two form a continuous articular surface but are separated by a vertical ridge. The *distal surface* is divided by a vertical ridge into two articular areas; the medial facet is quadrilateral and articulates with the base of the fourth metatarsal bone; the lateral facet, triangular in outline, with the apex on the lateral side, articulates with the base of the fifth metatarsal. The *proximal surface*—smooth, triangular and concavoconvex—articulates with the distal surface of the calcaneus; its medial plantar angle projects proximally as a process which helps to support the distal end of the calcaneus.



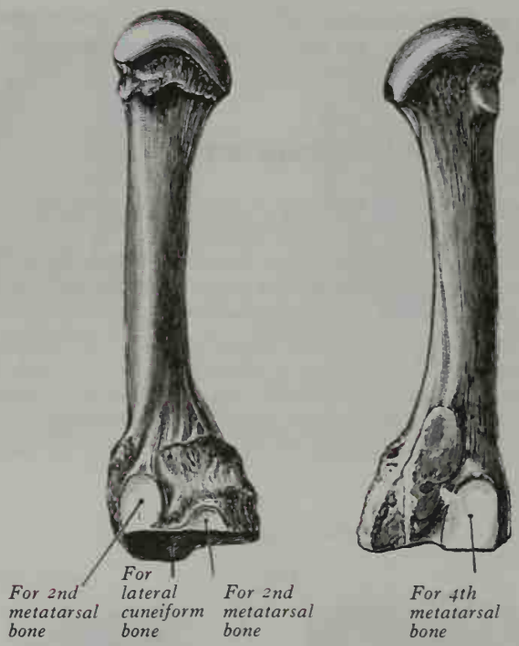
To the dorsal surface are attached the dorsal calcaneocuboid, cubonavicular, cuneocuboid and cubometatarsal ligaments. The ridge on the plantar surface gives attachment to the deep fibres of the long plantar ligament, which conceals the attachment of the short plantar ligament to the proximal border of this surface. The projecting proximomedial part of the plantar surface receives a slip from the tendon of the tibialis posterior and gives origin to the flexor hallucis brevis. The rough part of the medial surface of the cuboid affords attachment for the interosseous cuneocuboid and cubonavicular ligaments, and in its proximal part to the medial calcaneocuboid, which is the lateral limb of the bifurcated ligament.

The Metatarsus



The metatarsus consists of five metatarsal bones situated in the distal part of the foot, connecting the tarsus to the phalanges. They are numbered from the medial side. Like the metacarpals, the metatarsals are miniature long bones, and each possesses a shaft, a base or proximal end, and a head or distal end. With the exception of the first and, to a lesser degree, the fifth, the *shafts* are long and slender, and are slightly convex longitudinally on their dorsal aspects and concave on their plantar aspects. They are prismatic in section and taper from base to head. The *bases* articulate with the distal row of the tarsus and with one another. The line of each tarsometatarsal joint, excluding the first, passes proximally and laterally, and the bases of the metatarsals are therefore set somewhat obliquely relative to their shafts. The *heads* articulate with the proximal phalanges of their own digits, each by means of a convex articular surface which extends farther on the plantar than on the dorsal surface; the plantar extension ends on each side on the summit of a slight eminence. The sides of the heads are flattened, and each shows a depression surmounted dorsally by a tubercle, for one of the collateral ligaments of the metatarsophalangeal joint.

The Individual Metatarsal Bones



The first metatarsal bone (3.212) is the shortest and thickest. Its *body* is strong, and of well-marked prismatic form. The *base* has no articular facets on its sides, but there is occasionally a facet or ill-defined smooth area on the lateral side caused by contact with the second metatarsal. Its proximal surface, large and usually indented on both its medial and lateral margins, articulates with the medial cuneiform. Its circumference is grooved for its tarsometatarsal ligaments, and medially provides attachment for a part of the tendon of the tibialis anterior; its plantar angle presents a rough, oval prominence on its lateral aspect for the tendon of

peroneus longus. The lateral surface of the shaft is flat and gives origin to the medial head of the first dorsal interosseous muscle. The *head* is large; on its plantar surface there is a median elevation separating two grooved facets, of which the medial is the larger, on which sesamoid bones glide. For an account of the arterial supply of the first metatarsal consult Jaworek (1973).

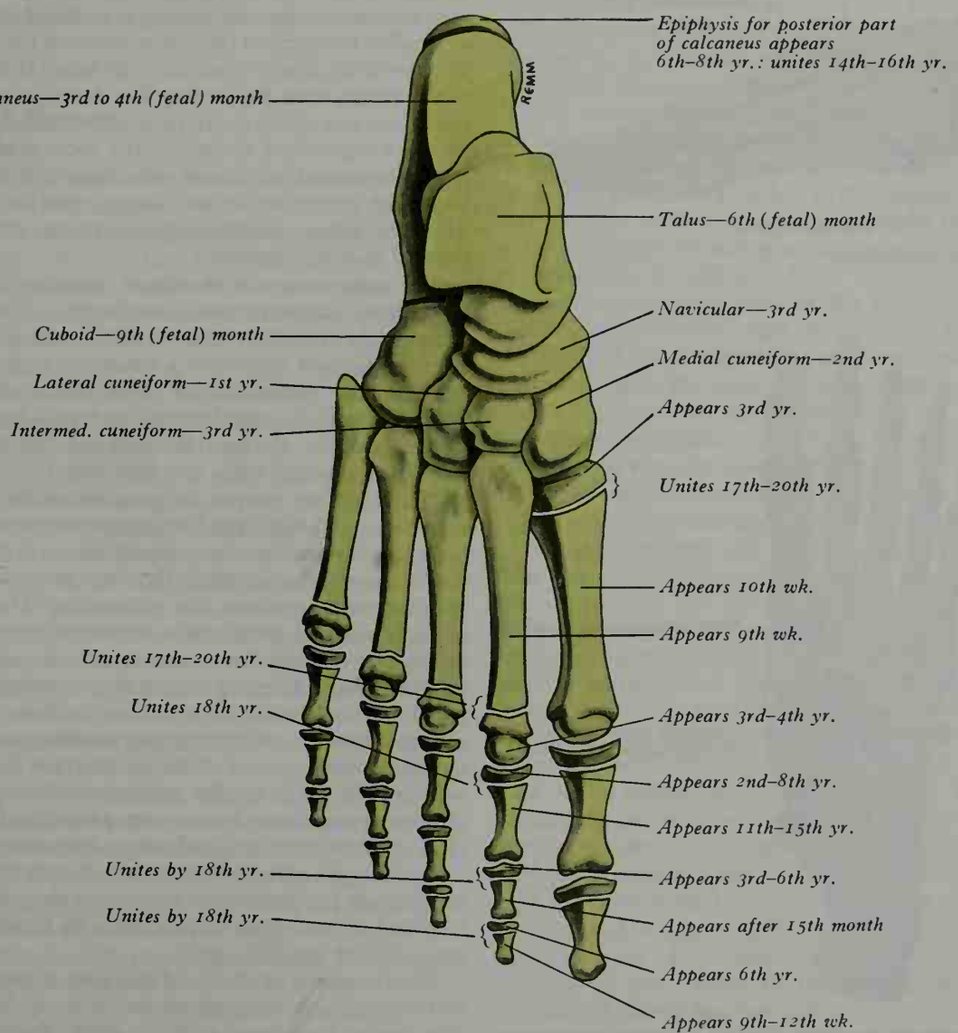
The second metatarsal bone (**3**.213) is the longest of the metatarsal bones. Its wedge-shaped *base* bears four articular facets: one on its proximal surface, of concave, triangular form, for articulation with the intermediate cuneiform; one at the dorsal part of its medial surface, for articulation with the medial cuneiform bone, very variable in size and usually continuous with the articular area for the intermediate cuneiform; two on its lateral surface, a dorsal and a plantar, separated by a rough non-articular interval. Each of these lateral articular surfaces is divided by a ridge; the distal demi-facets articulate with the third metatarsal bone; the proximal two (sometimes continuous) with the lateral cuneiform. These articular areas are very variable, particularly those on the plantar facet; this facet may even be absent (Singh 1960). A pressure facet is occasionally present due to contact with the first metatarsal bone; it is oval in shape, and is situated on the medial side of the base, plantar to the facet for the medial cuneiform. To the medial and lateral surfaces of the shaft are attached respectively the lateral head of the first dorsal interosseous muscle and the medial head of the second.

The third metatarsal bone (**3**.214) has a flat triangular *base*, which articulates proximally with the lateral cuneiform; medially it articulates by two facets, dorsal and plantar, with the second metatarsal bone, and laterally, by a single facet situated at the dorsal angle, with the fourth metatarsal. The plantar facet on the medial side of the base is frequently absent. From the medial surface of the shaft arises the lateral head of the second dorsal interosseous muscle and the first plantar; to the lateral surface gives origin to the medial head of the third dorsal interosseous muscle.

The fourth metatarsal bone (**3**.215) is smaller than the third. The proximal surface of its *base* bears an oblique quadrilateral facet for articulation with the cuboid, on its lateral side a single facet, for the fifth metatarsal bone, and on its medial side an oval facet for the third metatarsal bone, sometimes divided by a ridge, the proximal portion then constituting an articular surface for the lateral cuneiform (**3**.215). The medial surface of the shaft gives origin to the lateral head of the third dorsal and to the second plantar interosseous muscles; the lateral surface gives origin to the medial head of the fourth dorsal interosseous muscle.

The fifth metatarsal bone (**3**.216) has a rough eminence, its *tuberosity* (*styloid process*), on the lateral side of its base. The *base* articulates proximally with the cuboid by a triangular, obliquely cut surface and medially with the fourth metatarsal bone. The tendon of peroneus tertius is attached to the medial part of the dorsal surface, and along the medial border of the shaft, and that of the peroneus brevis on the dorsal surface of the tuberosity. A strong band of the plantar aponeurosis, sometimes containing muscle fibres, connects the projecting part of the tuberosity with the lateral process of the calcaneal tuberosity. The plantar surface of the base is grooved by the tendon of the abductor digiti minimi, and gives origin to the flexor digiti minimi brevis. To the medial side of the shaft are attached the lateral head of the fourth dorsal and the third plantar interosseous muscles. The tuberosity can be both seen and felt, half-way along the lateral border of the foot. In acute inversion of the foot it may be fractured.

The Phalanges of the Foot

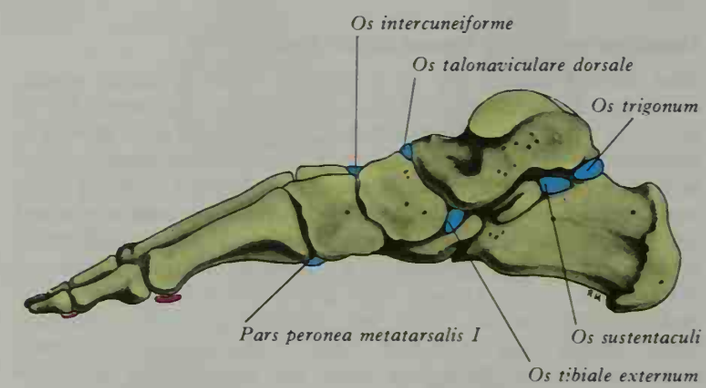


The phalanges (**3**.202, 203) of the foot correspond in number and general arrangement with those of the hand; there are two in the

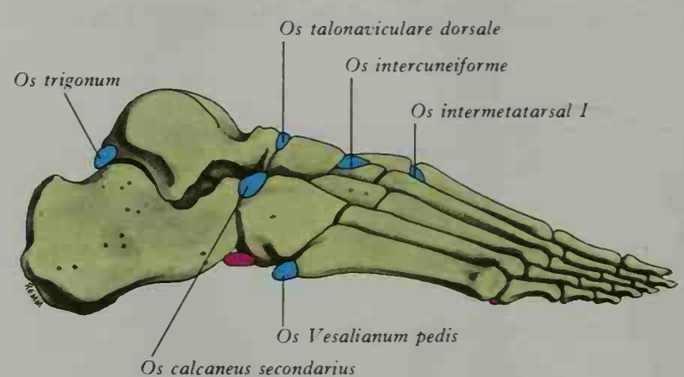
hallux, and three in each of the other toes. They are, however, much shorter, and their shafts, especially those of the bones of the first row, are compressed from side to side. The proximal phalanges closely resemble those of the hand. The *shaft* of each is compressed from side to side, convex dorsally, concave on its plantar aspect. The *base* is concave for articulation with the head of the corresponding metatarsal bone, and the *head* possesses a trochlear surface for articulation with the middle phalanx. The middle phalanges are remarkably small and short, but rather broader than the proximal phalanges. The distal phalanges resemble those of the fingers; but they are smaller, and are flattened; each presents a broad base for articulation with the corresponding middle phalanx, and an expanded distal extremity. Each bears a roughened *tuberosity* on the plantar aspect of its distal end, which gives attachment to the pulp of the tip of the toe and provides a wider area to take pressure.

The base of the distal phalanx of each of the lateral four toes gives attachment on its plantar aspect to a tendon of the flexor digitorum longus and on its dorsal aspect to the extensores digitorum. In the hallux the corresponding surfaces have attached to them the flexor hallucis longus and the extensor hallucis respectively. The base of the middle phalanx provides attachment on each side of its plantar aspect to the flexor digitorum brevis and on its dorsal aspect to the extensores digitorum. The base of the proximal phalanx of each of the second, third and fourth toes receives the attachment of a lumbrical on the medial side and to an interosseous on each side (Wood Jones 1949). The base of the proximal phalanx of the fifth toe receives the insertion of a plantar interosseous on the medial side and of the flexor digiti minimi brevis and abductor digiti minimi on the lateral side. In addition the margins of the proximal and middle phalanges of the lateral four toes provide the attachments for the fibrous flexor sheaths. The base of the proximal phalanx of the big toes receives, on its medial side, the insertion of the abductor hallucis and part of the flexor hallucis brevis and, on its lateral side, of the adductor hallucis and the remainder of the flexor hallucis brevis. The margins of the articular surfaces of all phalanges provide attachments for the capsules and ligaments of the corresponding metatarsophalangeal and interphalangeal joints. The terminal phalanx of the hallux normally shows a small degree of valgus (lateral) deviation; such deviation may also be seen in the proximal phalanx even in persons who have never worn shoes (Barnett 1962). A comparison of the angulation in 30 students (18–21 years) and 35 aged individuals showed no increase in the angle in the latter group. The deviation was also observed in fetal specimens (Wilkinson 1954).

Ossification of the Bones of the Foot



The tarsal bones are each ossified from a single centre, excepting the calcaneus, which has a scale-like epiphysis for its posterior part. The centres for the calcaneus and talus appear in intrauterine life, in the third month (Kleiger and Mankin 1961) and sixth month respectively. (A recent detailed study of early ossification in the calcaneus of 177 human fetuses between 49 and 150 mm crown–rump length showed about 16 per cent possessing a laterally placed perichondral mesenchymatous centre of ossification; some 11 per cent possessed a centrally placed endochondral centre, while only about 2 per cent possessed both—Meyer and O'Rahilly 1976.) The cuboid frequently commences to ossify before birth and its centre is generally present by six months after birth. The medial cuneiform, which may have two centres, begins to ossify in the second year, the intermediate cuneiform and navicular in the third and the lateral



3.217 A plan of the ossification of the bones of the foot.

cuneiform in the first year. The scale-like epiphysis of the calcaneus covers the greater part of the posterior surface and extends slightly on to the plantar surface; it begins to ossify in the sixth year in females and eighth in males and unites in the fourteenth year in the former and sixteenth in the latter. The posterior process of the talus is sometimes ossified from an independent centre, and may then remain separate or be connected to the rest of the bone by cartilage. This additional ossicle is named the *os trigonum*. A number of other accessory bones occur in the foot and may lead to radiological misinterpretation (*see* Trolle 1948; and **3**.218).

The metatarsal bones are ossified each from two centres: a primary centre for the shaft, and a secondary or epiphysial centre for the base of the first, and for the head of the other four. In the second, third and fourth metatarsals ossification begins in the middle of the shaft about the ninth week of intrauterine life and in the first and fifth about the tenth week. The epiphysis for the base of the first metatarsal appears about the third year; those for the heads of the other metatarsals between the third and fourth years; all unite with the shafts between the seventeenth and twentieth years. As in the first metacarpal bone (p. 376), so in the first metatarsal there is sometimes an epiphysis for the head as well as one for the base. An epiphysis is frequently present on the tubercle of the base of the fifth metatarsal bone.

3.218 The sites of sesamoid (*red*) and accessory bones (*blue*) in the human foot.

The phalanges are each ossified from two centres: a primary one for the shaft and an epiphysis for the base. The primary centres for the distal phalanges appear between the ninth and twelfth weeks of intrauterine life or even later in the fifth toe: those for the proximal phalanges between the eleventh and fifteenth weeks and those for the intermediate phalanges after the fifteenth week, with a wide range of variation. The epiphysial centres appear between the second and eighth years (usually in the second or third year in the big toe) and unite with the shaft by about the eighteenth year (Venning 1956). The variations in the order of appearance of these centres is apparent in different reports, and racial differences probably exist (Kraus 1961).

Comparison of the Bones of the Hand and Foot

The origin of the skeletal elements of the hand and the foot from the terminal segment of the primitive pentadactyl limb has already been considered in general principles (p. 350), and it is now possible to examine their similarities and differences in greater detail. Both hand and foot consist of proximal, intermediate, and distal series of components, i.e. carpus or tarsus, metacarpus and metatarsus, and phalanges. The carpus and tarsus both contain seven elements (omitting the sesamoid pisiform), and in a general way these can be described as more or less cubical bones; but they vary much in shape and size. The carpal bones are smaller, being concerned with the transmission of smaller forces; and they have retained the primitive alignment in rows more clearly than have the tarsal bones. The articulation of the tarsus with the foreleg is reduced to one bone (talus), and the tarsus as a whole is divisible into two moieties, corresponding to the longitudinal arches of the foot, with a small degree of independence of movement which is absent from the carpus. The lever-like extension of the calcaneus also has no equivalent in the primate carpus, though carpal elements arranged similarly are present in some mammals.

The components of the digits, metacarpus or metatarsus and phalanges, display more similarity. The metacarpals and metatarsals are much alike in form, and both series are bound together by soft parts into a structural entity. Their mobility is very limited proximally at their bases, where they not only articulate with the distal carpals or tarsals but also to some extent with each other. Between them lie the interosseous muscles, and closely associated with the first and fifth members are short intrinsic muscles proper to these particular digits. On the flexor aspects in both hand and foot are large arterial anastomoses in the form of vascular arches, superficial and deep to long flexor tendons crossing to enter the free parts of the digits, whose skeletal structures are the phalanges. The distal end of the metacarpals and metatarsals are slightly more mobile than the bases; but the third metacarpal and the second metatarsal are relatively fixed, forming axes in their respective extremities about which the neighbouring elements exercise their limited movements. These are concerned with the adaptation of the hand's grip to uneven objects and of the plantigrade foot to inequalities of surface. The digits can flex and extend through a considerable arc at the metacarpo- and metatarso-phalangeal joints, with a lesser range of abduction and adduction, better developed in the hand. The phalanges of the foot are much shorter than those in the hand; and though the phalangeal formula is the same, there is a greater tendency to reduction of phalanges by fusion or loss in the foot, especially in the fifth digit.

The functions of the hand and foot in mankind differ greatly, and their general skeletal similarity is much modified in details. The greater length and mobility of the fingers and especially the preservation of the free-ranging opposable thumb are associated

with the grasping habit of a prehensile limb. The divergent position of the metacarpal of the pollex and its specialized joint with the trapezium contrasts markedly with the arrangements in the hallux. The thumb is rotated about 90° around its own long axis relative to the fingers, so that it is already, in the resting position, halfway round to opposition with them. The great toe is in the same plane as the other toes, its flexor surface facing the ground like them. Moreover, it is tied by transverse metatarsal ligaments to the second metatarsal, thus forming an integral entity with all its fellows, adapted to the propulsive role of the foot. In association with this the digital formula is different in the foot; in the hand the middle digit projects furthest; in the foot it is the great toe, which takes the major stresses transmitted through the lever of the foot in locomotion. The dorsiflexion of the foot to a right angle with the leg is an obvious adaptation to plantigrade standing and progression. This position is sometimes said to be peculiar to man; but it is the primitive plantigrade adaptation of ancestral mammal-like reptiles; and while most become to varying degrees digitigrade, bringing the foot and hand into line with the rest of their limbs, most primates and some carnivores, such as bears display the plantigrade stance in the foot. The outstanding human peculiarity is the loss of opposition in the great toe, which distinguishes man even from other primates. The human foot is, indeed, in its general proportions far more specialized for bipedal habit than is the case in any other primate animal. The strong build of the great toe, both in its metatarsal and phalanges, and the elongation and stouter proportions of the tarsal bones, together constitute a powerful lever, on which the whole weight of the body can be elevated to add further impetus and spring in running and jumping. The arched form of the foot, and the development of a lateral arch to steady it on the ground and a medial to transmit the main force of thrust in propulsion, are specializations absent from the hand (pp. 350–353, **4**.92 and **4**.93). Finally, it is noteworthy that the rotational element in the foot, in the movements of inversion and eversion, is absent from the hand, which rotates with the forearm in supination and pronation.

The Sesamoid Bones

Sesamoid bones, like the seeds after which they are named, are usually more or less ovoid nodules a few millimetres in diameter, although their shape and size vary, some being quite large, for example, the patella (Bizarro 1921). They are not always completely ossified, and may consist of dense fibrous tissue, cartilage and bone, in varying proportions, but the majority are, to some extent at least, ossified. They are almost always embedded in tendons either in close relation to articular surfaces or in situations where tendons are sharply angled round a bony surface. In both cases, the surface of the sesamoid related to another bone is covered with articular cartilage and actually slides over the opposed bone, which is itself usually an extension of an articular surface, as in the metacarpophalangeal joint of the thumb. This arrangement entails that the tendons concerned are to some extent fused with the joint's articular capsule, as is most clearly seen in the relationship between the patella, quadriceps femoris tendon, and the knee joint (p. 483). In other situations, well exemplified by the sesamoid mechanism in the tendon of the peroneus longus (p. 606), the cartilaginous articular aspect of the sesamoid glides freely over a cartilage-covered surface of opposed bone, in this instance a facet on the inferolateral aspect of the tuberosity of the cuboid bone. Moreover, the arrangement is enclosed within a bursa, which could as well be termed a joint capsule, for the complete system has all the essentials of a synovial joint. Some authors consider that sesamoids are *primarily* articular in nature, i.e. embedded in articular capsules and that their association with tendons is a *secondary* phenomenon (Patterson 1946).

Despite their close association with articulations, the precise functions of sesamoids are regarded as still uncertain. It has been suggested that they may modify pressure, diminish friction, and sometimes alter the direction of pull of a muscle, the patella being commonly advanced as an example of the last of these suggestions. Where a tendon is acutely deflected in direct proximity to bone, the presence of a sesamoid, if ossified, may aid in maintaining the local circulation, bone being more resistant to pressures which could compress the vessels in tendon. However, the latter are never numerous and pressure is not likely to be long maintained, except perhaps in the foot.

The fact that sesamoid elements appear during fetal life, and indeed in greater numbers than in the adult, demonstrates that they are phylogenetically integral parts of the skeleton, and not merely the result of local physical circumstances; but the latter possibility cannot be dismissed in every instance. They are much more numerous in the extremities of many other mammals. In reptiles, intratendinous ossification in the proximity of the ends of some long limb bones produces nodules closely resembling sesamoids, but later some of these fuse and may be equated with traction epiphyses (Haines 1942). The proximal epiphysis of the olecranon is an example. Experimental procedures involving the patella suggest that both phylogenetic and other factors are involved in the formation of sesamoid bones. Transplantation of limb bud fragments from chick embryos to the chorio-allantoic membrane has been followed by development of a patella, indicating a self-differentiating mechanism (Murray and Huxley 1924/5). Conversely, removal of the patella in young dogs has been followed by regeneration of the bone, provided that the normal motor activities of the quadriceps femoris were permitted (Carey *et al.* 1927), suggesting that local mechanical factors are perhaps also operative in the formation of sesamoids. This may indicate an interesting parallel between sesamoids and bursae, in that the latter also appear regularly before birth in certain sites, but can also develop in other positions, as adventitious structures, apparently in response to disturbed local mechanical conditions.

The incidence of sesamoid bones has received much attention, at least insofar as their siting is concerned, but numerical data in regard to individual sites are not always available, and in particular the onset and progress of ossification in these elements has been but little studied.

In the upper limb, sesamoid nodules associated with joints are limited to the palmar aspect of the hand. Almost constantly present in the tendons of the adductor pollicis and flexor pollicis brevis, are two relatively large sesamoid bones, the medial being the larger. They articulate with special facets on the palmar aspect of the joint surface on the head of the first metacarpal bone, and since they are firmly attached in the capsule of the articulation, as well as in the tendons involved, it is likely that they conduct some of the pull of the thumb musculature to the ligaments of the joint. A sesamoid is embedded in the tendons anterior to the metacarpophalangeal joint of the index figure (35 per cent of hands), and of the fifth digit (70 per cent), where it is occasionally doubled. Less frequently, similarly placed sesamoids are encountered in the third and fourth digits, and in a majority of hands (73 per cent) one is present in the palmar aspect of the interphalangeal joint of the thumb (Gray *et al.* 1957). Sesamoid elements in non-articular sites are seldom present in the upper limb, but one is occasionally encountered in the biceps tendon near its insertion into the radial tuberosity.

In the lower limb, the patella is the largest articular sesamoid bone; its relationship to the tendon of the quadriceps femoris and the capsule of the knee joint exemplify the arrangement of structures around all the smaller sesamoids which are integrated into synovial articulations. In the foot, their distribution is similar to that in the hand. Two, both of which may be duplicated (sometimes leading to fallacious diagnosis of fracture), are always present in the tendons of flexor hallucis brevis, on the plantar aspect of the metatarsophalangeal joint of the hallux. As in the case of the pollex, they are firmly tied in with the ligamentous structures around them, including the most medial part of the plantar aponeurosis. Single sesamoids occur not infrequently in the plantar aspect of the capsule of the same joint in all the other toes, and also in the interphalangeal joint of the great toe.

Sesamoid bones, or cartilages, which are not associated with a synovial joint, occur more frequently in the lower limb. The element in the tendon of peroneus longus has already been mentioned above. Another sesamoid, usually appearing late in life and therefore perhaps adventitious in character, occurs in the tendon of tibialis anterior where it is in contact with the distal part

of the medial surface of the medial cuneiform bone. Similarly, the tendon of tibialis posterior may contain a sesamoid nodule where it glides over the medial side of the head of the talus. Sesamoids also occur occasionally in the lateral part of the gastrocnemius, behind the lateral femoral condyle, in the tendon of psoas major where it is in contact with the ilium, in the tendon of the gluteus maximus where it passes over the greater trochanter, and in tendons which are deflected round the medial and lateral malleoli. In some, if not all these sites, bursal arrangements occur, and the opposing bony surfaces involved are covered with articular cartilage, so that a true synovial articulation exists. The sesamoid which occurs in the gastrocnemius (lateral head) is sometimes called a *fabella*; when present, it articulates directly with the lateral femoral condyle, and this arrangement should therefore really be classified with the 'articular' sesamoids.

Sesamoid bones begin to ossify relatively late, apart from the patella (p. 397). Those in the hand are usually said to begin in the early teens. In a selected group of Caucasians, those associated with the thumb began to ossify in males between 12 and 15 years, and sesamoids in the other digits between 15 and 18, the dates for females being about three years earlier (Joseph 1951). No such data appear available for large mixed or other racial groups, and figures for sesamoid ossification in the lower limb are vague or lacking.

4

ARTHROLOGY

Introduction

Skeletal structures, both of vertebrate and invertebrate animals, are occasionally of a purely protective nature. Far more often, however, they provide for the attachment and leverage of muscles; they are essential to *motor* functions involving either the whole body, or the relative positioning of its members. Since *movement* of any kind, including locomotion, is almost always accomplished by the bending or straightening of appendages, or of the trunk itself, a skeleton of rigid bony members— in contrast to a pliant structure such as a notochord—must contain intervening arrangements permitting some degree of angulation, torsion, or displacement. This applies equally to exo- and endoskeletons. The jointed exoskeleton of crustaceans and insects accounts for the name of the largest phylum, the *Arthropoda*. All vertebrates possess joints; even those in which the skeleton is wholly cartilaginous display junctional regions of greater pliancy between their individual components.

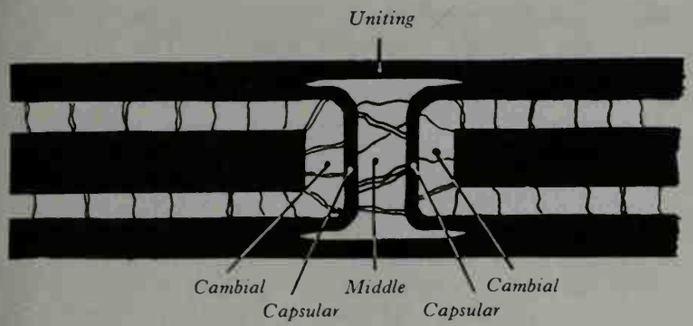
Not all junctions between bones, however, are primarily constructed to allow *movement*; thus, for example, mature sutures are usually so shaped as to *interlock*, despite the osseous discontinuities which they delineate. In bones with epiphyses, temporary zones of cartilage intervene between these regions of ossification and their ossifying diaphyses; these arrangements are clearly essential to the processes of *growth* rather than *mobility*. (It should perhaps be noted here, however, that the post-cranial cartilaginous masses, together with the cranial fibrous and cartilaginous sutures of the full-term fetus, possess a pliancy and flexibility that permits advantageous 'moulding' of the parts during childbirth: *see* illustration **2**.3B.) Nevertheless, to group these two forms of skeletal junction together with articulations whose function is locomotor may be convenient, but is otherwise uninformative; and the application to the various forms of juncture of terms which are largely morphological does little to improve matters. Moreover, joints at which motion *does* occur display a considerable variety of mechanism, and this again has led to a classification, based partly upon structural features and to some extent upon the kind of movement permitted, with an array of terms for different forms. This diverse assortment of osseous junctions is, indeed, held together by one criterion alone—that *joints* are merely the *meeting places of bones*.

Thus the study of arthrology brings together, in what is functionally a rather unsatisfactory association, skeletal dispositions concerned with *growth*, *rigidity* and *movement*. The undesirable nature of this custom is even more apparent in its **current textbook classification:**

Coaptations between skeletal components may be called *juncturae*, *articulationes*, *arthroses*, or by vernacular terms such as *joints* with little discrimination. They are habitually divided into three groups:

(1) **fibrous joints** (*'fixed' joints*, *articulationes fibrosae*, or *synarthroses*);
(2) **cartilaginous joints** (*'slightly movable' joints*, *articulationes cartilagineae*, or *amphiarthroses*);
(3) **synovial joints** (*'freely movable' joints*, *articulationes synoviales*, or *diarthroses*).

The inconsistencies of this classification can be illustrated at once by the fact that fibrous joints include not only *fixed* joints (*sutures*) but also *slightly movable* joints (*syndesmoses*, such as the one between the inferior ends of the tibia and fibula), and in addition the minimally resilient junctions between teeth and their sockets (gomphoses). Again, the cartilaginous joints comprise not only symphyses (*secondary cartilaginous joints*), which permit limited movement, but also *synchondroses* (*primary cartilaginous joints*), where movement is absent or minimal. (It may also be noted that whilst the majority of the 'sutures' of the facial skeleton and cranial vault vault are fibrous, those of the cranial base are cartilaginous—*see* p. 295.) The conventional classification also fails to emphasize the basic mechanical difference between joints at which rigid skeletal elements are able to move relative to each other through the interposition of a deformable tissue (fibrous *and* cartilaginous joints) and those where movement is dependent upon opposed sliding surfaces (synovial joints). In engineering practice this distinction is obvious, and there seems no reason against applying it as the primary feature separating biological joints into two, rather than three, major groups. There is, however, no overall term for fibrous and cartilaginous joints in current use, though Galen grouped them as *synarthroses*. In any case the histological distinction between them is also unsatisfactory, not only because it cuts across functional grouping as pointed out above, but also because many of these joints contain admixtures of fibrous tissue and cartilage, as will become apparent below. What might be termed the *non-synovial* joints could be separated more appropriately into growth mechanisms and true, mobile joints, but this also cuts right across established morphological custom.

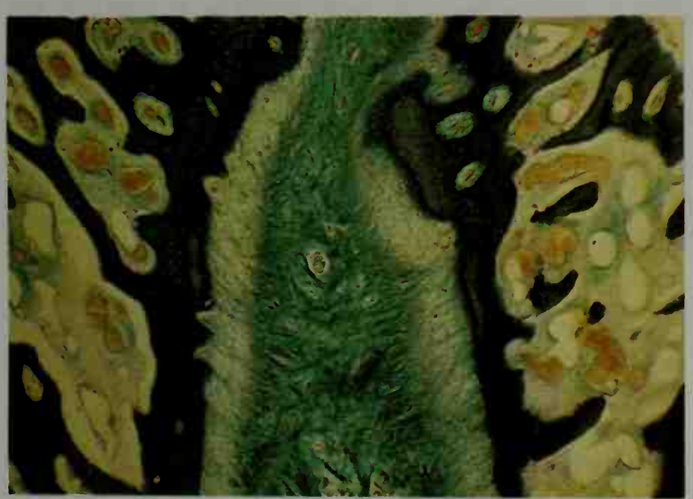


These preliminary remarks are occasioned by the defects of current classifications of joints, and by the confusion which may be entailed by the vagaries in their terminology. It is not proposed, nevertheless, to add to this confusion by disregarding the customary scheme, but its deficiencies cannot pass without comments, which may, perhaps, also help to encourage a more rational and practical order.

Fibrous and Cartilaginous Joints

Since all bones ossify in pre-existing fibrous tissue or cartilage, those two tissues inevitably appear at junctions such as sutures and synchondroses, where separate skeletal elements are still in the process of growth. The actual osseous margins or surfaces gradually approach, and when growth ceases the junctional tissue is obliterated, leading to complete bony continuity. Such junctures are therefore temporary; and although the obliteration of sutures is retarded relative to the fusion of epiphyses, it is ultimately as complete in most instances.

Synchondroses include the numerous temporary cartilaginous junctions between diaphyses and epiphyses in the immature post-cranial skeleton (**3**.3B), and also the regions of unossified cartilage between skull components developing in the chondrocranium (e.g. between the sphenoid and occipital bones). The structure and growth phenomena of these junctions have been considered elsewhere (p. 251). The cartilages involved are hyaline, but it is apposite to note that special accumulations of collagen fibres, aligned in a regular manner, occasionally appear in growth cartilages (Smith 1962). The majority of the latter, extended across the axis of elongated bones near their extremities, are thus subjected to compression forces approximately at right angles to their transverse planes. In some situations, notably in man where the superior tibial epiphysis inclines downwards to form the tibial tuberosity, the direction of pull of a muscle (quadriceps femoris in this example) is oblique in respect to the growth cartilage, thus introducing shearing forces. In such sites the cartilage may be almost completely replaced by collagen fibres. The microscopic structure of bone trabeculae in the metaphysis adjacent to the fibrous and cartilaginous regions in such mixed growth 'cartilages' also evinces interesting differences, which may be equated with the impress of tensile or compressive forces. Trabeculae immediately adjoining a fibrous zone in the cartilage are long, slender, parallel and sparsely linked by cross-connexions, as if adapted to tension, whereas the trabeculae elsewhere (adjacent to cartilage proper) exhibit the usual irregular cancellous pattern associated with compression.



Sutures are limited to the skull, occurring wherever margins or broader surfaces of bones meet and articulate, separated only by a zone of connective tissue, the *sutural ligament* or membrane. This is the surviving unossified part of the mesenchymatous sheet in which dermal bones develop (p. 295). The sutural ligament is not simple, displaying regions of differentiation concerned in the growth and binding together of the apposed bone surfaces (Pritchard *et al.* 1956). Each bone is covered on its sutural aspect by a layer of somewhat flattened osteogenic cells (the 'cambial' layer of some observers), which is itself overlaid by a lamella of fibrous tissue (**4**.1A, B, C). These two layers together correspond to periosteum, and are continuous with the latter at the margins of the sutural surfaces, both inside and outside the skull. Between these two layers of sutural periosteum is a central stratum of loosely arranged fibrous connective tissue, the width of which

4.1A The general structure of a suture. Note the five layers which intervene between the bone ends: cambial, capsular, middle, capsular and cambial. The cambial and capsular layers are continuous with similar layers on the inner and outer aspects of the bones, whilst the superficial fibrous strata of the periostea cross the suture as uniting layers. varies according to the interval between the bones involved. This central region of the sutural ligament contains thin-walled blood vessels, the veins of which communicate with diploic vessels and intracranial venous sinuses and with external veins such as those in the scalp. The fibrous element in the periosteum adherent to the surfaces of adjacent bones, connected by a suture, crosses the interval between them, thus closing in the sutural ligament and adding to its binding effect. There is some experimental evidence that during active growth the orientation of collagen fibres in sutural membranes is rapidly adaptable to a variety of factors, and particularly to the direction of growth of minute bone spicules (Koskinen *et al.* 1976).

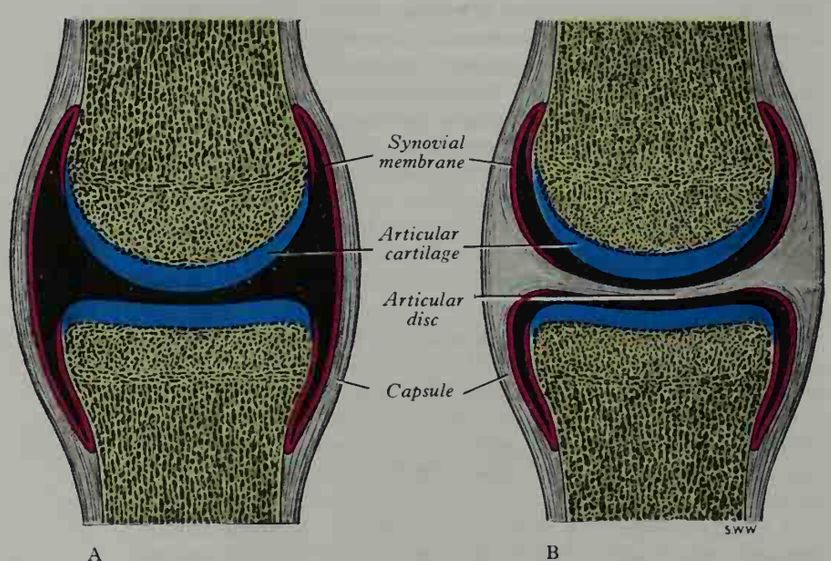
In view of the occurrence of patches of fibrous tissue in synchondroses, as noted above, it is of considerable interest to find that, during the period of growth, areas of secondary cartilage formation are frequently observed in sutural ligaments, a further evidence of the close relationship between fibrous and cartilaginous joints.

When growth at sutures comes to an end, the osteogenic cells bring about complete transformation of the sutural ligament into bone, a process which is slow (p. 260), but leads finally to obliteration and, of course, rigid synostosis. Sutural fusion does not even commence until the late twenties, proceeding slowly thereafter; yet it is clearly necessary that sutures should cease to function as mobile joints as rapidly as possible after birth. Although sutural ligaments may be sufficient to effect an immovable bond between large areas of bone, especially where these show reciprocally adapted irregularities, even if these be fine as in the junction between the two maxillae, no such immobility is to be expected at the narrow articulations at the edges of the bones of the cranial vault. At sutures such as these, however, the bone margins become highly complex and irregular, developing spikes and recesses which interlock so intimately that bones may be difficult to separate even when denuded of all connective tissue. Where the edges are like a saw, or serrated, the junction is a *serrate suture*. A *denticulate suture*, as its name suggests, is characterized by small toothlike projections, which often widen towards their free ends, providing an even more effective interlocking than do serrate sutures. When such sutures are closely tied by the sutural ligament and periosteum complete immobility results. The sagittal suture is serrate, and much of the lambdoid is usually denticulate. Where one bone overlaps its neighbour, as at the suture between the temporal and parietal bones, the arrangement is a *squamous suture*. At sutures of this kind the bone surfaces are reciprocally bevelled, one internally, one externally. The bevelled surfaces may be mutually ridged or serrated, in which case the junction is sometimes termed a *limbous suture*. Where there is simple apposition of contiguous surfaces, usually roughened and irregular in a complementary manner, the junction is nevertheless usually named a *plane suture*. An instance of this has been cited above, and others are the sutures between the palatine and zygomatic bones and the maxillae. Although the linear demarcations visible on the surface between such bones show none of the intricate interlocking evident at serrate or denticulate sutures, the irregular surfaces of contact, held together by wide expanses of sutural ligament, provide a high degree of resistance to shearing or torsional forces; like other sutures they are, for all practical purposes, immovable.

A schindylesis is an articulation where a ridged bone fits into a groove on a neighbouring element, as in the junction between the vomer and the rostrum of the sphenoid bone.



A gomphosis, or peg-and-socket joint, is the specialized type of fibrous articulation restricted to the fixation of teeth in the mandible and maxillae. It is more appropriate to describe it with the teeth (pp. 1284, 1292).

A syndesmosis is a form of articulation in which closely apposed bony surfaces are bound together by an interosseous ligament, affording a small degree of movement between adjoining bones. It is considered by some to be a rarity in mammals, in the current usage of the term at least, having for long been confined in man to the inferior tibiofibular joint (but *vide infra*). However, although not usually described as such, the dorsal part of the junction between the ilium and sacrum, through the medium of the interosseous sacro-iliac ligament, closely resembles a syndesmosis. Incidentally, the sacro-iliac joints themselves, which are primarily synovial, are frequently invaded by fibrous tissue in the later decades of life, and may become totally converted into fibrous articulations, differing little from syndesmoses p. 473). It would be reasonable to regard the inferior tibiofibular syndesmosis as no more than an interosseous ligament, adjacent to the ankle joint or to a synovial extension of it when this exists, as it occasionally does in man and regularly in some other primates. If this be accepted there is little valid objection to extending the designation syndesmosis to numbers of

4.2 Section through the pubic region to show the structure of a symphysis.

other interosseous ligaments, such as those in the carpus and tarsus, or to including the interosseous membranes of the forearm and foreleg, especially since the latter are already described as intermediate joints in the radio-ulnar and tibiofibular series. In fact, since ligaments are almost all 'interosseous', it would become difficult to restrict the use of the term 'syndesmosis' at all, unless it be insisted that only short ligaments in close proximity to a synovial joint be so designated. These would appear to be the criteria which limited the term in orthodox nomenclature to a single joint in the human skeleton, and this restricted usage rendered all the more unsatisfactory the suggested substitution of the term 'syndesmology' for arthrology. The former is a word of unfamiliar derivation and usage and hence obscure in meaning, whereas the stem **arthron**, a joint, is widely employed and

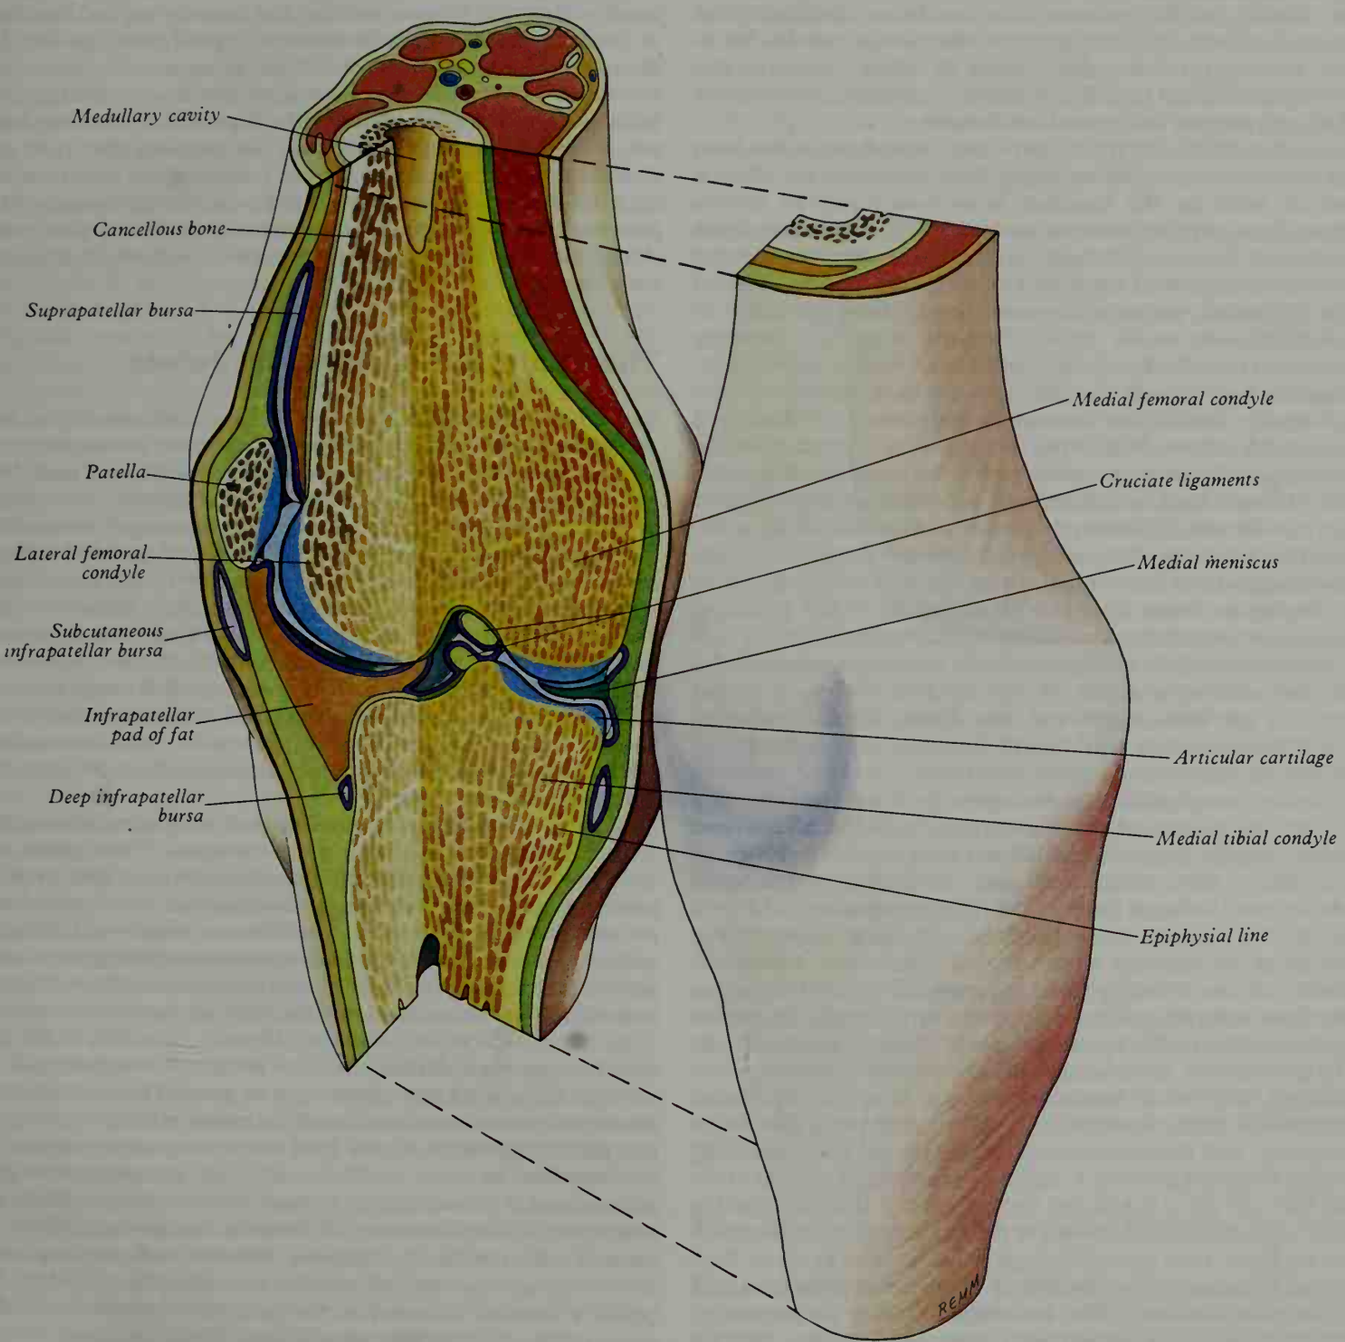
familiar in both medical and biological applications – witness: arthritis, arthroplasty, and the name of the largest animal phylum, the arthropods. The re-adoption of the internationally accepted term **arthrology** is thus most welcome. The reader will, in addition, be interested to note that in the recently published *Nomina Anatomica* (1977) the term **syndesmosis** has now been extended to include the following ligaments: pterygospinous, stylohyoid, interspinous, supraspinous, intertransverse, the ligamenta flava, and the ligamentum nuchae. The *syndesmosis radio-ulnaris* includes the antebrachial interosseous membrane and oblique cord, while the *syndesmosis tibiofibularis* includes the crural interosseous membrane and ligament, together with the anterior and posterior tibiofibular ligaments. This particular choice of ligaments does, however, seem somewhat arbitrary, for many others could lay equal claim to inclusion in the list.

A symphysis is a cartilaginous or, more precisely, a fibrocartilaginous articulation, of non-synovial form, at which a limited range of movement is enabled by deformation of a connecting pad or disc of fibrocartilage (**4**.2). Synchondroses are associated with symphyses by the terms *primary* and *secondary* cartilaginous joints, often applied respectively to them, a usage of dubious morphological value and also confusing, in view of their functional dissimilarity. However, a symphysis resembles a synchondrosis in one small histological feature – in containing some hyaline cartilage, arranged as a thin film covering the articular surfaces, to the growth of which it contributes. Nevertheless, the distinguishing feature of this kind of joint is the resilient bond provided by the fibrocartilage, whose thickness is a prime factor in the range of movement possible. It is to be emphasized that all strata of the joint – bone, hyaline and fibrocartilage – are intimately united, there being no internal surfaces between any elements in the articulation. However, in some symphyses, such as the pubic and manubriosternal joints, cavities filled with fluid do occur, but there is no development of sliding surfaces. While these arrangements lack the distinctive specializations of synovial joints, they may represent an intermediate phase in the evolution of the latter, as will be noted later (p. 424). Fibrous ligaments extend across symphyses from one bone to the other, fusing with the periphery of the fibrocartilage and thus providing an additional flexible linkage; but such structures do not form a complete capsule, as they do in synovial joints, although they are like the latter in containing terminal plexuses of afferent nerves, which also invade the marginal zone of the fibrocartilage.

Unlike synchondroses, which are temporary junctions disappearing after the period of growth, symphyses are permanent and concerned with movement. There are some exceptions to this: the manubriosternal symphysis may be obliterated by bony union (synostosis) in the later years of life. The fibrocartilages in different symphyses are not of uniform structure, and there are often regional variations in them, especially in regard to the distribution and alignment of collagen and elastic fibres. The latter features are most probably local adaptations to the stresses imposed by the specific activities of the joints in question (e.g. *see* the structural details of intervertebral discs, p. 444).



It is sometimes pointed out that all symphyses are in the median plane of the human body. Since they are confined to the axial skeleton, save for the symphysis pubis, this is to be expected. The articulation between the two halves of the mandible is usually described as a symphysis, and the symphysis menti does bear some resemblance in its histological features (p. 318). It is rapidly abolished during the first postnatal year, and since it is improbable that it is the site of any functionally significant movement while present, it is of doubtful propriety to assign it to this group of joints.

Synovial Joints

Articulations of the *synovial* type utilize an entirely different principle from the *non-synovial* fibrous and cartilaginous joints (**4**.3A, B; **4**.4A). Although the bones involved are linked together by a fibrous capsule, and frequently by accessory ligaments inside or outside of this, the major parts of the osseous surfaces concerned are in contact but *not* continuity. They are covered by a relatively thin stratum of specialized hyaline cartilage (occasionally of fibrocartilage), and the actual contact is between these cartilaginous surfaces, which are characterized by a very low coefficient of friction (Charnley 1959). This sliding contact is facilitated by a viscous *synovial fluid* (synovia), which acts like a lubricant in some respects, and is also concerned in the maintenance of living cells in the articular cartilages. The somewhat complex properties of this fluid are considered later (p. 428). The low level of friction in synovial joints has been picturesquely described as equivalent to 'ice on ice'.

The fibrous capsule encloses the joint completely, with certain exceptions, such as the hip joint (p. 477), where its continuity is interrupted by protrusions of the synovial stratum; these exceptions are described with the individual articulations concerned. The capsule is lined throughout by *synovial membrane*, which also extends on to all intra-articular surfaces except those actually involved in compression contact during the activities of the joint. This includes nonarticulating bone surfaces and also the tendons and ligaments which may be partly or wholly within the fibrous capsule, as at the shoulder and knee. Where a tendon is attached within a joint and issues from it, a prolongation of the synovial stratum commonly accompanies it for a short distance external to the capsule. In some situations tendons which are extracapsular may be separated from it by a synovial bursa (p. 458), continuous with the interior of the joint. Such details of synovial arrangements are important in that they offer avenues for the spread of infection from extra-articular sites into the joint itself.

A third type of intra-articular structure, which is *not* covered by synovial membrane, is an *articular disc* or *meniscus*. Such structures intervene between certain articular surfaces, where the degree of congruity is low, and they consist of fibrocartilage, the fibrous element usually predominating. If they extend wholly across a synovial joint, they effectively divide it into two parts, both structurally and functionally, i.e. there are two separate synovial cavities. Peripherally, articular discs are connected to the fibrous capsule, usually through the medium of vascularized connective tissue; but the union between the two is sometimes more intimate and strong, as in the knee and jaw joints. The peripheral zone of the disc is invaded by vessels and afferent and motor (sympathetic) nerves. The main bulk of the disc contains few cells, but its surface may display an incomplete stratum of

4.4A The general organization of the knee joint, which is compounded of three pairs of articular surfaces and also possesses two menisci of fibrocartilage. Note the following bony parts and their covering of articular cartilage: (1) the patella, (2) the patellar surface of the femur, (3) the medial femoral condyle, (4) the medial tibial condyle. Note also, (5) the cut edge of the synovial membrane (*purple*), (6) menisci in section (*green*), (7) the cruciate ligaments, which are intra-articular in position, (8) the suprapatellar synovial bursa, continuous with the general joint cavity, (9) the deep infrapatellar bursa, (10) the infrapatellar pad of fat and its associated infrapatellar fold or synovial membrane, which passes back to the anterior wall of the intercondylar fossa of the femur, (11) sectional surfaces of patellar, femoral and tibial articular cartilages (*bright blue*), (12) the epiphysial line of dense bone indicating the zone of fusion between epiphysis and metaphysis.

flattened cells, continuous at the attached perimeter with the adjacent synovial membrane. There is, nevertheless, little structural similarity between the two groups of cells (p. 427). Strictly, the term meniscus should be reserved for incomplete discs, such as those in the knee joint and, occasionally, the acromioclavicular joint. Complete fibrocartilages occur in the sternoclavicular and inferior radio-ulnar joints, while the disc in the temporomandibular joint may be complete or incomplete, with about equal incidence. Complete discs often present small perforations and, where menisci are usual, complete discs may occur, or they may be merely slightly perforated. The functional role of intra-articular fibrocartilages remains unproven. An experimental approach to this problem is difficult to devise or to put into effect. Therefore the views advanced are largely deductions from structural or phylogenetic data, with the help of mechanical analogies. The plethora of suggestions is hence not surprising, and it includes such activities as shock absorption, improvement of fit between joint surfaces, facilitation of combined movements, limitation of translation movements at joints such as the knee, distribution of weight over a larger surface, protection of the edges of articular surfaces, facilitation of rolling movements, and spread of lubricant.

In studies of the evolution of articular discs attention has been focused more often upon equating them with vestigial skeletal elements, such as the quadrate bone (jaw joint) or the os intermedium carpi (inferior radio-ulnar joint), rather than upon comparative function. Such contentions are in any case usually based upon somewhat tenuous evidence, although nodules of bone, or lunules, do occur in some primate discs, but rarely in mankind (Lewis *et al.* 1970). Perhaps a more interesting observation from the functional point of view—also derived from comparative studies—is that those joints which contain articular discs usually also display translation movements, combined, of course, with others (*vide infra*, p. 430). For example, in the temporomandibular joint translation of the mandibular condyle in forward and backward directions accompanies angulation or hinge movements. However, the disc, though usually thin, is also present in carnivores, despite the negligible amount of translation in their hinge-like joints. It is also apposite to note (Moffet 1957) that during evolution of the mammalian from the primitive reptilian jaw joint, the tendon of the lateral pterygoid muscle may have become partially incorporated into the temporomandibular disc; but such a structure is nevertheless absent in earlier mammals, the monotremes and marsupials. These conflicting observations illustrate very clearly how indecisive attempts to elucidate function from morphological data must often remain.

Despite these phylogenetic discrepancies, it is a most plausible view that the pliant and sometimes elastic qualities of discs and menisci provide adaptable additional articular surfaces in the joints where they occur, not only facilitating synchronous movements of different kinds in the two compartments of a joint thus divided (p. 440), but perhaps also ensuring uninterrupted lubrication (MacConaill 1932). In joints in which translation movements can occur, complete congruity is impossible, except in the theoretical case of an entirely plane articulation, the nearest approximation to this being the joints of some sesamoids. In general, however, all articular surfaces exhibit some degree of curvature, and hence translation is almost always compounded with another form of motion (p. 434). Nevertheless, translation does occur, and intra-articular cartilages may aid in controlling the shift from one position to another, as in rolling motion in the knee joint (p. 437). It has also been suggested that the tapering profile of menisci enables them to fit easily between incongruent joint surfaces, thus obviating large collections of synovial fluid between them and preserving a filmy distribution of the fluid over the articular surfaces. The advantages of this in preventing turbulence and drag accord with lubrication theory, and the argument provides a most attractive hypothesis; unfortunately, it is difficult to envisage at present how it could be experimentally demonstrated.

It is important to appreciate that a complete articular disc creates in effect two joints in series, a fact which can be compared with the concatenation of multiple joints, each affording a relatively small range of movement, which nevertheless summate to produce a much larger motion. This kind of arrangement is present in the carpus and tarsus, but is perhaps more clearly appreciable in the multiplication of interphalangeal joints in the flippers of many extinct aquatic reptiles and certain extant aquatic mammals, such as some whales. It is even possible in this kind of analysis to liken the talus in some mammals to a meniscus, in terms of function, of course; it may also be equally tempting to equate some menisci with degenerate skeletal elements. It should be added that the various views which have been propounded in connexion with intra-articular discs are not reciprocally exclusive; such structures may have arisen by more than one morphological route, and likewise they may contribute in more than one way to the smooth and steady performance of synovial joints.

The functions of two other types of intra-articular structure are also uncertain, these being *labra* and *fat pads*. A labrum is a fibrocartilaginous annular *lip* (as the word implies), which is usually triangular in cross-section, like a meniscus, and attached to the margin of an articular surface. Typical examples are the glenoid and acetabular labra. These deepen their respective sockets and add to the area of contact between articulating bone surfaces. The latter fact prompts the supposition that they may act as lubricant spreaders and that, like menisci, they may cut down synovial fluid space to capillary dimensions, thus limiting drag. It is important to note that, unlike menisci, labra are not in a position to be compressed between articular surfaces. Fat pads are closely associated with synovial membrane, with which they are therefore described (p. 427).

The Evolution of Synovial Joints

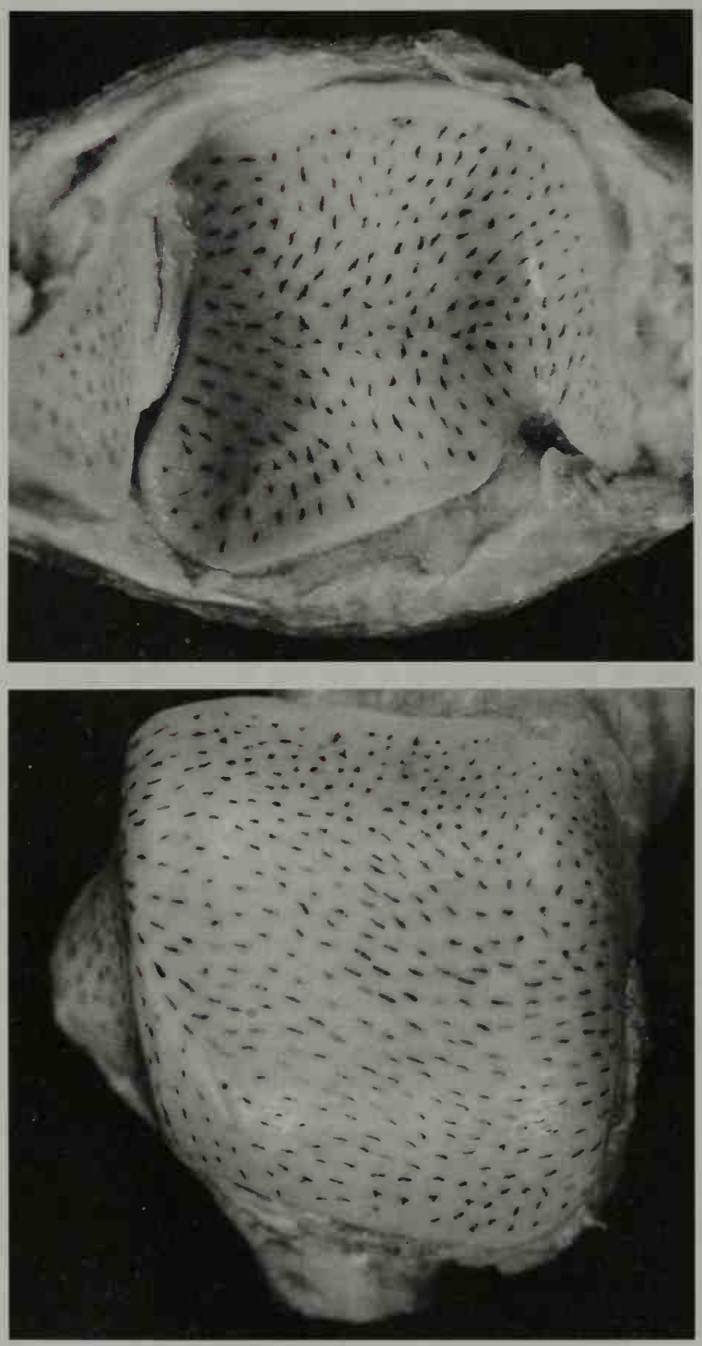
Much speculation and a considerable volume of observation and experiment have been directed in recent years to the mechanics of synovial joints by workers in several disciplines, including orthopaedic specialists, physicists and engineers. The basic problem is to account convincingly in terms of movement, loading and lubrication for the unusual and perhaps unique efficiency with which biological joints preserve their smoothness of action, without any real tendency to jamming, even under the most variable conditions, except when diseased. It is at present impossible even to postulate satisfactorily, much less to construct, a single mechanical joint capable of meeting all the requirements of the biological arrangement. Accepted lubrication theory has not yet provided a connected explanation of the outstanding effectiveness of synovial joints, though considerable progress has been made (p. 428).

Since not all joints are synovial it is pertinent to inquire into the specific advantages of sliding articulations. That these are considerable is indicated by the general observation that synovial joints have become increasingly dominant as vertebrates have evolved to higher forms. The evolutionary history of joints has attracted little attention, and few joints or vertebrate groups have received systematic study. It is clearly established that synovial articulation occurs as far down the scale as the more primitive bony fishes, such as the lungfishes (Dipnoi), especially in the jaw joint (Haines 1942). Hence, the synovial type of joint is not, *per se*, a particularly novel arrangement, in its general features at least. Nevertheless, the great majority of the movable bony junctions in the piscine ancestors of the land vertebrates were simpler in construction, as is so in their surviving representatives and relatives today. These simpler forms of joint are likely to illustrate stages in the development of synovial joints themselves. It appears acceptable to consider fibrous and cartilaginous junctures, as described above, the simplest and probably the primary form of articulation, the next step forward being the appearance of multiple small fluid-filled cavities in the deformable tissue of the joint. A further advance is held to be the union of these spaces into a single joint cavity, centrally placed and still surrounded by a substantial cuff of the fibrous or fibrocartilaginous tissue uniting together the skeletal components involved. This pattern of organization resembles those symphyses in which cavitation occurs. The final step would be the complete dissolution of continuity between the two bones,

leading to a markedly increased potential for amplitude of movement. With the subsequent development of a synovial stratum and external to this a fibrous capsule, the fluid-containing cavity of the joint becomes more strictly confined, the fluid component being reduced to a mere film between joint surfaces now approximated in smooth, sliding contact.

Examples of all the stages mentioned above can be demonstrated in living vertebrates; it is of some interest to note that in the more primitive land animals the synovial joints, which increasingly replace other arrangements in their limb articulations, are in some respects less well organized than the piscine jaw joint. It is not improbable that the jaw joint was the first vertebrate articulation to reach the refinement of synovial status.

The hypothetical stages described above are in general accord with the major events in the prenatal development of human synovial joints. Perhaps the most significant happening is the breakdown of the interzonal mesenchyme (p. 154) to form the precursor of the synovial cavity. This potentiality of mesoderm for cleavage (with the formation of either considerable cavities or spaces which are no more than clefts between surfaces in appositional contact and hence freely moving) is obviously most significant to the evolution of synovial joints. In addition to the regularly occurring mesodermal discontinuities, including the whole range of coelomic and synovial arrangements, fully differentiated connective tissue appears to retain this potentiality, which may be considered to reveal itself in the occurrence of such acquired dispositions as adventitious bursae. In view of this, it is reasonable to suppose that, once a region of pliant connective tissue is established between rigid skeletal elements, their ultimate separation by a synovial cavity appears to be an evolutional probability.



It is considered likely that synovial joints may have developed not only as discontinuities in previously uninterrupted skeletal bars, but also by the approximation of already separate elements. This may have occurred in the formation of the tibiofibular joints of mammals, the two bones being out of contact in reptiles, but the synovial arrangements in this instance are probably extensions of the knee and ankle joints, and not new formations. Perhaps a better example is the occasional synovial joint between the clavicle and the coracoid process (p. 455), with articular cartilages covering the opposed bone surfaces (Lewis 1959). Even more interesting is the observation that the joint may consist merely of a bursa or, more frequently than either of these arrangements, that it may be a fibrocartilaginous junction. This provides an excellent indication of the lability of joints both in occurrence and in structure. As we have seen, a synovial joint such as the sacro-iliac may exhibit retrogression to a simpler form, and this, and other joints such as the interphalangeal, carpal and tarsal articulations, may disappear entirely, either by synostosis in the individual or as an evolutionary phenomenon in a whole group of animals. The tibiotarsus and tarsometatarsus in the avian leg illustrate simplification by re-union of once separate bones, whereas the opposite tendency towards the multiplication of elements by new joint formation is apparent in the phalangeal pattern in the paddle-like extremities of some aquatic mammals (and extinct reptiles).

The further evolution of synovial articulations at the mammalian level shows two particular tendencies. Firstly, the proportion of such joints increases by the replacement of non-synovial arrangements; this change affects in particular the limbs, eventually reaching even their smallest terminal articulations. Secondly, synovial joints display an increasing specialization, especially towards limitation of their potentiality for movement to what is required at individual joints. A typical non-synovial joint, such as a symphysis, is essentially multi-axial, inasmuch as it permits movement in all directions, however limited in range. These movements are basically bending or angulation, and torsion or rotation ('swing' and 'spin'—*see* p. 434) and translation; all other movements are combinations of these basic possibilities. Judging from the restricted data available, it is probable that the earliest synovial joints are likely to have permitted the same repertoire of movement, with improvement in range and smoothness. This implies that the ancestral vertebrate limb contained joints roughly approximating to a 'ball-and-socket' form of construction; paleontological data, as well as the status of synovial joints in extant primitive amphibians and reptiles, support this supposition. This viewpoint also entails that the proximal joints of the limbs have in this sense remained less specialized than the more distal articulations; they certainly evince a closer approximation to multi-axial activity. A multi-axial joint requires considerably more complex muscular control than a bi-axial one, in which more reliance can be placed upon ligaments, an advantage which is even more marked in uni-axial joints. This advantage obtains in both dynamic and static situations: for when a multi- or bi-axial articulation is involved in a substantially uni-axial form of movement, muscle effort must be utilized to some extent to prevent unwanted movement in other axes. Similarly, when a joint is to be maintained static in some phase of movement or stance, this can be effected more economically and efficiently if the joint surfaces themselves, together with the disposition of adjoining ligaments, impose limitations upon movement in some directions. Unless this interferes with the overall activity of the joint, the ultimate trend will be towards uni-axial functioning, and this appears to be the evolutionary tendency in the limbs. This is really tantamount to saying that joints are adapted to the range of motion required of them in the characteristic activities of any particular animal form. To take the argument further, a joint may even disappear if its activity ceases; examples of this can be indicated in many mammals, and in the human skeleton the process is apparent in synostosis of the segments of the sternum and sacrum, an abolition of joints present and functional in other mammals.

The refinement of a joint evident in the limitation of its direction and range of movement to whatever is functionally habitual in motor behaviour is conducive to the development of skilled control, and this is linked to the most advantageous distribution of available muscle power. There are practical limitations to the sheer bulk of muscle concentrated around a joint, and it is clearly an advance if restraining activities can be transferred from muscle to the influence of ligaments and to the shape of the articular surfaces. A marked instance of this is the arrest of joints in temporary but perhaps prolonged static positions, as is required of the human hip and knee in standing. If the joints can be maintained in a nearly close-packed position (p. 438) by the action of gravity, muscular effort can be reduced to a minimum, and this is, of course, the basis of the mechanism of standing in mankind (p. 617). This commonly cited example of joint control is associated with the concept of *stability* at joints, a now somewhat overworked term, whose *static* implications are obvious. Joints are, however, primarily dynamic, and during actual movements the qualities which render them stable in one position are equally important in controlling transit from one attitude to another. In the medical context it is perhaps natural to view these factors as preserving the integrity of the articulation, a somewhat negative approach, which appears to be more concentrated upon the features of joints likely to prevent dislocation than upon a functional interpretation of their structural details. The synovial joints of higher vertebrates such as man are superbly engineered to accomplish their customary movements with greatest effectiveness commensurate with the limited resources available. However, before taking analysis of these activities further, it is appropriate to consider in greater detail the intimate structure of the tissues involved in synovial joints.

The Structure of Synovial Joints

The articular surfaces of the majority of bones are formed of a special variety of hyaline cartilage which reflects their preformation as cartilaginous models in embryonic life (Barnett *et al.* 1961; Ghadially and Roy 1969). In contrast, the clavicular surface at the sternoclavicular joint and both surfaces at the temporomandibular joint are of dense fibrous tissue containing only isolated groups of chondrocytes with little surrounding matrix, again reflecting the initiation of these bones by mesenchymatous centres of ossification. Nevertheless, it is an oversimplification to regard the cartilaginous articular surfaces as unmodified hyaline

4.4B Articular surfaces of the talocrural joint (left), demonstrating the patterns of split-lines in the articular cartilages produced by multiple insertions of a round-bodied needle, previously immersed in Indian ink. *Above*, tibiofibular mortice; note interosseous ligament. *Below*, superior (tibial) and lateral (fibular) surfaces of the talus. For possible significances of split-line configuration, *see* p. 250.

cartilage and merely a surface sector of the primitive model which has grown, but remained unossified. In long bones it can be recognized as a specialized tissue long before the subjacent bone has ossified (Davies and Edwards 1948), whilst mature articular cartilage shows a highly distinctive radial organization with marked variations in cell type and arrangement, fibrous architecture and calcification level with increasing depth from the surface. Four strata have been described and these are considered in greater detail elsewhere (p. 349). The split-line phenomenon in articular cartilage, and its possible relationships to the architecture and mechanical properties of the cartilage are discussed on p. 250. Illustration 4.4B displays examples of the split-line patterns in a talocrural joint.

Essentially articular cartilage provides a wear-resistant, low-friction lubricated surface, both slightly compressible and elastic, which is ideally constructed for ease of movement over a similar surface but able to accommodate the relatively enormous forces of compression and shear generated during weight-bearing and muscle action. The latter properties are of especial importance at one end of the range of the most habitual movement of the joint, when it enters the so-called close-packed position (p. 438).

The thickness of articular cartilage varies considerably and is often stated to range from 1 to 2 mm, but this is more typical of small bones in individuals of advanced age. In youth it may reach a maximum thickness of 5–7 mm in the larger joints, and such young cartilages are typically white, smooth and glistening to the naked eye, with well marked compressibility. In contrast, ageing cartilages are thinner, less cellular, firmer, more brittle, with a less regular surface, and they develop a yellowish opacity. Despite the 'glassy' appearance of moist, freshly exposed articular cartilage, and the earliest measurements which supported this impression of smoothness, later estimates using more refined techniques emphasized the relative 'roughness' of the surfaces (Dowson *et al.* 1969; Longfield *et al.* 1969). The 'centre-line average' of the undulations described by these authors varied between 30×10^{-6} inch and 200×10^{-6} inch, which compares very unfavourably with an engineering bearing (5×10^{-6} inch to 15×10^{-6} inch); but when lubricated with synovial fluid the surface exhibits an extremely low coefficient of friction ($<0{\cdot}002$). It was proposed that under conditions of loading the 'valleys' between the 'peaks' trap pools of synovial fluid. Others (McCutchen 1959) have discussed the porous nature of articular cartilage (a hypothetical pore size of 6 nm was estimated) and suggest that it may be regarded as a spongework, which under resting conditions is saturated with synovial fluid. With increasing load and compression of the cartilage it is presumed that synovial fluid 'weeps' from its porous surface. The advent of scanning electronmicroscopy has greatly renewed interest in articular surfaces. When *detached* blocks of articular cartilage were prepared for the scanning microscope many authors described, initially, patterns of ridges and undulations as a constant and characteristic feature of the surface (e.g. McCall 1968; Gardner and Woodward 1969; Walker *et al.* 1969; Redler and Zimney 1970; Gardner 1972; Mow *et al.* 1974; Redler 1974). However, this view has been strongly challenged, since the ridges and undulations were absent when the cartilage was *still attached* to subchondral bone; such appearances were therefore regarded as artefactual, atypical or pathological (Clarke 1973a; Ghadially *et al.* 1976). The only constant feature seen with the scanning microscope in what the authors regarded as 'normal', mature articular cartilage was the occurrence of numerous oval, fusiform or rounded *shallow pits*, thought to correspond to the sites of underlying chondrocytes (Clarke 1973a, b; Ghadially *et al.* 1974, 1975, 1976). However, in juvenile cartilage, instead of pits, these features were replaced by elevations or small '*humps*' of similar dimensions. Doubt was therefore expressed concerning the 'enrichment theory' of joint lubrication (p. 428 and *see* Ghadially *et al.* 1977). It must be stressed, however, that despite the impressive micrographs produced, and the fact that the articular cartilage was still attached to subchondral bone (unquestionably of great technical importance), the fact remains that the cartilage was subjected to all the rigorous preparative procedures for scanning microscopy. To what extent the observed pits and humps reflect this is uncertain.

Recently, however, some of the problems associated with tissue preparation for scanning electron microscopy have been circumvented by studying fresh, moist, necropsy specimens of the weight-bearing area of the lateral femoral condyle using reflected light interference microscopy (Longmore 1976, 1978; Longmore and Gardner 1978). Curvatures, undulations and irregularities of the articular surface were classified into four groups of decreasing dimensions: (1) the *primary anatomical contours*, e.g. ovoid or sellar surfaces; (2) *secondary undulations* of 100–500 μm crest to crest; (3) *tertiary hollows* which were 20–50 μm in diameter and 0·5–2 μm deep. (4) *quaternary ridges* which were 1–4 μm in diameter and 130–275 μm deep. In their most recent publication (Longmore and Gardner 1978) the four classes were confirmed; particular emphasis was placed on the tertiary hollows, and their size, shape, and distribution were shown to be strongly age-dependent (a phase of *maturation* from 0–21 years

being followed by *ageing* from 22 to 50 years). In the youngest age group the tertiary hollows were predominantly circular and tightly packed, when viewed *en face*. With increasing age they gradually separated, becoming circular to oval, sometimes appearing in clusters or 'figure of eight' pairs, while the areas between hollows although 'granular and fuzzy' were relatively smooth. From 21 years onwards, quaternary ridges, that had first appeared sporadically between 10 and 20 years, were now present more frequently in focal patches occupying some of the 'inter-hollow areas'. It was concluded that the tertiary hollows almost certainly corresponded to underlying chondrocyte lacunae, and that the quaternary ridges may represent incipient cartilage fibrillation.

Articular cartilages are closely moulded to the bone ends but their zonal variations in thickness often accentuate the overall surface geometry of the underlying bone. Typically male (convex) surfaces are thickest centrally, gradually thinning peripherally, whilst the converse holds for female (concave) surfaces. The precise configurations of these, their degree of congruence (closeness of mutual fit) in various positions, together with the disposition and mechanics of the surrounding fibrous capsule and ligaments are, of course, intimately related to the types and ranges of movement permitted at any specific joint (*vide infra*). (For a simplified classification based upon the approximate geometry of joint surfaces *see* p. 432, and for more detailed comments *see* p. 437.)

Articular cartilage contains neither nerves nor blood vessels (except occasional looped vessels which penetrate as far as and sometimes even through the calcified zone (p. 251). Its nutrition is considered to be derived from three sources: the vascular net in the synovial membrane near its periphery (the *circulus vasculosus articuli*), from the synovial fluid, and from the blood vessels in the underlying marrow spaces, but the relative importance of these sources is still disputed.

The free surface of articular cartilage has no covering of perichondrium and was for long regarded as a thin, fibre-free *lamina splendens* (*vide infra*) but recently this has been shown to consist of a feltwork of fine filaments—probably a form of collagen with minimal interstitial substance (p. 250), and, more deeply placed, their attendant, flattened, elongate fibroblasts. This view, having received further support, implies that the boundary layer on the articular surface of *all* synovial joints is composed almost exclusively of collagen. (The origin of the term lamina splendens is explained on p. 250, and it is appropriate that its systematic use should now be abandoned.)

With advancing age, undulations of the articular surfaces increase in prominence and they become studded with minute, irregular, shred-like projections, perhaps indicating the effects of prolonged wear and tear. Erosive effects undoubtedly occur in pathologically 'dry' joints and also in those with an altered viscosity of the synovial fluid, but in substantially normal joints such processes are extremely slow. There is no direct evidence for any continual replacement of eroded surface layers by proliferation of the deeper tissues—mitotic figures are absent in adult articular cartilage and previous claims of amitotic cell division have not been substantiated.

The fibrous capsule consists of parallel and interlacing bundles of white connective tissue fibres. It forms a cuff or brassard, each end of which is attached to a continuous line around the articular end of one of the bones concerned, usually in the immediate neighbourhood of the periphery of the articular surface, but this arrangement is subject to considerable variation. It is perforated by the articular vessels and nerves, and may present one or more apertures through which the synovial membrane protrudes to form a pouch or sac. The fibrous capsule usually shows two or more localized thickenings in which the constituent fibre bundles are generally parallel to one another. These thickenings are the *capsular ligaments* of the joint and they are named according to their position or attachments. In some joints the fibrous capsule is reinforced or replaced by the tendons, or by expansions from the tendons of neighbouring muscles. Some joints possess *accessory ligaments* which stand clear of the fibrous capsule. Such accessory ligaments may be either *extracapsular* or *intracapsular* in position.

All ligaments are tough and unyielding, but at the same time flexible and pliant, so that they offer no resistance to normal movements. They are designed to prevent the occurrence of excessive or abnormal movements, and every ligament becomes taut at the normal limit of some particular movement (p. 439). They are elastic only within narrow limits, and are protected from excessive tension by reflex contraction of appropriate muscles (Smith 1954).

Synovial membrane (Barnett *et al.* 1961) is a characteristic tissue derived from embryonic mesenchyme which lines the nonarticular parts of synovial joints, synovial bursae and synovial tendon sheaths—all regions where the essential function of the tissues entails movement between contiguous planes. In each case, the apposed surfaces are lubricated by a fluid which superficially resembles egg-albumin (therefore named *synovia*), and which is secreted and absorbed by the synovial membrane.

In joints, the membrane lines the fibrous capsule and clothes any bony surfaces, ligaments and tendons which are intracapsular in position. It is absent, however, from the surfaces of intra-articular discs or menisci and ceases at the margins of the articular cartilages. The peripheral few millimetres of the latter are a *transitional zone*, with intermediate grades of structure between typical membrane and cartilage surface.

Pink, smooth and shiny throughout much of its extent, the inner surface of the synovial membrane bears occasional small finger-like projections, the *synovial villi* (Ghadially and Roy 1969). Elsewhere the membrane is thrown into folds and fringes which project into the joint cavity—some of these are sufficiently constant and prominent to be named, e.g. the alar folds and the ligamentum mucosum of the knee joint. Accumulations of adipose tissue are characteristic of the synovial membrane of many joints, and these *articular fat pads* were mistakenly identified as 'mucilaginous glands' by earlier anatomists. These folds, fringes and pads form flexible cushions which fill those potential spaces and irregularities in the joint 'cavity' which are not filled with the small volume of synovial fluid, and they accommodate to the changing shape and volume of these irregularities with joint movement. They effectively increase the surface area of the synovial membrane and they may promote an adequate distribution of lubricant synovial fluid over the articular surfaces (cf. intra-articular discs and menisci). The synovial villi are few in number in normal joints but are more numerous where the synovial membrane rests upon loose areolar tissue near the articular margins and over the surfaces of folds and fringes. They increase in number with age and become very prominent in various pathological states.

Structurally, synovial membrane varies considerably in different regions of a joint but essentially consists of a cellular *intima* which rests upon a vascular fibrous *subintimal lamina* (often less fittingly called the *subsynovial tissue*). The latter is often loose and areolar, but sometimes contains organized laminae of collagen and elastin fibres running parallel to the membrane surface, between which are scattered fibroblasts, macrophages, mast cells and fat cells (Davies 1950). The elastic component prevents the formation of excessively redundant folds during joint movement which would become compressed between the articular surfaces.

The subintimal adipose cells which accumulate as fat pads are unremarkable, but they are arranged in compact lobules surrounded by fibro-elastic interlobular septa. These septa are richly vascularized and they impart a firmness, deformability and elastic recoil, which again are important during joint movement.

In contrast, where synovial membrane lines prominent intrinsic ligaments or clothes intracapsular tendons the subintima is difficult to distinguish as a separate zone, being formed of fibrous tissue which merges with that of the adjacent capsule, ligament or tendon.

The synovial lamina intima (*lamina propria synovialis*) also shows regional variations but consists basically of one to four layers of *synovial cells* embedded in a granular, amorphous, fibre-free intercellular matrix. The cells vary from polyhedral with round or oval nuclei, to flattened, elongate cells with spindle-shaped nuclei. Many possess delicate branching processes which pass horizontally and intermingle with those of adjacent cells.

The free surface of some superficial cells carries a few filopodia, whilst others are uncomplicated or slightly wavy. In many areas, but particularly over areolar subintimal tissue, the cells are ill-opposed with intervening narrow gaps which sometimes contain extensions of the subintimal connective tissue (which therefore borders the synovial cavity at these points). Conversely, over a fibrous subintima, the cells are more flattened, approach each other more closely and may even form endothelioid sheets.

Ultrastructurally, two cell types (A and B cells) have been recognized (Barland *et al.* 1962), but cells with intermediate characteristics are common, and perhaps the described differences merely reflect quantitative variations in functional activity rather than distinct cell lineages.

Synovial cells of *type A* predominate and are characterized by surface filopodia, plasma membrane invaginations and associated micropinocytotic vesicles. Their cytoplasm contains numerous mitochondria, varieties of lysosome, a system of cytoplasmic filaments and a particularly prominent Golgi apparatus and associated smooth-walled vesicles, but profiles of endoplasmic reticulum are scanty. Neighbouring cells are often separated by distinct gaps, but where they approach more closely their surfaces may be complex and interdigitate. The latter is common in compact areas of rat synovial membrane, as are tight junctions and desmosomes between adjacent cells, but these have not been identified in human joints.

In *type B synovial cells* most of the above characteristics are poorly developed, but in contrast they contain a wealth of rough endoplasmic reticulum, varying from small round or oval profiles to large flattened, intercommunicating cisternae, together with scattered free cytoplasmic ribosomes.

Both cell types contain glycogen deposits, but lipid inclusions are rare, as are paranuclear centrioles. The latter correlates well with the low mitotic rate of intimal synovial cells, and any cell replacement of the surface layers probably follows transformation of primitive fibroblast-like subintimal cells.

The significance of the synovial cells is best considered in relation to synovial fluid production and absorption, and the removal of other substances from joint cavities.

Synovial fluid is found in the cavities of synovial joints, bursae and tendon sheaths, but its composition has not been extensively investigated in the latter two sites. That obtained from synovial joints is a clear or pale yellow, viscous (glairy) fluid, of slightly alkaline *p*H at rest (though diminishing on exercise), which carries a small mixed population of cells and some amorphous particles which exhibit metachromatic staining. Its viscosity, volume and colour vary widely between different joints and species, and it has proved difficult to correlate these variations with a particular joint or with the size, weight or condition of exercise of the animal studied. In man its volume is low, and usually less than 0·5 ml can be aspirated from a large joint such as the knee.

The physical properties of synovial fluid are particularly characteristic and it shows viscous, elastic and plastic components. Many of the wide divergencies and inconsistencies of earlier investigations stemmed from the relatively crude technical methods available and a failure to appreciate the non-Newtonian properties of the fluid, i.e. with low rates of shear, the fluid is highly viscous, but the measured viscosity drops dramatically with increased rates of shear. It was therefore proposed that with slow joint movement the weight-bearing capacity would be maximal and that with fast movement there would be reduced impedance by fluid drag. However, more recent workers have pointed out that the *product* of the viscosity and shear rate is approximately constant and therefore also the weight-bearing capacity. Additionally it has been shown that the viscosity is very sensitive to changes in dilution and that it falls with increasing temperature, and increasing *p*H. The elasticity of the synovial fluid is similarly affected by changes in dilution, *p*H and temperature, but it increases with increased rates of shear, in contrast to the viscosity changes under similar conditions. (For extended earlier reviews of the physical properties of synovial fluid and theories of lubrication consult Barnett 1958; McCutchen 1959; Barnett *et al.* 1961; Dintenfass 1963; Negami 1964; Davies and Palfrey 1965; MacConaill 1966; Dowson *et al.* 1969; Longfield *et al.* 1969. For a more recent, excellent, collection of essays on the physical and biological properties of adult articular cartilage including nutrition and lubrication, *see* Freeman 1973; and for an analysis of the structure, properties and biochemistry of cartilage in general *see* Serafini-Fracassini and Smith 1974.)

The composition of synovial fluid is consistent with the view that it is a dialysate of blood plasma containing some protein (about 0·9 mgm/100 ml) and with added mucin. The latter is principally hyaluronate, a sulphate-free mucopolysaccharide containing equimolar concentrations of glucuronic acid and N-acetyl-glucosamine, and much evidence has accumulated to show that the visco-elastic and thixotropic (plastic) properties of the fluid are largely determined by its hyaluronate content. The origin of the synovial mucin proved elusive for many years and was variously ascribed to an attrition product of the matrix of articular cartilage, transformed products of synovial mast cell secretion, or products of the synovial cells themselves. Investigations by light microscopy, histochemistry and tissue culture have proved inconclusive, but recent studies using colloidal iron techniques combined with electronmicroscopy revealed a strong positive reaction for polysaccharides in relation to the plasma membrane, filopodia, cytoplasmic vesicles and Golgi apparatus of the A type of synovial cells. This evidence, together with comparable results in other cells synthesizing polysaccharides, is regarded as strong support for the view that A cells are the site of synovial hyaluronate synthesis.

Synovial fluid protein is partly free and partly bound to mucopolysaccharides including hyaluronate. Most workers agree that much of this protein derives from the blood plasma, but the possible addition of some of the hyaluronate-bound protein by secretion from the B synovial cells cannot be excluded.

The small content of cells in synovial fluid (about 60 per ml in resting human joints) consists of monocytes, lymphocytes, macrophages, free synovial cells and occasional polymorphonuclear leucocytes (Bauer *et al.* 1940). The higher cell counts characteristic of younger age groups, and many species other than man, probably reflect more active movements of the joints in the period immediately before sampling of the fluid. The amorphous, metachromatic particles, and the fragments of cells and fibrous tissue sometimes found in synovial fluid, are thought to be the result of slow wear and tear of the joint surfaces.

The functions of synovial fluid are considered to include the provision of a liquid environment, with a narrow *p*H range for the joint surfaces, a nutritive source for the articular cartilages, discs and menisci, and as a lubricant which increases joint efficiency and reduces erosion of surfaces. To what degree it operates as a source of nutrition compared with direct diffusion from neighbouring vascular plexuses, remains unclear. Similarly, whilst most are agreed concerning the general lubricant significance of the fluid, and in particular, its hyaluronate content, the detailed analysis of its action is still disputed.

Various models have been proposed for the lubrication phenomena in joints and, interestingly, these have largely paralleled the current advances in engineering physics. Initially, it was proposed that the principal mechanism involved was 'fluid film' or 'hydrodynamic' lubrication, familiar in engineering practice, and that the bearing surfaces are usually separated by a substantial layer of lubricant fluid, the effectiveness of which depends upon the rheological properties of the fluid when in bulk. A later refinement of this view included the important consequences of the elastic properties of the fluid—the so-called 'elastohydrodynamic model'. However, some investigators criticized the suitability of a joint environment for simple fluid-film lubrication on several counts, and the principles of 'boundary lubrication' were proposed, in which the properties of the solid surfaces, probably combined in some way with an extremely thin layer of lubricant molecules, were considered most important. Then followed the new concept of 'weeping lubrication' in which particular emphasis was placed on the porous, sponge-like, fluid-filled nature of the deformable articular surfaces. Under conditions of load, it was proposed that the surfaces were lubricated by a fine film of fluid expressed from the interstices of the sponge. Recently a theory of 'boosted lubrication' is receiving

increasing attention, which suggests that as articular cartilages are compressed, fluid pools become trapped in the 'valleys' on their irregular surfaces. With increasing compression, the small-moleculed, mobile fraction of the synovial fluid passes *into* the cartilage over the contact area, and that the fluid remaining in the pools becomes increasingly enriched in hyaluronate content (and therefore of greater viscosity) and thus forms a progressively more effective coat which protects and lubricates the surfaces. However, as pointed out on p. 426, the presence of major ridges and valleys are almost certainly preparative artefacts, and the existence of small 'pits' or 'humps' *in vivo* cannot be regarded as proven.

When consideration is given to the wide variations in joint geometry, structure and activity, it seems quite possible that multiple mechanisms may operate under different conditions, and whilst many investigations are currently in progress, no statement of joint lubrication theory can yet be regarded as definitive (*see* references quoted above, and in particular Freeman 1973).

The synovial membrane is involved not only in the *production* of synovial fluid, but also in the *removal* of materials from the joint cavity. Small molecules of crystalloids and soluble dyes can cross the membrane and pass directly into subintimal capillaries and venules. The former are fenestrated according to Kos (1970). Particulate substances, however, pass preferentially into the subintimal lymphatic capillaries and are transported to the regional lymph nodes. Studies using thorotrast, colloidal carbon and ferritin as tracers, introduced into the joint cavity, followed by electronmicroscopy, have emphasized the marked phagocytic powers of the A-cells of the synovial intima, which rapidly enclose the particles within their micropinocytotic vesicles. The origin of the subintimal macrophages is not certain; some may enter the joint tissues from the bloodstream, but many are probably phagocytic A-cells of intimal origin which have passed into the deeper tissues (Ghadially and Roy 1969).

The Classification and Movements of Synovial Joints

Various criteria have been used as the bases for several classifications of synovial joints including their movements, and they differ considerably in their universality, scientific accuracy and practical utility. These criteria include the complexity of organization and number of articulating surfaces; the number and distribution of the principal axes about which movements occur; the approximate geometrical form of the articular surfaces and the gross movements permitted; finally, a much more precise attempt to define the geometry of the surfaces and their associated movements. The latter study forms the basis for part of a now rapidly advancing science of *human kinesiology*, and whilst this important subject can only be considered briefly in this volume (p. 431) several excellent extended treatments of the subject are available (Steindler 1955; Barnett *et al.* 1961; MacConaill and Basmajian 1969).

Complexity of organization—Many synovial joints possess only two articulating surfaces (*male* and *female*) and are termed *simple joints*. In some, one surface is convex in all directions (male) and is always greater in surface area than that of its adjoining concave (female) surface. In other simple joints, however, both surfaces are concavo-convex and in these cases, the one of greater area is considered male.

A joint possessing more than one pair of articulating surfaces is termed *compound* (e.g. at the elbow joint the distal end of the humerus presents two distinct male surfaces, the capitulum and the trochlea, which articulate with the female surfaces of the radius and ulna respectively, forming two mating pairs. In addition the convex, male articular circumference of the head of the radius articulates with the female radial notch of the ulna at the superior radio-ulnar joint. This makes a third mating pair all contained within a common articular capsule.) In all such compound joints the articulating territory of each pair remains distinct, the male surface of one pair never passing on to the female surface of an adjoining pair in any position of the joint.

Finally, where an intracapsular disc or meniscus of fibrocartilage is present, the joint is termed *complex*.

Degrees of freedom of joints. When the main positional changes of one member of a pair of articulating bones are analysed, it is often useful to consider them as rotations of the bone around one or more of three mutually perpendicular axes. The directions of the particular set of axes chosen may, for convenience, vary with the joint under consideration. In many cases they are referred to the principal planes of the body when in the anatomical position, i.e. a vertical, a transverse and an anteroposterior axis. Alternative directions may, however, be more appropriate; for example, many anatomists prefer to consider movements of the humerus on the scapula at the shoulder joint to occur around a vertical axis, an obliquely transverse axis in the plane of the body of the scapula, and a third axis at right angles to these (4.5).

When the movement of a bone at a joint is substantially limited to rotation about a single axis, the joint is termed *uni-axial* and it possesses *one degree of freedom*. Similarly, if *completely independent* movements can occur around two axes, the joint is classed as *bi-axial* and it possesses *two degrees of freedom*. Since there are three axes about which independent rotations may occur, a joint may exhibit one, two or *three degrees of freedom*, but no more.

When using this apparently straightforward classification, however, a number of additional points should constantly be borne in mind.

Firstly, a bone articulating at a so-called ball-and-socket joint can not only rotate about the three main axes, but also around many others intermediate in position. Such a *multi-axial* joint is still considered to possess only three degrees of freedom, since all these intermediate rotations can be resolved mathematically into components involving only three mutually orthogonal axes.

Secondly, if the movement of a bone referred to one plane is carefully examined throughout its full range, it is found that a relevant axis cannot be adequately described by a single line fixed in space, but rather by a succession of such lines which change continuously in position as the movement progresses. This positional change reflects the fact that articular surfaces are not simple geometric forms, but that their degree of curvature changes at each point across any profile (*see* p. 433). Such changes vary greatly in amount with different forms of joint (*vide infra*), but it should be fully realized that it is an approximate *mean position* of such a moving axis that is often referred to as *the axis* of conventional description. For many purposes, however, such compromise axes can be a most useful concept, particularly when a study of only the gross aspects of movement of a part are sufficient.

Thirdly, movements which superficially appear simple and limited to one plane only are, on closer examination, seen to be compound. For example, what initially appears as a simple change in angulation between two long bones is often seen to be accompanied by some degree of rotation of one of the bones about its long axis. This is an inevitable consequence of the curved nature of biologic joint surfaces (p. 432) and when, as is often the case, such a rotation cannot be carried out independently, it does not constitute an additional degree of freedom (e.g. *see* movements of the ulna, p. 465).

Finally, it should be noted that many movements at joints contain an element of *translation*, in which one articular surface slides bodily across its partner, and in which any element of rotation or angulation may be slight (but *see* plane joints, below). Translations are also a feature of many joints in association with large angulation changes (e.g. the shoulder joint). It will be appreciated that such movements of translation are not accommodated by the foregoing classification, which includes only three rotational degrees of freedom.

GROSS MORPHOLOGICAL CLASSIFICATION OF SYNOVIAL JOINTS

The approximate shape of synovial joints has formed the basis for a widely used classification and whilst seven varieties have been recognized officially, and may indeed have some practical utility, a closer examination shows that there is no

exclusive basis for their separate classification. They are, as we shall see, merely variations (although sometimes extreme) of two basic geometrical forms (*see* p. 432).

Plane joints are formed by the apposition of fairly flat articular surfaces (e.g. the intermetatarsal joints and some of the intercarpal joints) but even here close examination shows them to possess some degree of curvature. For many purposes the latter are disregarded, and the movements are considered to be pure translations, or slides, of one bone on its neighbour. In more advanced treatments of joint dynamics, however, the consequences of the slight curvatures assume a greater importance (*vide infra*).

Hinge joints (ginglymi) roughly resemble the hinges of a door, where the surfaces are so moulded as to largely restrict the to-and-fro movement to one plane, i.e. they are uni-axial joints. The sides of the joint are typically provided with strong collateral ligaments, and the interphalangeal and humero-ulnar joints are good examples. However, the surfaces of a biological hinge depart from the regular cylinders of the engineer, and in section their profiles are not arcs of circles, but varieties of spiral. Consequently the main to-and-fro swing of the bone is inevitably accompanied by some rotation about its own long axis (*vide infra*).

Pivot (trochoid) joints are also uni-axial and comprise a central bony pivot surrounded by an osteoligamentous ring. Movement is restricted to a rotation around a longitudinal axis through the centre of the pivot. The pivot may habitually rotate within the ring, as in the case of the proximal radio-ulnar joint, in which the head of the radius rotates within a ring formed by the annular ligament and the radial notch of the ulna. Conversely, the ring may rotate around the pivot, as in the articulation between the dens of the axis and the ring formed by the anterior arch of the atlas and its transverse ligament.

Bicondylar joints are allied to the other uni-axial joints having a principal movement occurring largely in one plane, but in addition, a limited amount of rotation is possible about a second axis set at 90° to the first. These joints have male surfaces formed by two distinct, convex, knuckle-shaped *condyles* which articulate with two concave female surfaces (which in some cases are also, less appropriately, known as condyles). The condyles may be almost parallel as in the knee joint, where they are enclosed in a common fibrous capsule. Alternatively, the condyles may be in line and even enclosed in separate capsules. An example of this is the pair of temporomandibular joints which necessarily cooperate in all mandibular movements, and which *together* form a true condylar mechanism (and should always be studied as such).

Ellipsoid joints are bi-axial and formed by the reception of an oval, convex, male surface into an elliptical female concavity. Examples are the radiocarpal joint and the metacarpophalangeal joints. Primary movements are possible about two axes at right angles (e.g. flexion-extension, and abduction-adduction). Whilst these movements may be combined as a movement of circumduction (*vide infra*), there is little appreciable rotation around the third axis, as this is prevented by the overall shape of the articular surfaces.

Sellar (saddle) joints are also bi-axial and their apposing surfaces are concavoconvex. If either surface is examined it is found to have a particular direction in which it is maximally convex, whilst at *right angles* to this, it is maximally concave (p. 433). In the articulated joint, of course, the convexity of the larger (male) surface is apposed to the concavity of the female surface and vice versa. Primary movements occur in two planes at right angles, but because of the articular geometry these are accompanied by a degree of axial rotation of the moving bone. Such *conjunct rotations* cannot occur independently, but they must not be regarded as simply a by-product of 'imperfect' mechanics. As we shall see, they are of considerable functional significance during the habitual positioning of bones and in the limitation of joint movement (pp. 438, 439).

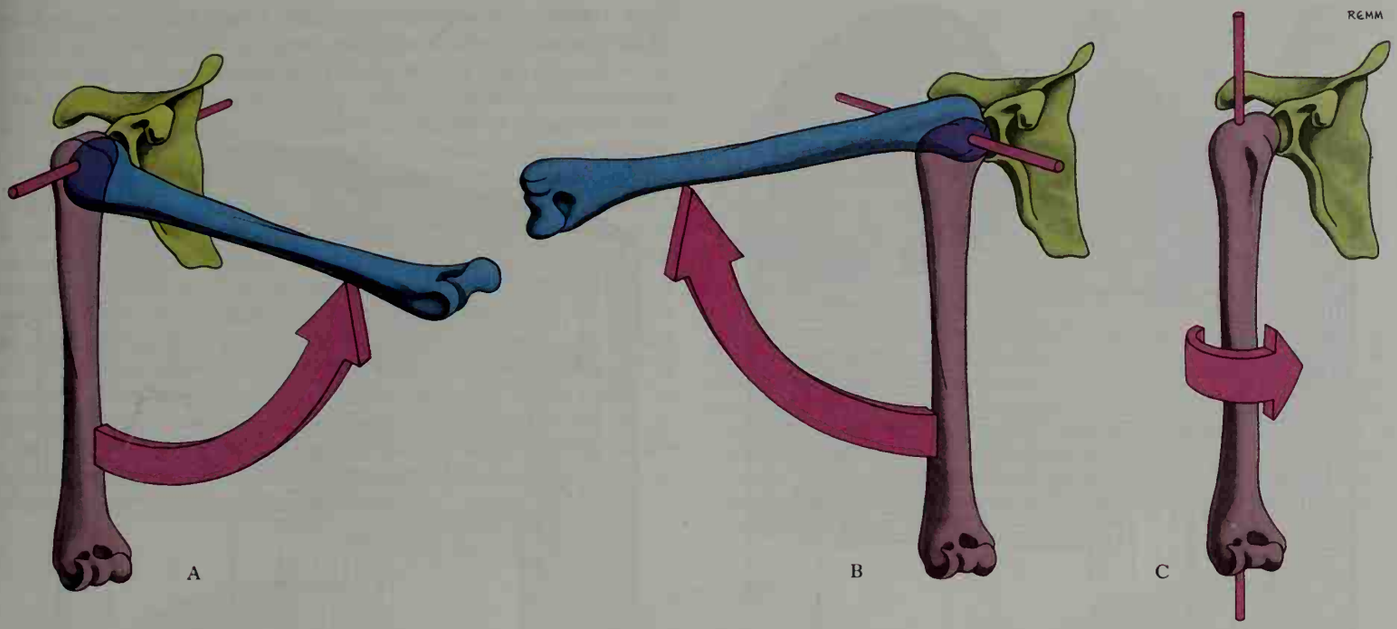
Perhaps the best known and most fully investigated saddle joint is the carpometacarpal joint of the thumb; others include the talocrural (ankle) joint and the calcaneocuboid joint.

Spheroidal joints (often, somewhat loosely, termed ball-and-socket joints) are formed by the reception of a male globular 'head' of one bone into a cup-like concavity—excellent examples are the hip and shoulder joints. Such joints are, of course, multi-axial and possess three degrees of freedom. However, it is important to realize that their articular surfaces, although superficially resembling parts of spheres, are in fact not spherical, but slightly egg-shaped (*articulatio ovoidalis* has been proposed as an appropriate term for official recognition). Consequently, in most positions of the joint there is *not* a perfect fit (or congruence) between the apposed surfaces. The latter occurs only in one position of the joint, at the end of the range of its commonest movement (*vide infra* for further discussion).

The Movements and Mechanisms of Joints

In the following section the subject of joint movement will first be considered using the terms and concepts usually encountered in standard textbooks of anatomy. This is then followed by a brief review of the more important approaches and ideas which are emerging in modern texts on kinesiology.

The movements permitted in joints are conventionally considered to be of four kinds: gliding and angular movements, circumduction and rotation. Almost always these are combined to produce an infinite variety. Where movement is limited in extent, the reciprocal articular surfaces approach each other in size, but where movement is free the bone which is habitually more mobile possesses the larger surface.



Translation is the simplest kind of motion that can take place in a joint, one surface sliding over another without any appreciable angular or rotatory movement. It occurs as an important element combined with other movements in many joints, but in some carpal and tarsal articulations it is often regarded as the only motion permitted. However, even here, examination of cineradiographs reveals a considerable degree of rotation and angular change in the relative positions of the small bones during most movements of the carpus and tarsus.

Angular movement implies diminution or increase in the angle between adjoining bones. Two types of angular movement are so common, especially in the limbs, that attempts must be made to define them. They occur around axes set at right angles to each other and are named (1) *flexion* or bending, and its opposite, *extension* or straightening, and (2) *abduction* and also its opposite, *adduction*.

Flexion, although in wide biological use, is difficult to define with precision. It often occurs around a transverse axis and results in the approximation of two morphologically ventral surfaces. The thumb, however, lies in a plane set almost at right angles to that of the fingers. Its dorsal surface is directed laterally and, accordingly, flexion and extension at each of its joints occur around an anteroposterior axis. At the shoulder joint flexion is more appropriately considered to occur around an obliquely transverse axis through the centre of the head of the humerus, and in the plane of the scapular body. Thus the arm is carried forwards and medially and is brought no nearer to the ventral aspect of the trunk. Again, at the hip joint, flexion which here occurs around a transverse axis, approximates a morphologically *dorsal* surface of the thigh, to the *ventral* aspect of the trunk—this reflects the characteristic rotation of the hind limb bud in early embryonic life (p. 153).

The status of the movements at the talocrural (ankle) joint is again complicated by the posture of the foot, which is set at a right angle to the leg. Elevation of the foot produces a diminution of this angle and is sometimes termed flexion, but it results in the approach of two morphologically dorsal surfaces and might, with equal justification, be called extension.

Flexion has also been defined as the posture of the fetus 'in utero' and this implies that elevation of the foot at the talocrural joint is flexion. Such a view is also supported by an examination of withdrawal reflexes in which elevation of the foot is always associated with flexion at the knee and hip, whereas the converse holds in the crossed extensor reflexes. Thus the definitions of flexion based on morphological and physiological grounds are contradictory. To avoid confusion the self-explanatory terms

4.5 The shoulder joint, which is polyaxial and possesses three degrees of freedom. In A, B and C the three mutually perpendicular axes around which the principal movements of flexion-extension (A), abduction-adduction (B), and medial and lateral rotation (C) occur are shown. Note that in the case of the shoulder the axes are referred to the plane of the scapula and not to the coronal and sagittal planes of the erect body as a whole. An infinite variety of additional movements may, of course, occur at such a joint, e.g. those involving intermediate planes, or there may be movement combinations or sequences. However, these can always be resolved mathematically into components related to the three axes which are illustrated.

dorsiflexion and *plantar flexion* will be used throughout this volume when talocrural movements are being considered.

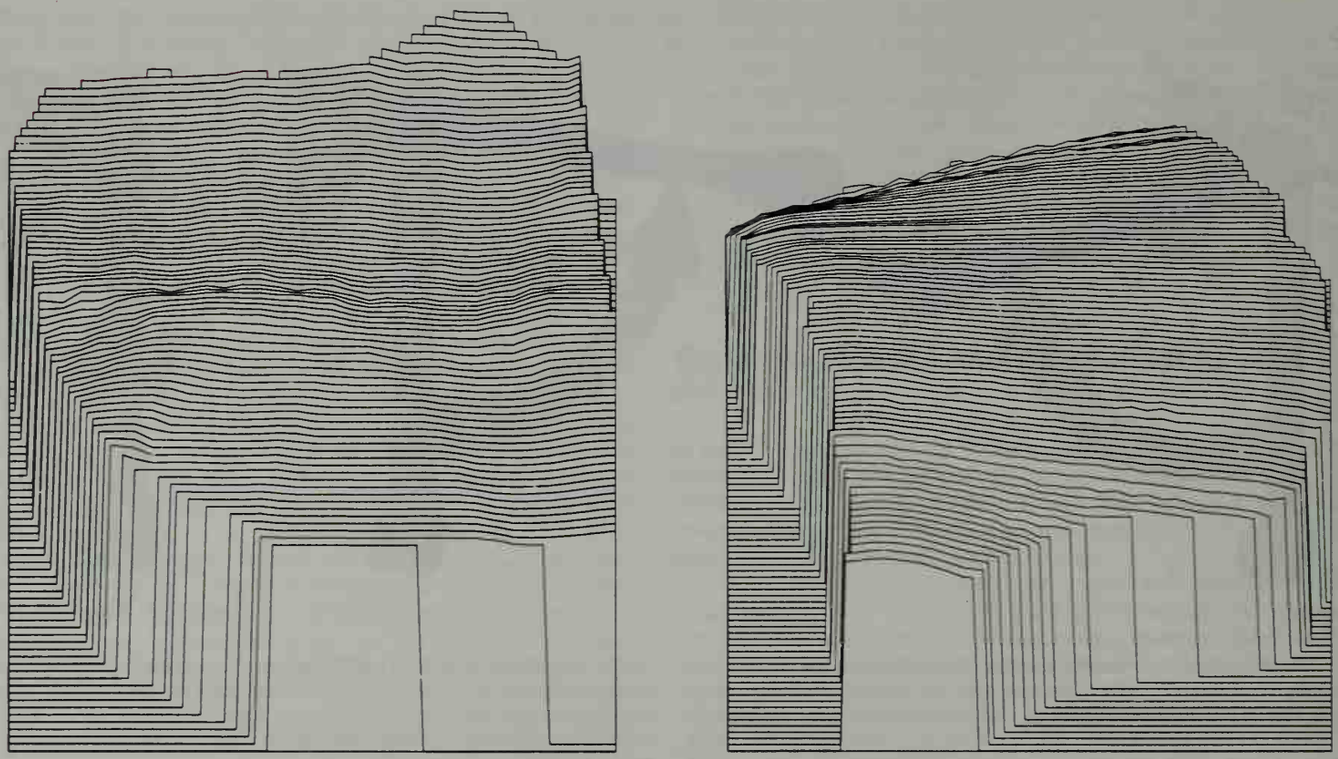
Abduction and adduction occur around an anteroposterior axis except in the case of the carpometacarpal joint of the thumb, and the shoulder joint, for reasons already stated. The terms generally imply movement away from, and towards the midline of the body, except in the case of the digits, where the arbitrary planes of reference chosen are the midline of the middle digit in the hand, and the midline of the second digit in the foot, because these are least mobile in this respect. Abduction of the thumb occurs around a transverse axis and carries the thumb away from the palm, the movement occurring in a plane at right angles to that of the palm. Similarly, abduction of the humerus on the scapula at the shoulder joint occurs in the plane of the scapula around an oblique axis at right angles to this plane (**4**.5).

Circumduction occurs when a long bone circumscribes a conical space—the base of the cone is described by the distal end of the bone, whilst its apex is at the articular cavity; it is best seen in movements at the shoulder and hip joints. It is, of course, a derived movement in which elements of flexion, extension, abduction and adduction are compounded.

Rotation is another term which is widely used but imprecisely described in many textbooks of anatomy. *In a restricted sense*, it is often used to denote a form of movement in which a bone moves around some 'longitudinal' axis. This may be in a separate bone, as with the pivot formed by the dens of the second cervical ('axis') vertebra around which the (cranium and) atlas vertebra rotates. Alternatively, the axis may roughly coincide with the shaft of a long bone, as in medial and lateral rotation of the humerus (**4**.5). Again, the axis may not be quite parallel to the long axis of the bone, as in the movement of the radius on the ulna during pronation and supination, where it joins the centre of the head of the radius to the base of the ulnar styloid process. Another example is medial and lateral rotation of the femur, where the axis joins the centre of the femoral head and the lateral femoral condyle (p. 478).

In the examples given, the rotations can be carried out as independent movements; they are termed *adjunct rotations* and they provide an additional degree of freedom. They must be carefully distinguished from the *conjunct rotations* which occur at many joints as an inevitable accompaniment of some other main movement resulting from the geometry of the articular surfaces (*see* p. 437). As will be noted below, however, in some types of articulation, conjunct rotations may be combined with some additional degree of adjunct rotation, and in different circumstances, the latter may either increase or relatively nullify the effect of the former.

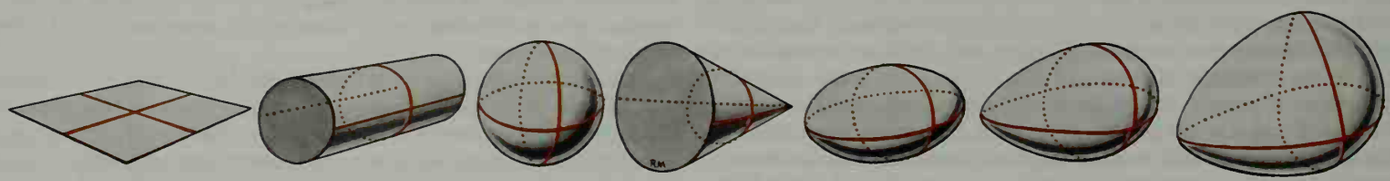
Further, it should be noted that with the exception of simple movements of translation, *all* other movements of bones are in fact rotations. For example (p. 459), as we have seen, medial and lateral rotations of the humerus occur around its own longitudinal axis (which is vertical, with the body in the anatomical position). However, the swinging 'angular' movements called flexion-extension and abduction-adduction are clearly rotations of the bone around the other two axes.



Kinesiology

The preceding account of joint movement embodies many of the more conventional views and terminologies built up over many years, often following simple inspection of articular anatomy and the more obvious positional changes of limb segments and the axial skeleton. For many purposes this will be found adequate.

In recent years, however, a closer examination of these matters has led to the rapid accumulation of a body of more objective observations, experimental results, and theory, in relation to the study of movement (the emerging science of kinesiology—a branch of biomechanics). This has necessitated a new terminology, a revision or expansion of many older concepts, and, to many, unfamiliar mathematical treatments. Only a few of these terms and ideas are considered briefly here and the interested reader should consult MacConaill (1946; 1950; 1953; 1964; 1966; 1969); Steindler (1955); Barnett *et al.* (1961), Kapandji (1970; 1974).



In the present context two fields of study are relevant, (*a*) *osteokinematics* which deals primarily with the overall movements of bones, with little reference to their related joints, and (*b*) *arthrokinematics*, concerned with the more intimate mechanics of joints.

It is appropriate to consider first certain generalizations about the shape of articular surfaces, and then the concept of replacing an irregularly shaped bone by a single straight line called the

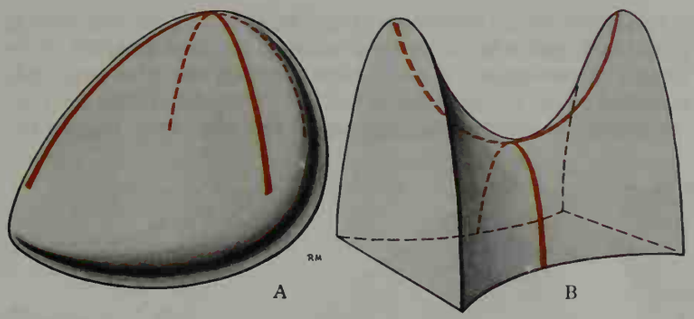
4.6A *Left:* A computer reconstruction of a sagittally sectioned cast of the trochlear surface of a fresh human tibia (left side, female, aged 63) viewed posteriorly. The medial malleolar surface is not included. It is a modified female sellar surface and reciprocally curved to its mating surface on the talus. Anteroposteriorly the surface is concave; lateromedially (left to right) there is a central convexity flanked by anterior and posterior concavities.

Right: A computer reconstruction of a coronally sectioned cast of the trochlear surface of a fresh human talus (left side, male, aged 62) viewed anteriorly. The triangular facet for the 'inferior transverse ligament' part of the posterior tibiofibular ligament has been excluded. It is a modified male sellar surface, which is convex anteroposteriorly; mediolaterally (left to right) it presents a medial convexity, a central concavity, and a rather flattened lateral convexity. Reconstructions kindly provided by Drs. A. J. Palfrey and Linda K. Ziemer of the Department of Anatomy, Charing Cross Hospital Medical School, London.

4.6B A variety of geometric figures to which reference is commonly made in simple classifications of synovial joints. However, such comparisons are rough approximations only—no synovial joint possesses articular surfaces which are truly plane, cylindrical, spherical, conical or ellipsoid. A simple and compounded ovoid which are commonplace are included for comparison.

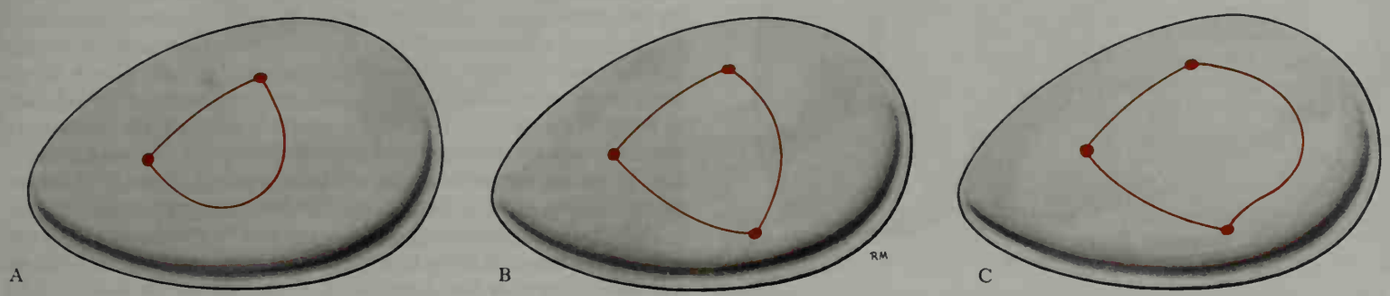
mechanical axis. Using these, certain basic types of movement of bones and of joint surfaces may be contemplated. Finally, the significance of certain joint positions will be discussed.

The Shape of Articular Surfaces



Despite the official recognition of seven types of synovial joint based on their general form, this does *not* reflect a similar number of fundamentally different surface shapes. Close examination of articular surfaces shows that they are never perfectly flat, neither are they parts of spheres, cylinders, cones, or true ellipsoids (4.6). They approach much more nearly parts of the surface of *ovoids* (egg-shaped bodies, which are compared with some other solid forms in illustration 4.6), or are compounded of more than one ovoid surface. When such surfaces are either convex in all directions or concave in all directions, they are termed male or female *ovoid articular surfaces* respectively. The other well-recognized type of surface is *sellar* or *saddle-shaped*, and it is convex in one plane and concave at right angles to this; even here the principal curvatures can be seen in section to be convex or concave ovoid profiles. Whilst, of course, there are great variations in the degree of curvature of different joint surfaces from 'nearly flat' to 'nearly part of a sphere' (spheroidal), evidence is increasing that they may *all* be classed as either **ovoid** or **sellar** (4.7). It should, however, be emphasized at this point that the detailed quantitative examination of the topology of conarticular surfaces has, until recently, been lacking, particularly in relation to human joints. It is of particular interest, therefore, that Palfrey and Ziemer (1978) have attempted such analyses on three fresh talocrural joints (amputation specimens). Physical damage and desiccation of the surfaces were avoided and multiple casts, using dental wax, were made of the trochlear surfaces of the talus and tibia; coronal and sagittal slices (3 mm or less in thickness) were prepared. Multiple points were then marked along the curved profiles of the articular cartilage and their spatial coordinates determined by projection and tracing upon grid paper. Similar data were then accumulated for the subchondral bone surfaces. The information obtained was subsequently subjected to computer analysis resulting in two-dimensional contour maps, and three-dimensional reconstructions. In this manner a much more intimate knowledge of the geometry, congruence, thickness variations in cartilage, conarticular surface areas, and contrasting profiles of cartilage and subchondral bone was obtained.

It is convenient to consider next certain descriptive terms applied to ovoid surfaces and certain of their properties, because they are relevant both to the movements of articular surfaces and to those of the bone as a whole.



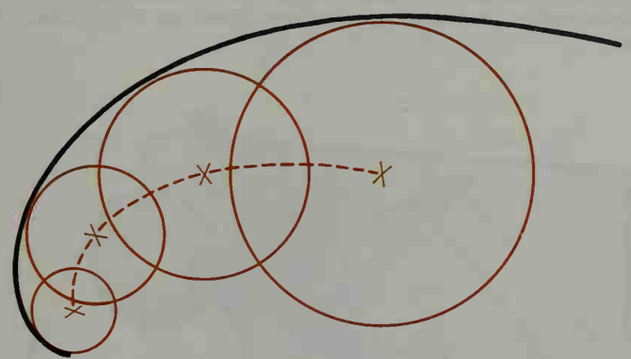
Two points on an ovoid surface may be joined by a curved line across the surface which is the shortest distance between the

points (as when a thread is tightly stretched between them). Such a line has been termed a *chord*, and it is distinct from any other, longer, curved line joining the points, which is an *arc* (4.8)—*see* MacConaill and Basmajian (1977). Obviously, any point moving across an ovoid surface traces either a chordal or an arcuate path (or a succession of these)—these will be considered further below.

The terms chord and arc as used in the present context may be unfamiliar (more commonly they refer to a chord or an arc *of a circle* on a plane surface in Euclidean geometry). To assist understanding, one may imagine two points on a plane but deformable surface. The two points may be joined by the shortest route between them which is of course a straight line—in this application—a *chord* (or *geodesic*). In a general sense *any* longer route between them may be called an *arc* (or *non-geodesic*). The surface with the points and lines drawn upon it may now be deformed in any number of ways (e.g. into a sphere, cylinder, or ovoid or sellar surfaces) but the relationship of the shortest route between the points (chord or geodesic), and longer routes (arcs or non-geodesics) is of course preserved.

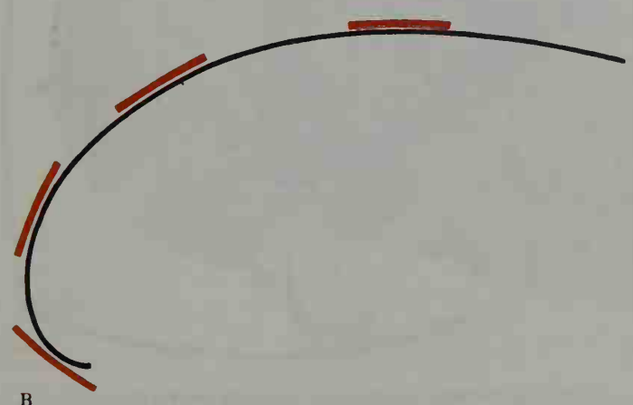
4.7 The two fundamental geometric types of articular surfaces. (A) Ovoid, which may be convex (male) or concave (female). Note that the solid body illustrated presents ovoid profiles in two planes at right angles and that the curvatures of the two may be different. (B) Sellar or saddle-shaped surfaces, which are concavo-convex. In practice both types of surface may vary from only slightly, to highly curved. Thus ovoid surfaces may be 'almost flat' or 'almost spherical', but the majority show intermediate grades of curvature, and much variation in change of radius from place to place.

4.8 Geometric paths across ovoid surfaces, and three-sided figures enclosed by such paths.



A A chord (the shortest path between two points), and one example of an arc (any longer path between the points), are illustrated.

B A triangle—enclosed by three chords.

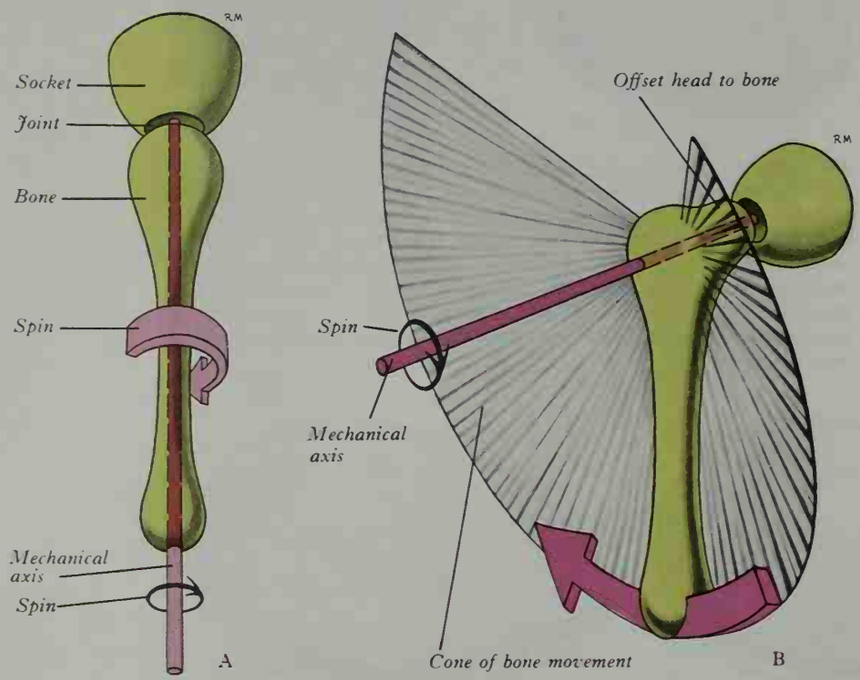


C A trigone—a three-sided figure in which one or more sides is an arc.

The figure enclosed by three chords is termed a *triangle* (4.8), and the sum of its angles exceeds 180° on an ovoid surface, is less than 180° on a sellar surface, and is, of course, precisely 180° if the surface is flat. It is clear that the amount that this sum deviates from 180° depends upon the degree of curvature of the surface, and this is of importance in joint movements (*vide infra*). Any other three-sided figure in which at least one side is an arc, is called a *trigone*.

Examination of the profile of a longitudinal section through an ovoid surface (4.9A) reveals two properties of importance in joint mechanics. Firstly, the radius of curvature of the surface varies continuously across the profile, which may be considered as being formed of a series of short segments of circles of changing diameter; the line joining their centres is known as the *evolute* of the profile. Clearly, the rotation of a body sliding across such a profile cannot be referred to any single axis, but to successive points on the evolute. Secondly, if we consider a more extensive male ovoid surface, and a smaller segment of a similarly curved female surface slides across it (4.9B), it is evident that the two will only fit perfectly in one position (cf. the close-packed position of a joint, described below). In all other positions, the surfaces are not congruent, the area of contact between them is greatly reduced, and elsewhere, wedge-shaped intervals separate the two. (Theoretically, in a 'perfect', incompressible ovoid, the contact would be linear, but in practice it is an *area* because of the fine undulations of the surface—p. 426—and the compressibility of articular cartilage.)

4.9A The profile of a section through an ovoid surface showing that it may be considered as a series of segments of circles of changing radius. The line joining the centres of the circles is the evolute of the profile.



4.9B A small section of an ovoid profile in various positions, in relation to a more extensive profile—the two fit perfectly (i.e. are fully congruent) in only one position.

The Mechanical Axis of a Bone

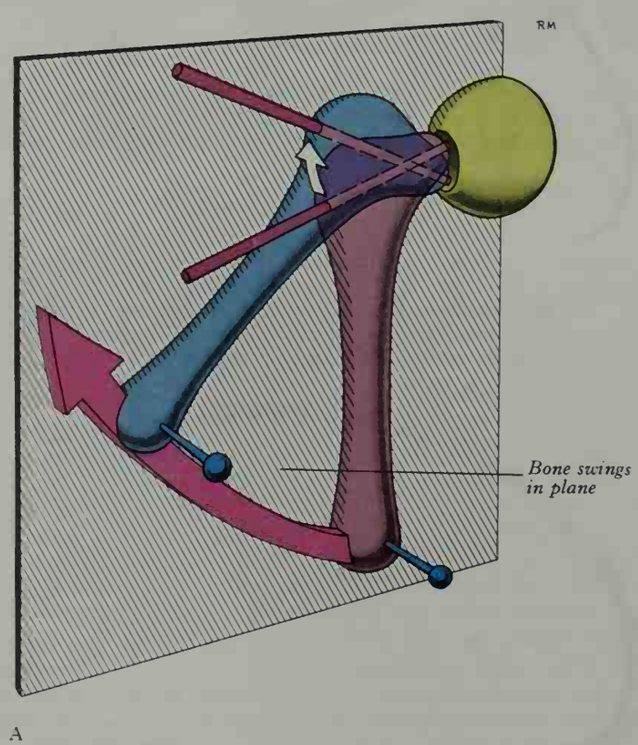
Bones are irregular in shape and in general their articular surfaces bear no simple symmetrical relationship to the rest of the bone. Because of this, comparison of the movements of individual *bones* may be quite misleading in terms of the *joint mechanics* involved, and for this reason, to allow more effective comparisons, the concept of the *mechanical axis* has been introduced. This is perhaps understood more easily by reference to illustrations

4.10A and B. In A, a hypothetical simple, symmetrical long bone is illustrated and it has a terminal joint in the mid-position of its ranges of movement. A rod passes through the bone and ends perpendicular to the centre of its articular surface. This constitutes its mechanical axis, and it can effectively replace the bone when *movements* are being considered. This is particularly obvious, because in this special case of symmetry, it coincides with the long dimension of the bone. In B, however, the bone is not symmetrical, but the joint is again in its mid-range and the mechanical axis is again shown. It is clear that similar *articular movements* will result in similar displacements of the mechanical axis, but that the accompanying movements of the remainder of the bone may appear dissimilar. However, despite the usefulness of the concept of a mechanical axis in some contexts, in others it is less so, because of the somewhat arbitrary choice of a 'central point' on the articular surface which is difficult to define with precision. (The chosen axis would, perhaps, be better defined as that around which the *most habitual conjunct rotation* occurs, and the limiting position of which is the *close-packed* position of the joint under consideration—*vide infra*.) Again, in the case of spheroidal multi-axial joints, the definition of a *single* mechanical axis may be an insufficient reference system for the many movement combinations which are possible.

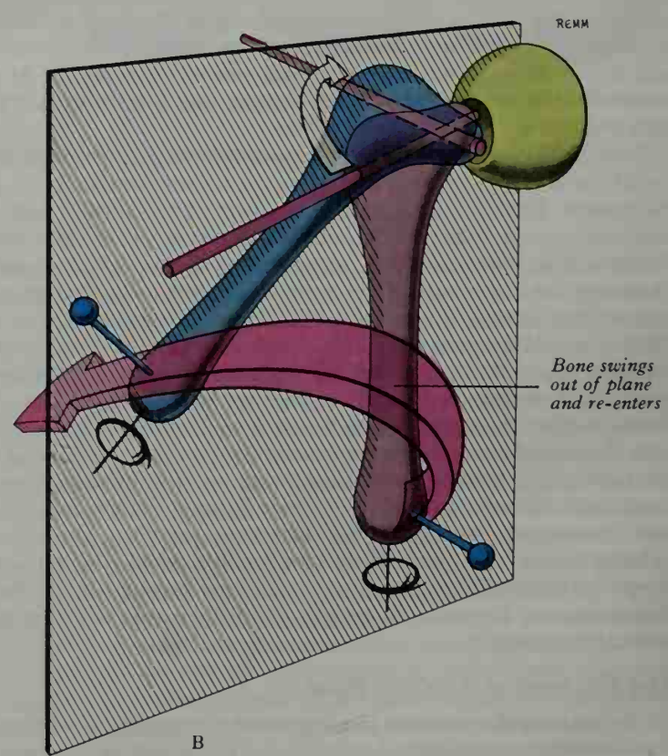
4.10 The mechanical axis.

A In a hypothetically simple, symmetrical long bone, with a terminal joint. A 'spin' is occurring around this axis.

B In a bone with an offset head. A similar 'spin' is occurring between the articular surfaces, but the shaft of the bone traces part of the surface of a cone.



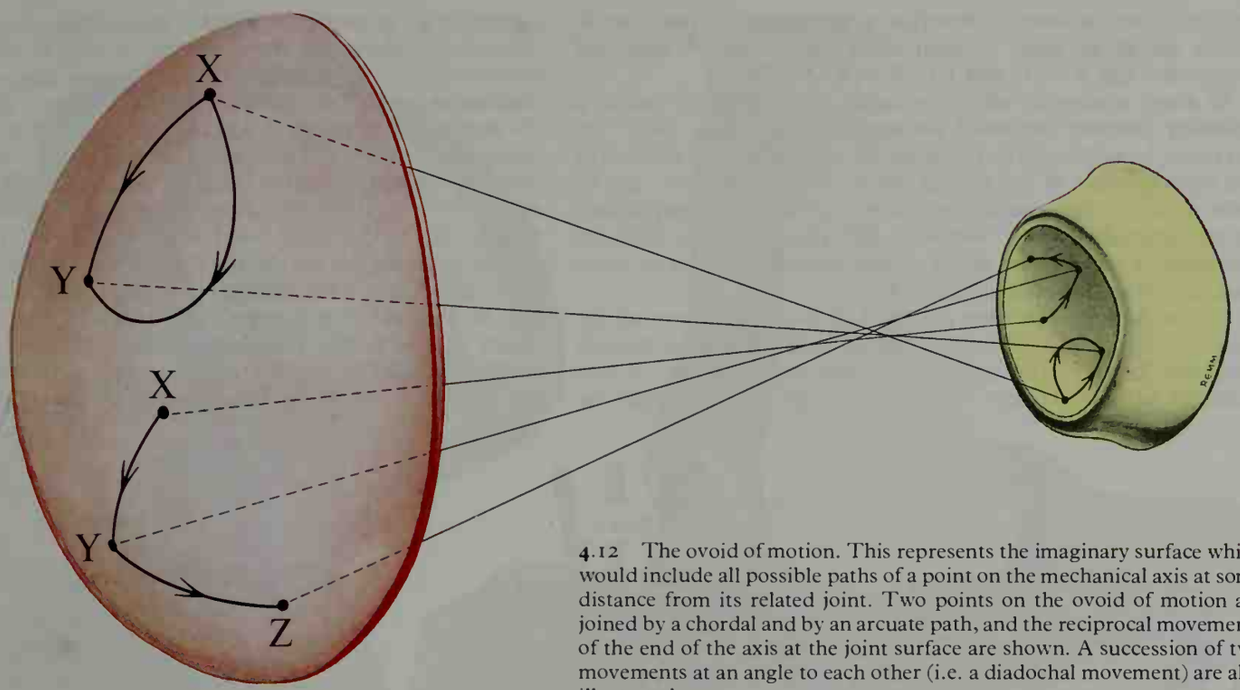
Movements of Bones



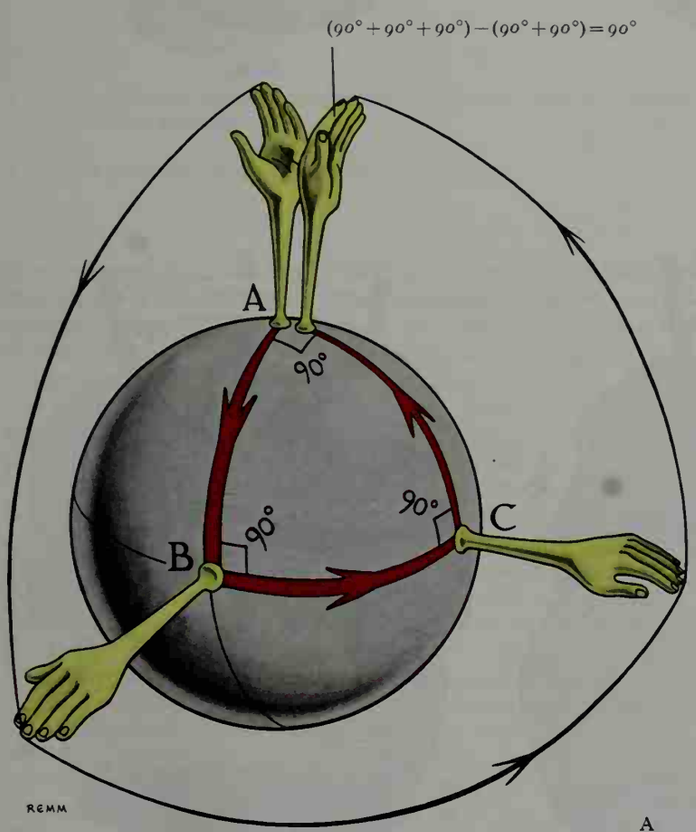
Apart from certain passive accessory movements of bones caused by the application of external forces (p. 437), all other movements are forms of rotation, and since the word 'rotation' is often used in a restricted sense in conventional anatomy (p. 431), new terms have been introduced in more advanced treatments of the subject.

Any bone which is simply rotated around its stationary mechanical axis has been said to undergo a pure *spin*, and clearly, any point on the bone or its articular surface, outside the axis, describes the arc of a circle, with the axis as its centre (4.10).

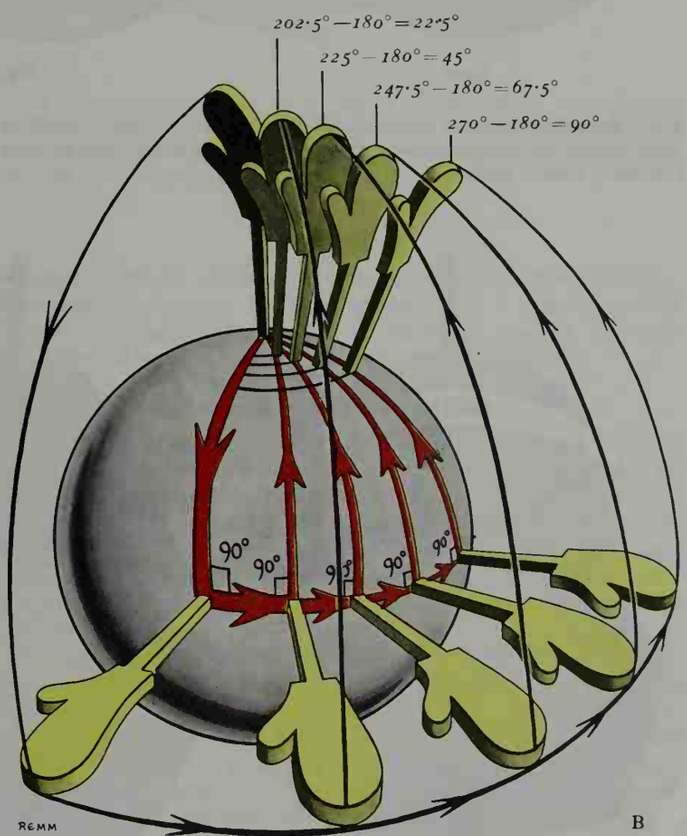
All other displacements of the bone and its mechanical axis are termed *swings*, and these may be *pure* (4.11A), or *impure*, when an element of spin is also present (4.11B). (However, it should be realized that although the mechanical axis is a useful concept, in a spheroidal joint, pure spin is theoretically possible around a large number of alternative 'mechanical axes'.)



Another useful concept when considering positional changes of a bone, is the so-called *ovoid of motion*. During any swing, a point on the mechanical axis of the bone some distance from its related joint, will describe a curved path in space, and if all such possible



4.11 Further movements of the bone and joint shown in 4.10B.
A A cardinal swing. Note that the mechanical axis moves in one plane (its proximal end traces a chordal path at the joint, and its distal end a chordal path on the ovoid of motion—*see* 4.12). There is no spin.

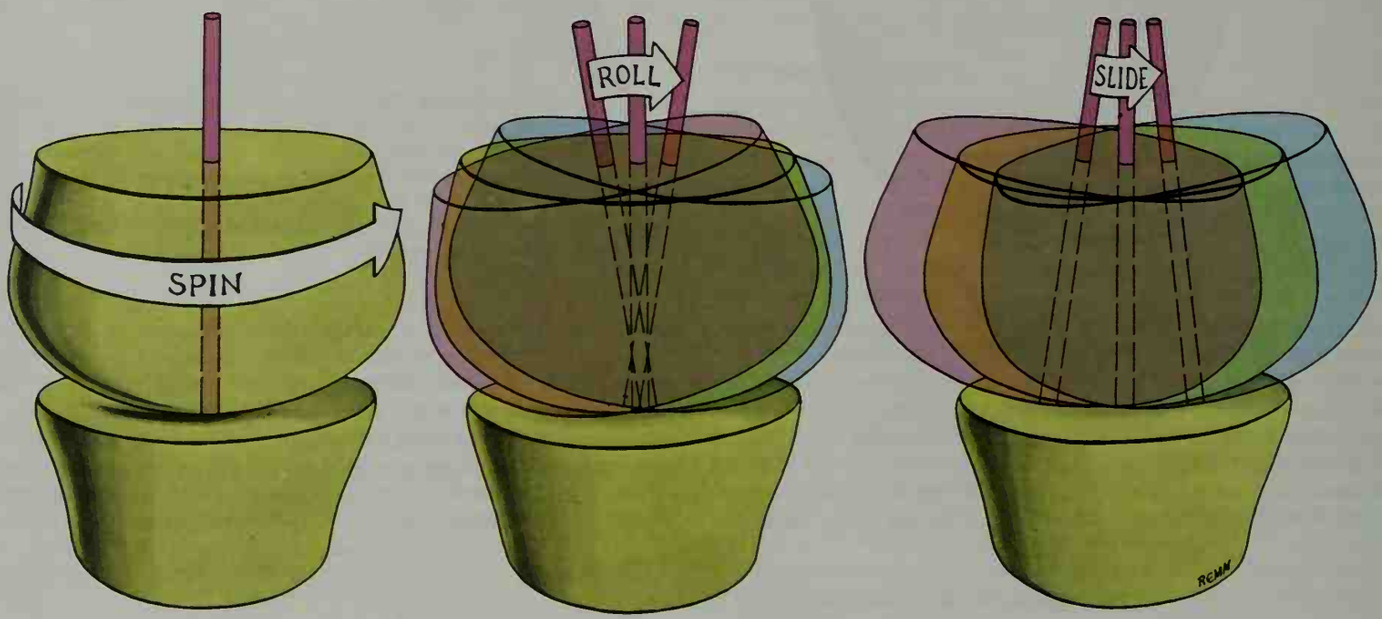


B An arcuate swing. Note that the bone moves out of the plane illustrated and then returns to it. The ends of the mechanical axis trace arcuate paths at the joint and on the ovoid motion. There is an associated spin or conjunct rotation around the mechanical axis (and a rotation around the long axis of the bone shaft).

4.12 The ovoid of motion. This represents the imaginary surface which would include all possible paths of a point on the mechanical axis at some distance from its related joint. Two points on the ovoid of motion are joined by a chordal and by an arcuate path, and the reciprocal movements of the end of the axis at the joint surface are shown. A succession of two movements at an angle to each other (i.e. a diadochal movement) are also illustrated.

paths are considered, they are found to fall upon part of the surface of an ovoid (4.12). The area and shape of such ovoids of motion will of course vary greatly with individual bones and articular surfaces. During any particular swing, therefore, the point on the mechanical axis will move from position X to position Y on the ovoid of motion, either along a chord (i.e. the shortest distance, a so-called *cardinal swing*), or it may take a longer route from X to Y during an *arcuate swing*. At the same time, the articular end of the axis is tracing a reciprocal chordal or arcuate path across its neighbouring joint surface. An important consequence of these distinct kinds of swing relates to the presence or absence of any associated spin of the bone. During a single cardinal swing along a chord (in practice an unusual kind of movement), there is *no associated spin* of the bone. In an arcuate swing, however, there is inevitably an associated spin of the bone, which is of functional importance (*vide infra*). Similarly, a spin is

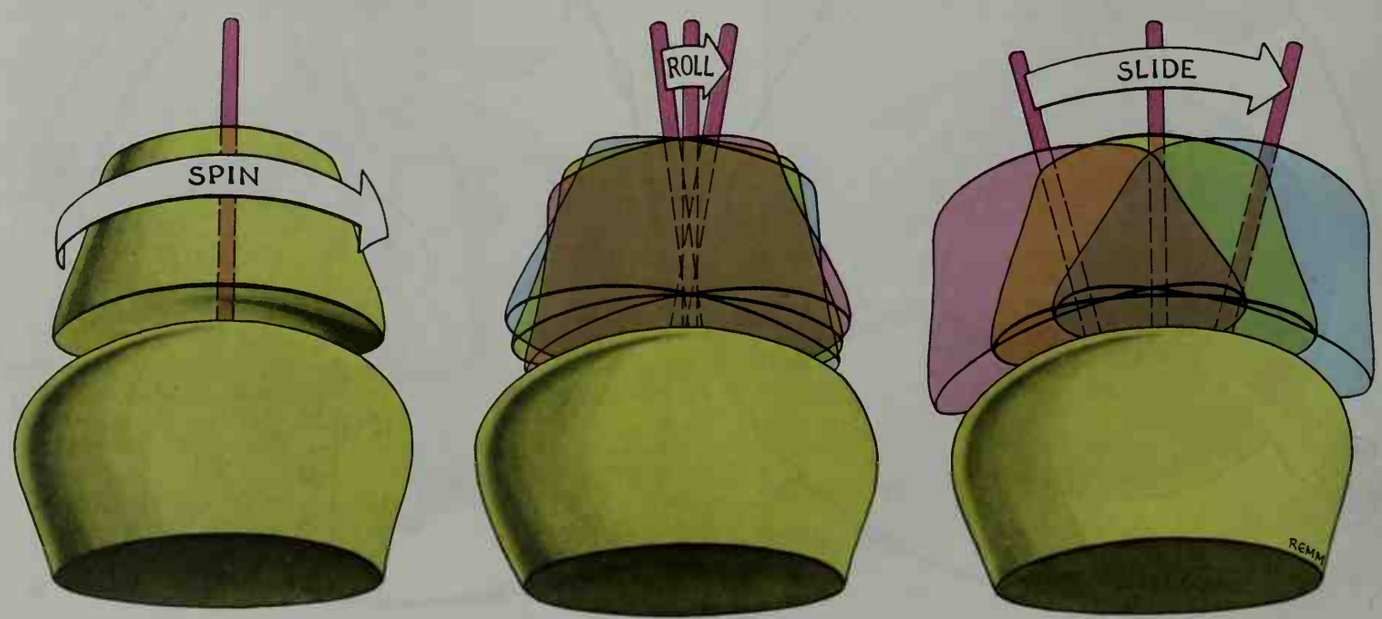
4.13 The 'spin' or conjunct rotation which accompanies a diadochal movement. A model hand and arm moves over the surface of a sphere, first along a line of longitude, then one of latitude to return along a line of longitude.



A The arm traverses three chordal paths which enclose a 'triangle' with three right angles (i.e. the sum of the angles = 270°). Note that as it passes along the line of latitude from B to C, a spin of 90° is imparted.

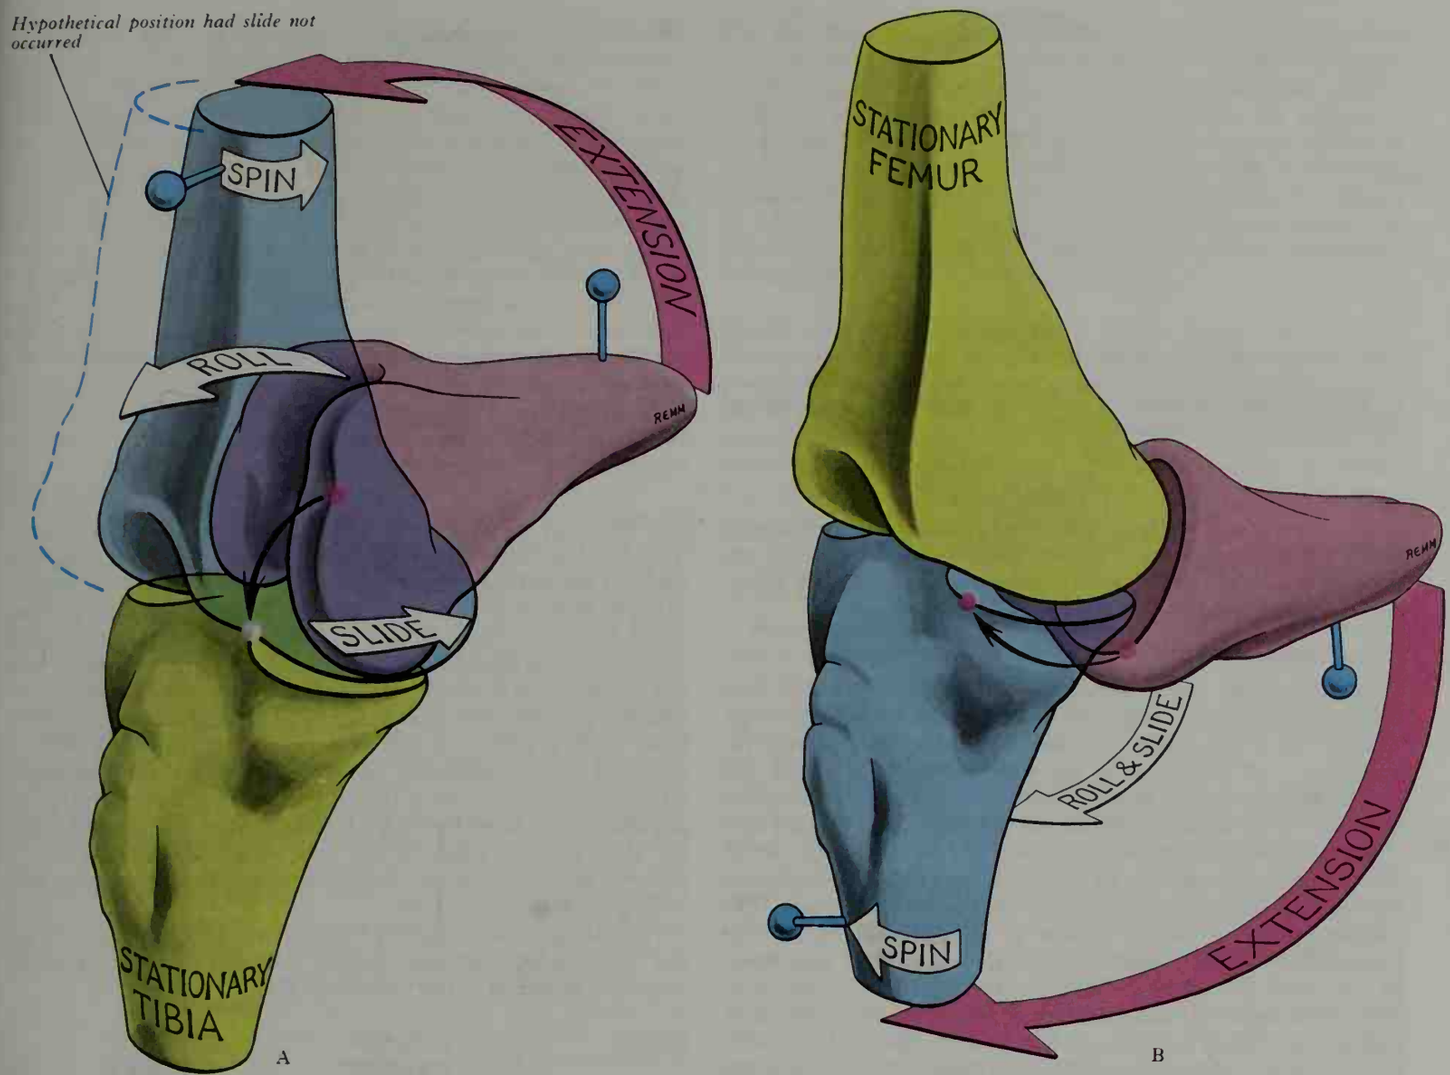
B This illustrates how the amount of spin imparted during a diadochal movement varies with the length and angulation of the second stage of the movement.

present if the movement involves a succession of two chords which are at an angle to each other (one form of *diadochal movement*), e.g. X to Y, and Y to Z, in **4**.12.



In some apparently single swinging movements of bones, a spinning element remained unsuspected for many years. Its presence, however, can be predicted by a mathematical analysis of the consequences of the curved nature of joint surfaces, and in most instances they can be verified by careful simple inspection, or by cineradiography. Whilst a full review of the relevant geometry is beyond the scope of this volume, a series of basic diagrams may assist understanding.

In illustration **4**.13A three points, A, B and C are shown on the surface of a sphere, and the lines AB, BC, and CD are the shortest distances between the points (i.e. they are chords). In this instance AB and AC are 'lines of longitude' and they cut the equator at 90° at the points B and C. A model hand and arm moves successively along the three chords, A→B, B→C, C→A and examination of its initial and final postures shows that it has undergone a spin of 90° (i.e. the number of degrees that the sum of the angles of the 'triangle' ABC *exceeds* 180°). Fig. **4**.13B shows intermediate 'lines of longitude' and in each case it will be seen that the amount of spin is equal to the sum of the three angles minus 180°. A rigorous mathematical proof shows that simple relationship holds for all ovoid or sellar surfaces. The spin is of course imparted during the B→C movement (i.e. along a second chordal path which is at an angle to the first path). An arcuate path may be thought of as compounded of a series of chordal paths which change angle. These spins which inevitably accompany certain varieties of swing are termed *conjunct rotations* and are characteristic of movements at both sellar joints and the majority



A Spin. B Roll. C Slide.

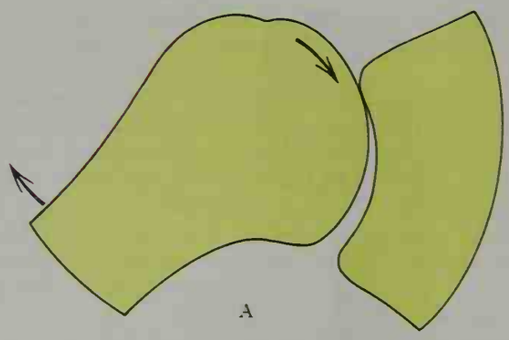
A Spin. B Roll. C Slide.

4.15 Articular movements—a female surface moves on a stationary male surface.

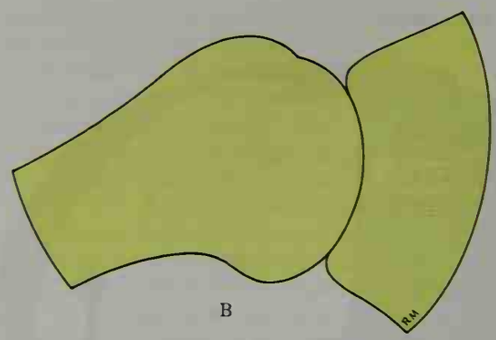
4.16 An analysis of the articular movements which are combined during extension at the knee joint.

A With a stationary tibia, i.e. a moving male surface.

B With a stationary femur, i.e. a moving female surface. Notice that in each case elements of slide, roll and spin occur together. In A the roll and slide are in opposite directions, whereas in B they are in the same direction. *See* text for further description.



of movements at ovoid joints. It has been shown that the *habitual* movements at *all* joints are always accompanied by some degree of conjunct rotation, and an important consequence of this can be best appreciated after the brief consideration of the related types of movement and 'fit' of the articular surfaces (*vide infra*).



The fundamental arthrokinematical considerations that explain concepts of *conjunct rotations* that *necessarily* accompany particular movements or successions of movements, at a joint has been noted in the foregoing paragraphs. Any other rotation of the bone (resulting from the interplay of gravity, additional externally applied forces, and muscle action) is defined as an *adjunct rotation*. Such adjunct rotations are restricted to joints with two or more degrees of freedom, and they may either involve a bone that is undergoing *no* simultaneous conjunct rotation, or one in which the latter *is* to be considered. In the first case, the factors causing the adjunct rotation may, of themselves, generate a *pure spin* of the bone. In the second case, the effects of the adjunct rotation may be of the *same sense* (e.g. both may be 'clockwise' when viewed from a particular aspect), i.e. the effect of the adjunct rotation additive, increasing the rotation, and it is thus termed a *cospin*. Alternatively, the adjunct rotation may be of the *opposite sense*, reducing or completely nullifying the effect of the conjunct rotation; such adjunct rotations are termed *antispins*. Thus a bone which is embarking upon one or a succession of arcuate swings which, if unmodified, would involve some degree of conjunct rotation, may also be subjected to a *nullifying antispin*: the latter may occur *gradually*, being applied throughout the evolution of the movement, or *suddenly*, near its termination. It will be clear, therefore, that whilst the *path* of the bone is a more or less complex *arcuate* swing, it is so modified that it becomes *quasichordal* because there is no net accompanying spin.

Movements at Articular Surfaces

When considering some general properties of ovoid surfaces (p. 433) it was seen that in one position only do the surfaces fit together precisely. This occurs at the end of the most common excursion of the joint and is but one important feature of the close-packed position of a joint discussed below. In all other positions the surfaces are a poor fit and the joint is said to be loosely-packed. These changes in congruity are illustrated with reference to the shoulder joint in 4.17.

Provided the surfaces are ill-adapted, any relative movement between two articular surfaces can be analysed into three basic components, namely, spin, slide and roll. It is convenient to consider these in two circumstances, firstly with a concave, female surface moving over a stationary male surface, and vice versa—reference to illustrations 4.14, 15, should make the distinction between these components clear. However, in most actual movements these are combined in various ways (4.16A, B). It can be seen that with a moving male surface, slide and roll occur simultaneously in *opposite* directions, whereas with a moving female surface they occur in the *same* direction, and these combinations increase the amount of angulation possible without increasing the size of the articular surfaces.

4.17 Congruence of articular surfaces.

A In loose-packed positions of a joint, the surfaces are not congruent (this has been over-emphasized for clarity).

B The close-packed position of the joint, with close-fitting, or full congruence, of the surfaces.

The significance of these various types of articular movement and variations in congruity are best considered in relation to the two fundamental states which a joint may assume, namely 'loose-pack' and 'close-pack'.

Joint Positions

It has been seen that a mating pair of ovoid or of sellar joint surfaces are perfectly congruent in only one position of the joint. This occurs at one extreme of the *most habitual movement* of the joint (e.g. full extension in the case of the knee, wrist and interphalangeal joints, dorsiflexion at the ankle, and abduction combined with lateral rotation at the shoulder joint). As this state of full congruence is approached, other important changes occur. The points of attachment of the fibrous capsule and ligaments become increasingly separated and their tension increases. The conjunct rotation which occurs in all habitual movements increases this effect by imposing a spiral twist on these structures. In the final position of **close-packing** therefore, the joint surfaces become fully congruent, their area of contact is maximal, and they are tightly compressed, having in a sense been 'screwed-home', whilst the fibrous capsule and ligaments are maximally spiralized and tense, and no further movement is possible. In a close-packed joint the surfaces cannot be separated by distractive forces (as they often can in other positions) and the two articulating bones can be regarded as temporarily locked together, as if they had no joint between them. Such an extreme position is only assumed when a special effort is to be undertaken and, because of the rigidity of the position and the enormous stresses which may be generated, the articular structures are maximally liable to trauma.

Whilst the close-packed position is a final, limiting position of a joint and any force which tends to further change the position is actively resisted by reflex contraction of the appropriate musculature, the final stages of the movement *just short* of close-packing are physiologically of great importance. Ligaments and articular cartilage are, as we have seen, to a small degree elastically deformable tissues, and in these final stages the actual position taken up by a joint is an equilibrium in which the external torque applied to the joint (often the effect of gravity) is balanced by the resistance to further deformation of the joint by the stretched and twisted capsule and the compressed articular surfaces. Thus, in symmetrical easy-standing the knee and hip joints approach their close-packed positions sufficently to maintain the erect posture with the minimal expenditure of muscular energy (Joseph 1960).

In all other positions of the joint, the articular surfaces are not congruent and some parts of the articular capsule are lax—the joint is said to be **loose-packed**. The laxity of the capsule is sufficient in many cases near the mid-range of joint movement to allow a separation of the articular surfaces by an externally applied distractive force. The ill-fitting of the surfaces (in which the male surface has a smaller radius of curvature than the female) is advantageous in a number of ways. Firstly it is necessary to allow the combined elements of spin, roll and slide, which characterize most movements at joints. Secondly, the contact area between the surfaces is greatly reduced, and frequently changing, and this may well diminish the frictional and erosive effects. Thirdly, the small wedge-shaped intervals which separate the surfaces around the contact area are filled with a small volume of synovial fluid, and their shape has been proposed as an important factor in maintaining efficient joint lubrication and nutrition of the avascular articular cartilages. Finally, it should be noted that the combination of simultaneous sliding and rolling movements of articular surfaces increases the effective range of movement at a joint. With a slide or a roll alone, such a range could only be achieved by considerably more extensive articular surfaces. Reference to illustration **4**.16 will make it clear how the range of angulation of a bone bearing a female surface is increased when the slide and roll occur in the *same* direction, whereas with a moving male surface the increased range follows sliding and rolling in *opposite* directions.

According to one authority (MacConaill and Basmajian 1977) the close-packed and least-packed positions of some principal joints are as shown in the following table:

JOINT	CLOSE-PACKED POSITION	LEAST-PACKED POSITION
Shoulder	Abduction + lateral rotation	Semiabduction
Ulnohumeral	Extension	Semiflexion
Radiohumeral	Semiflexion + semipronation	Extension + supination
Wrist	Dorsiflexion	Semiflexion
Metacarpophalangeal (2–5)	Full flexion	Semiflexion + ulnar deviation
Interphalangeal (fingers)	Extension	Semiflexion
First carpometacarpal	Full opposition	Neutral position of thumb
Hip	Extension + medial rotation	Semiflexion
Knee	Full extension	Semiflexion
Ankle	Dorsiflexion	Neutral position
Tarsal joints	Full supination	Semipronation
Metatarsophalangeal	Dorsiflexion	Neutral position
Interphalangeal (toes)	Dorsiflexion	Semiflexion
Vertebral	Dorsiflexion	Neutral position

Whilst general concepts such as the foregoing have greatly increased our knowledge of general joint mechanics, many aspects of joint lubrication, the maintenance of normal articular cartilage, and the detailed mechanics of many individual joints still await resolution (*see*, for example, Freeman 1973).

Accessory movements. The movements which can be performed actively at any joint do not necessarily include all the

movements which the structure of the joint would permit. Certain movements which cannot be performed voluntarily can nevertheless be produced when resistance is encountered to active movements (accessory movements, first type), e.g. it is only when some solid object, such as a cricket ball, is grasped in the hand, that the fingers can be rotated at the metacarpophalangeal joints (*see* p. 472). Other movements can be produced only passively (accessory movements, second type) and their widest range is obtained when the muscles acting on the joint are fully relaxed, e.g. when the supported arm is partially abducted at the shoulder joint, a distractive force can draw the humerus away from the glenoid cavity, and this is characteristic of many joints when they are in a loose-packed position. Such movements are commonly termed 'passive movements', but as all movements, whether active or not, can be performed passively when the muscles concerned are relaxed, the term 'accessory movements' will be used to designate all movements which cannot be performed actively in the absence of resistance (Salter 1955).

Limitation of movements is effected by a number of different factors, of which the tension of ligaments is very important, as can be seen when attempts are made to produce hyperextension of the dissected knee or hip joints, and as we have seen (p. 438) increasing ligamentous tension is an integral factor in producing the close-packed position of a joint which limits its most habitual movement. In life, however, the tension of the muscles which are antagonistic to the movement is equally important as a limiting factor. The latter involves both the *passive elastic component* of the muscles (and the other soft tissues which cross the joint) and the *reflex contraction* of the appropriate musculature which occurs when the stimulation of mechanoreceptors in the articular and periarticular tissues reaches a critical level. The part played by muscles in limiting movement is well seen in flexion of the hip joint. When this movement is performed with the knee extended, it is much more limited in range than when it is performed with the knee flexed. In the latter case flexion of the knee relaxes the hamstring muscles, and this permits the thigh to be flexed until it comes into contact with the anterior abdominal wall. The movement is then limited by *the approximation of the soft parts concerned*—a third factor which is present in connexion with some other movements, e.g. flexion of the elbow and knee. Similarly, contact of the teeth obviously limits elevation of the mandible.

In synovial joints, where the bones concerned are connected by ligaments and muscles only, some part of their articular surfaces are in constant apposition in all positions of the joint. (Some authorities maintain that 'apposition' in this sense implies a fine film of synovial fluid between the adjacent surfaces of about 10 μm *or less*.) The maintenance of this apposition is assisted by atmospheric pressure and by cohesive forces between the articular surfaces, but these factors are merely subsidiary to the influence exerted by the balanced contraction of the various muscle groups which cross the joint. When such muscles contract the force generated may be resolved (vectorially) into various components (*see* p. 528). Some are directed towards maintaining or altering the three-dimensional positions of the bones ('swing' and 'spin' components), and oppose any internal and external resistances, including, on occasion, the effects of gravity. Another component of the force is termed *transarticular* (the 'shunt' component), and it increases the compression between the articular surfaces and helps to maintain their apposition in various postures, and during movement. (See also p. 528.) The reader should also note, however, that the effects of externally applied compressive or tensile forces, including gravity, will vary greatly according to the particular posture of the whole body and its various members in space, and the direction of the applied force. Thus, for example, gravity or load bearing may, on occasion, provide a *distractive force* tending to separate the conarticular surfaces, alternatively they may predominantly exert a *translatory/swing* force between the surfaces, and finally, they are often so directed that they, themselves, exert a considerable *compressive force* between the conarticular fellows.

The preceding pages have furnished an elementary introduction to some aspects of the theoretical biology currently engaging kinesiologists. Further brief references to myokinetics will be found on p. 525. For more thorough analyses, the references quoted should be consulted: for readers with a greater facility in mathematics and physics, it will be of considerable interest that attempts are now being made to present a 'generalized mechanics of articular swing', ranging from Aristotelian and Newtonian physics, to embrace relativity theory and quantum mechanics! (consult MacConaill 1978 a, b and c).

Blood supply and lymphatics. Joints receive blood vessels from periarticular arterial plexuses, from which numerous rami pierce the capsular ligament to form a vascular plexus in the deeper parts of the synovial membrane. The blood vessels of the synovial membrane terminate around the articular margins in a fringe of looped anastomoses termed the *circulus articularis vasculosus*. (See also, the blood supply of bones and their epiphyses, p. 257.)

The lymphatics form a plexus in the subintima of the synovial membrane and drain along the blood vessels to regional deep lymph nodes.

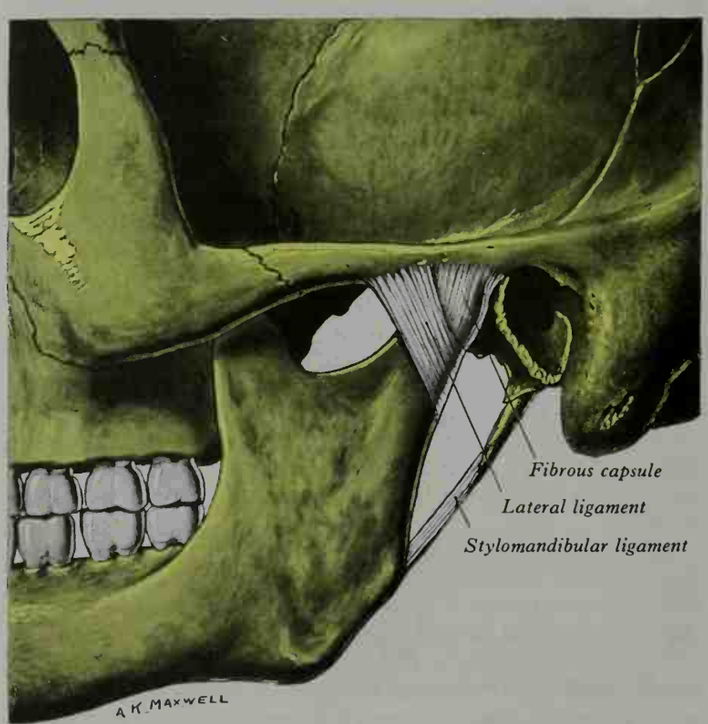
Nerve supply. Movable joints are innervated in general by the nerves of supply to the muscles which act on them, and it is probable that this arrangement establishes local reflex arcs involved both in active movements and postural maintenance. Though the branches concerned vary, each nerve innervates a specific region of the capsule but the territories of supply of adjacent nerves freely overlap. The part of the articular capsule which is rendered taut on the contraction of a given muscle or group of muscles is usually innervated by the nerve or nerves supplying their antagonists (Gardner 1948). For example, the inferior part of the articular capsule of the hip joint, which is put on the stretch in abduction, is supplied by the obturator nerve. Tension of this part of the capsule produces a reflex contraction of the adductor muscles which, usually, is successful in preventing over-stretching or tearing of the ligament. This concept does not hold good for the shoulder joint, where the axillary nerve is described as innervating the antero-inferior part of the articular capsule.

The myelinated fibres in articular nerves terminate in Ruffini endings, lamellated articular corpuscles and endings similar to the neurotendinous endings of Golgi. Free nerve endings are numerous at the attachments of the fibrous capsule and ligaments. They are the terminals of non-myelinated and finely myelinated fibres and are believed to mediate pain sensation (Gardner 1950). The Ruffini endings are orientated in various directions, and in the knee joint they are found principally on the flexor aspect of the fibrous capsule. They respond to stretch and are slowly adapting. The lamellated articular corpuscles are less numerous than the Ruffini endings, placed laterally and are quickly adapting. They respond to rapid movement and vibration. Together with the Ruffini type they register the speed and direction of movement. The Golgi type of end organs are connected to the largest myelinated nerve fibres (10–15 μm diameter), are similar to those at neuromuscular junctions and are slowly adapting (Boyd and Roberts 1953; Boyd 1954; Skoglund 1956). Such articular innervation mediates position sense (Stopford 1921; Mountcastle and Powell 1959; Gardner 1967), and is also concerned in stereognosis—the recognition of shape in objects held in the hand (Renfrew and Melville 1960). Many of the non-myelinated fibres are sympathetic in origin; they terminate in relation to the smooth muscle of blood vessels and are believed to be vasomotor or vasosensory in function but little evidence of this function is available.

In the synovial membrane no special end organs and few free nerve endings are present, apart from those which are associated with the blood vessels. The membrane is relatively insensitive to pain (Kellgren and Samuel 1950; Barnett *et al.* 1961).

(For further histological and functional details, and a proposed classification of nerve endings in joints, *see* p. 858.)

THE INDIVIDUAL ARTICULATIONS



The Temporomandibular Joints

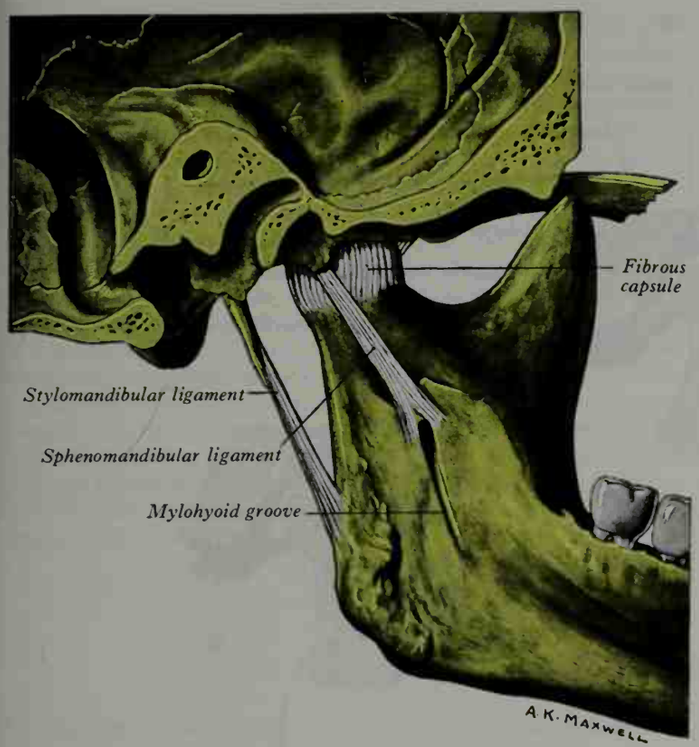
Each temporomandibular joint involves the articular tubercle and the anterior region of the mandibular fossa of the temporal bone above and the condyle of the mandible below. The articular surfaces are covered with a variety of white fibrocartilage in which collagen fibres predominate and cartilage cells are few. An articular disc divides the joint into upper and lower parts. The joint is commonly described as 'condylar' but a preferable term is *ellipsoid*. The right and left joints constitute together a *bicondylar* articulation and they always work in concert.

The fibrous capsule is attached, above, to the articular tubercle in front, to the lips of the squamotympanic fissure behind, and between these two attachments to the circumference of the mandibular fossa; below, to the neck of the mandible. Above the articular disc, the capsule forms a loose envelope, but below the disc it is taut. The **synovial membrane** lines the fibrous capsule. Below it is reflected upwards on the neck of the mandible, and the lateral pterygoid tendon to the margin of the articular cartilage of the condyle.

The lateral temporomandibular ligament (4.18) is intimately related to the fibrous capsule. It is attached, above, to the tubercle on the root of the zygoma, below, to the lateral surface and posterior border of the neck of the mandible. Its fibres are directed obliquely downwards and backwards, covered superficially by the parotid gland.

The sphenomandibular ligament (4.19) is medial to the joint and clearly separated from the articular capsule. It is a flat, thin band attached above to the spine of the sphenoid; becoming broader as it descends, it is fixed to the lingula of the mandibular foramen. Laterally it is related, above, to the lateral pterygoid and the auriculotemporal nerve; lower down, it is separated from the neck of the mandible by the maxillary vessels; still lower, the inferior alveolar vessels and nerve and a lobule of the parotid gland lie between it and the ramus of the mandible, and it is pierced here by the vessels and nerve to the mylohyoid. Medially it is related, below, to the medial pterygoid muscle; above, it is separated from the pharynx by fat and pharyngeal veins and, near its upper end, it is crossed by the chorda tympani. Some of its fibres can be traced through the medial end of the petrotympanic fissure to its primary attachment, the anterior process of the malleus, a vestige of the dorsal extremity of Meckel's cartilage. These fibres are a part of the anterior ligament of the malleus (p. 1198). The ligament is a vestige; its participation in the mechanics of mandibular movement is doubtful.

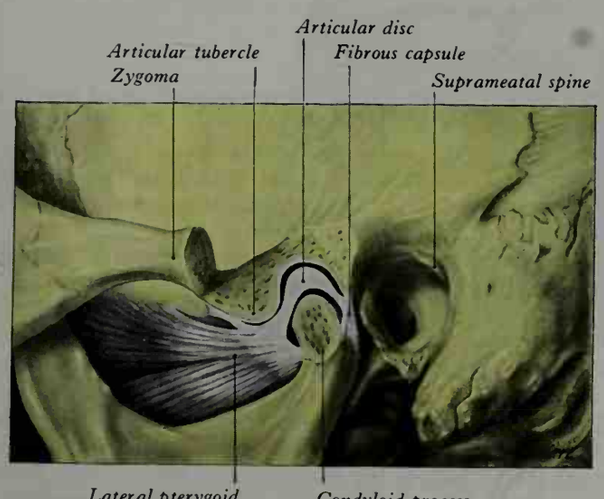
4.18 The left temporomandibular joint. Lateral aspect.



The articular disc (4.20, 21A, B, C) a roughly oval plate consisting of fibrous tissue, which has been likened in general form to a schoolboy's peaked cap, and which completely divides the joint. Its upper surface is saddle-shaped or concavoconvex from before backwards, accommodated to the form of the articular fossa and articular tubercle. Its inferior surface, in contact with the head of the mandible, is concave. Its circumference is connected to the fibrous capsule and, in front, to the tendon of the lateral pterygoid (p. 535). Medially and laterally, short but strong fibrous bands pass from the margin of the disc to the medial and lateral poles of the mandibular condyle. These ensure that the disc and condyle move together during protraction and retraction of the mandible. Posteriorly the disc contains a venous plexus and divides into upper and lower lamellae. The upper lamella consists of fibro-elastic tissue and is attached to the posterior margin of the mandibular fossa. The lower lamella is white fibrous tissue and is attached to the back of the condyle; it is not elastic. It varies in thickness in its different parts and is thickest a little behind its centre, where it occupies the deepest part of the mandibular fossa. A more detailed analysis of the structure of the disc (Rees 1954), has revealed two relatively thick regions (the anterior and posterior bands) with thinner zones intervening. These various subdivisions have been named from before backwards—the anterior extension, anterior band, intermediate zone, posterior band and finally the bilaminar region mentioned above; these are illustrated in lateral and superior view, and in section in illustration 4.21A, B, C. The postnatal development of the disc, up to the age of 21, has been described by Wright and Moffet (1974); at no stage were chondrocytes observed in the disc, which is flat at birth and develops its sigmoid profile as the articular eminence enlarges. The disc shows, from the fifth decade of life onwards, macroscopic evidence of degeneration (from fraying and thinning to actual perforation) so frequently, that such changes can be regarded as 'normal' ageing. Weisengreen (1975) found about 40 per cent of 183 individuals, between the ages of 40 to 90 years, showing such frank degeneration. The disc is often incomplete, being perforated to a variable degree.

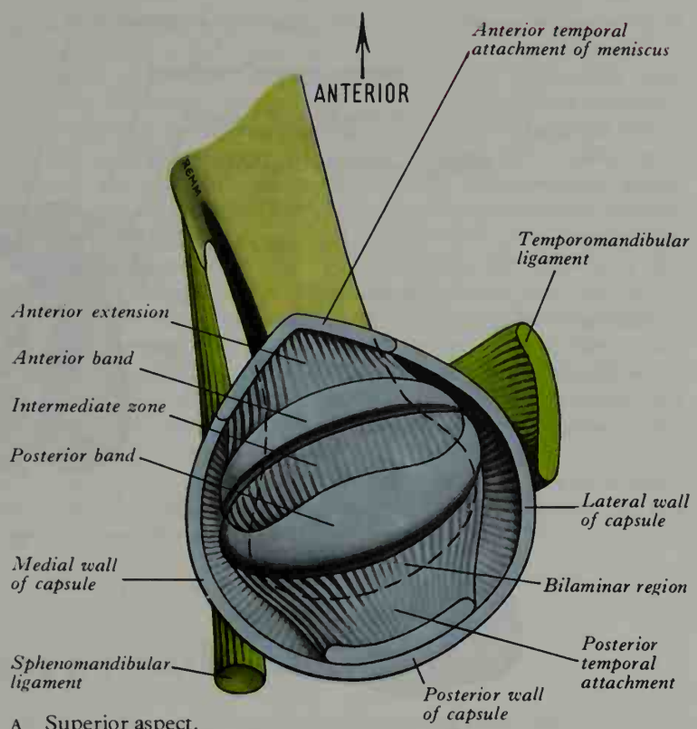
The stylomandibular ligament (4.18) is a specialized band of the deep cervical fascia (p. 537), which stretches from the apex of the styloid process to the angle and posterior border of the mandibular ramus. Although classed among the ligaments of the joint, it can only be considered as accessory and its functional status is uncertain.

The *nerves* of the joint are derived from the auriculotemporal and masseteric branches of the mandibular nerve, the *arteries*, from the superficial temporal and maxillary arteries.

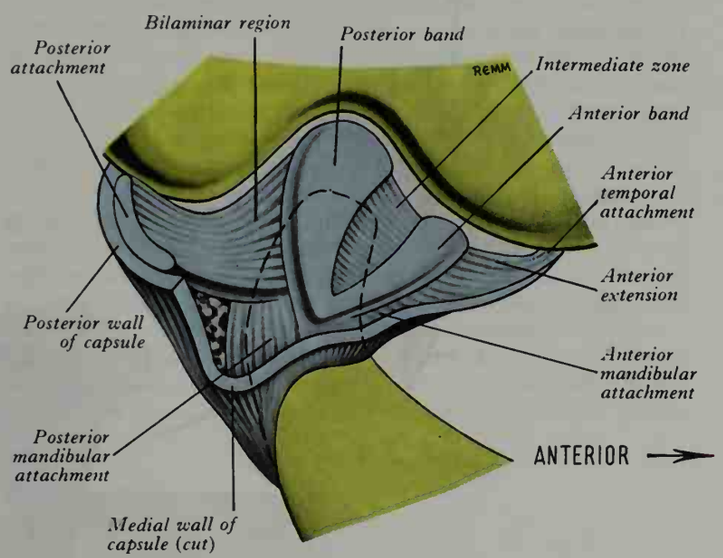


Movements. The mandible may be depressed or elevated, protruded or retracted; a considerable amount of rotation also occurs. These activities involve gliding, spin, and angulation.

In the *position of rest* the teeth of the mandible and maxillae are not in contact but slightly separated. On closure of the jaws the teeth come into apposition in the *occlusal position*. When the mouth is *opened* the mandibular heads or 'condyles' rotate around a common horizontal axis and this movement is then combined with gliding forwards and downwards in contact with the lower surface of the articular discs. At the same time the discs slide forwards and downwards on the temporal bones. This movement results from the attachments of each disc to the medial and lateral poles of the head of the mandible and from the contraction of the lateral pterygoid which carries each head with its articular disc on to the articular tubercle. The forward sliding of a disc ceases when the fibro-elastic tissue attaching it to the temporal bone posteriorly has been stretched to its limit. Thereafter, there is some further hinging and gliding forwards of each head of the mandible until it articulates with the most anterior part of the disc



4.19 The left temporomandibular joint. Medial aspect.



and the mouth is opened fully. In *closure* of the mouth the movements are reversed. In the first phase of this movement each mandibular head glides backwards and then hinges on its disc, which is held forwards by the lateral pterygoid; finally this relaxes gradually to allow the articular disc to glide backwards and upwards on the temporal bone. The sequential changes in the position of disc and condyle during a full cycle of opening and closing the mouth are illustrated in **4**.22, which is derived from observations by Rees (1954). In *protrusion* the teeth are retained parallel to the occlusal position, but variably separated, and the lower teeth are drawn forwards over the upper teeth by both lateral pterygoid muscles. In *retraction* the mandible is drawn backwards to the position of rest. In the rotatory movements of grinding or chewing the head of one side with its disc glides forwards, rotating around a vertical axis which passes immediately behind the head of the opposite side. It then glides backwards rotating in the opposite direction as the head of the opposite side comes forwards in its turn. These alternating movements swing the mandible from side to side (Sarnat 1951). It is important to note that *both* temporomandibular joints are necessarily involved in every jaw movement, forming together a *bicondylar* arrangement. Consult Hylander (1975) for recent literature and discussion.

4.22 The changing relationships of the condyle of the mandible, the articular disc and the articular surface of the temporal bone during one complete opening (A→D) and closing (D→A) cycle of the mouth.

4.21 and 4.22 are based upon Rees (1954) with kind permission of the late Professor J. J. Pritchard, on behalf of the late Leonard A. Rees, and the *British Dental Journal*.

Measurement of the range of mandibular movements is of some clinical importance. In adults the mandibular and maxillary incisors may be separated by 50–60 mm, maximal lateral displacement and protrusion being about 10 mm (Ingervall 1970). There is much individual variation. The full adult range is reached earlier in females (*c.* 10 years) than in males (*c.* 15 years). These observations accord with the postnatal development of the articular profiles of the joint (Wright and Moffet 1974); its adult conformation is established between 6 and 12 years.

Muscles producing the movements.

Depression. Lateral pterygoids; they are aided when the mouth is opened wide or against resistance by the digastrics, geniohyoids and mylohyoids.

Elevation. Temporalis, masseter, medial pterygoid, of both sides. In closing the mouth the head of the mandible is retracted by the posterior fibres of the temporalis and then the mandible is elevated. The temporalis maintains the position of rest (Latif 1957).

Protrusion. Lateral and medial pterygoids.

Retraction. Temporales (posterior fibres). In forcible movements they may be assisted by the middle and deep parts of the masseters, digastrics and geniohyoids.

Lateral movements. Medial and lateral pterygoid (of each side, acting alternately).

A simple listing of muscles, such as the foregoing, fails to convey the fact that, in practice, mandibular movements are the result of complex integrated patterns of simultaneous contraction and lengthening of groups of muscles. Similarly, alternative methods of describing mandibular movements have been proposed (Kraus *et al.* 1969). If all the possible positions of a fixed point on the surface of the mandible are plotted, they form a complex three-dimensional shape (the so-called *envelope of movement*). *Border movements* of the mandible involve movement

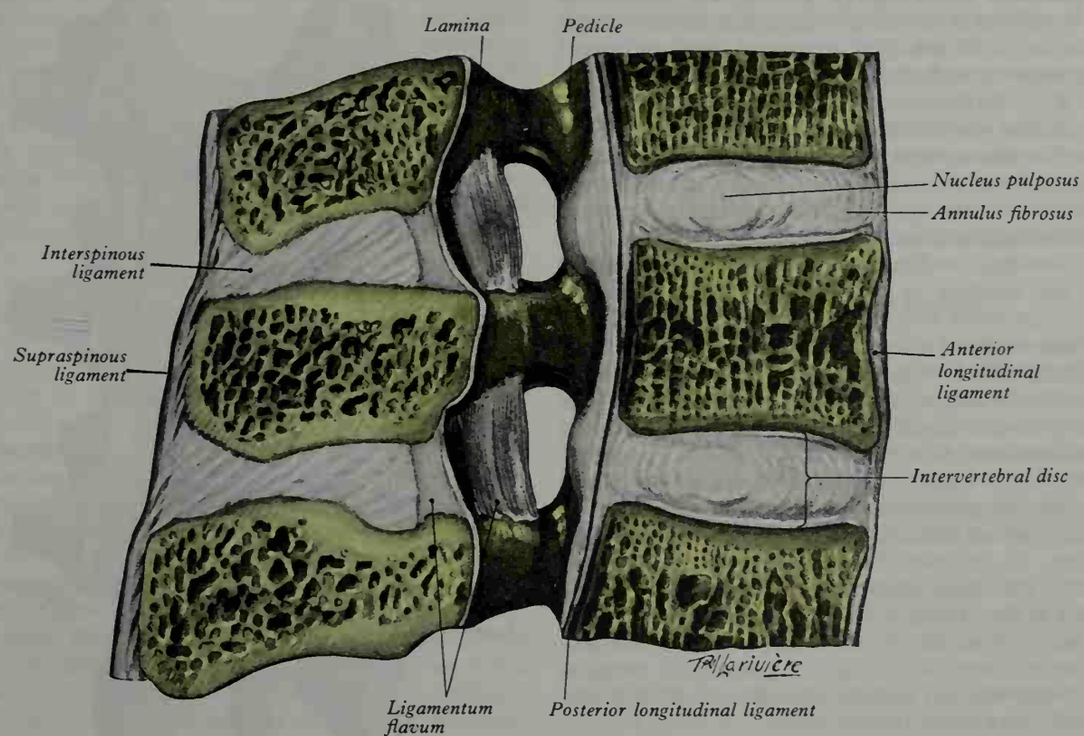
of the fixed point over the surface of the envelope; in *free movements* the point moves within the envelope and in *contact movements* the maxillary and mandibular teeth maintain apposition. For a more detailed analysis of mandibular positions and movements in relation to incision, chewing and deglutition the reader should consult Kraus *et al.* (1969).

Mention must be made of the unresolved controversy concerning the forces transmitted at the temporomandibular joints. A hypothesis that the joints carry no load or, at least, are subject to little transarticular compression during biting has been supported by Wilson (1920), Scott (1955) and others, while later views (e.g. Smith and Savage 1959; Turnbull 1970) are opposed to this. Most of the literature concerns vertebrates other than mammals, and no reliable experimental data are available for man (*see* Gingerich 1971). Biomechanical analysis favours a force-transmitting function (Barbenel 1972), which is supported by experimental observations (on the opossum) by Crompton and Hiiemäe (1969) and (on the cat) by Buckland-Wright (1978). In view of the complex sliding and rotatory activities at the temporomandibular joints, both the above views may be at times correct. It is only concerning almost pure hinge movements of limited extent, as in biting, that any controversy need exist.

Applied Anatomy. The mandible can be dislocated only forwards. When the mouth is open, the condyles of the mandible are on the articular eminences, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace one or both forwards into the infratemporal fossa. Reduction is accomplished by depressing the jaw with the thumbs placed on the last molar teeth, and at the same time elevating the chin. The downward pressure overcomes the spasm of the masseter, temporal, and pterygoid muscles, and elevation of the chin throws the head of the mandible backwards. Derangement of the articular disc may follow trauma, overclosure of the mouth with backward displacement of the head of the mandible or malocclusion, and results in clicking and pain on movement of the jaw. In operations on the joint care must be taken to preserve the branches of the facial nerve overlying it.

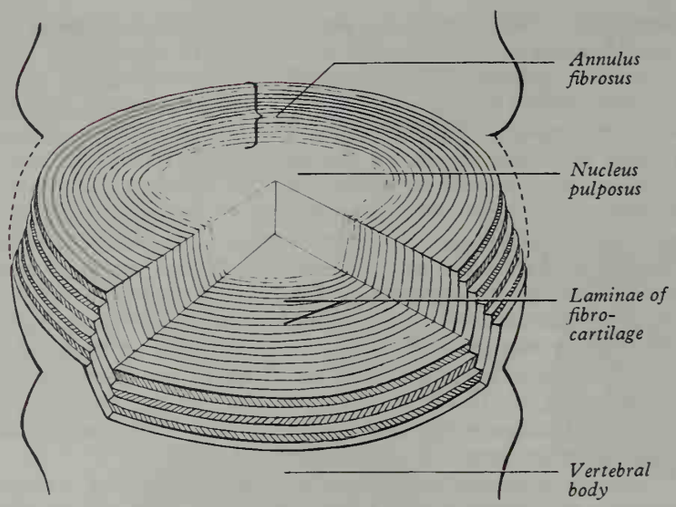
Changes in the occlusal relationships of the teeth lead to small degrees of remodelling of the articular surfaces of the temporomandibular joints (Moffet *et al.* 1964).

THE JOINTS OF THE VERTEBRAL COLUMN AND THORAX



The vertebrae from the second cervical to the first sacral inclusive are articulated to one another by a series of cartilaginous joints between the vertebral bodies, and a series of synovial joints between the vertebral arches (**3**.35, 38, 42).

The Joints of the Vertebral Bodies



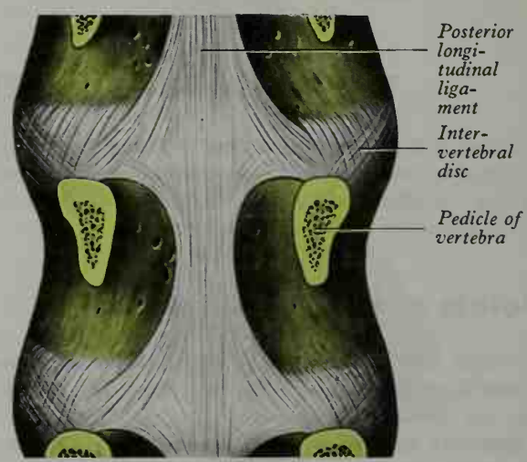
The vertebral bodies are united by anterior and posterior longitudinal ligaments, and by intervertebral discs of fibrocartilage; they are classed as symphyses.

The anterior longitudinal ligament (**4**.23A) is a strong band which extends along the anterior surfaces of the vertebral bodies. It is broader below than above, thicker and narrower in the thoracic than in the cervical and lumbar regions, and somewhat thicker and narrower opposite the bodies of the vertebrae than opposite the intervertebral discs. It is attached, above, to the basilar part of the occipital bone, from which it extends to the anterior tubercle of the atlas, then to the front of the body of the axis and is continued down as far as the upper part of the front of the sacrum. It consists of longitudinal fibres, firmly fixed to the intervertebral discs and to the margins of the vertebral bodies, but loosely attached at intermediate levels of the bodies. In the latter situation the ligament is thick and fills up the concavities on the anterior surfaces, and makes the profile of the vertebral column flatter (**4**.23A). It is composed of several layers of fibres, of which the most superficial are the longest and extend over three or four vertebrae. The intermediate fibres extend between two or three vertebrae, while the deepest reach from one vertebra to the next. At the sides of the bodies the ligament consists of a few short fibres which connect adjacent vertebrae.

The posterior longitudinal ligament (**4**.23A, 24A) is inside the vertebral canal on the posterior surfaces of the bodies of the vertebrae. Above, it is attached to the body of the axis, and is

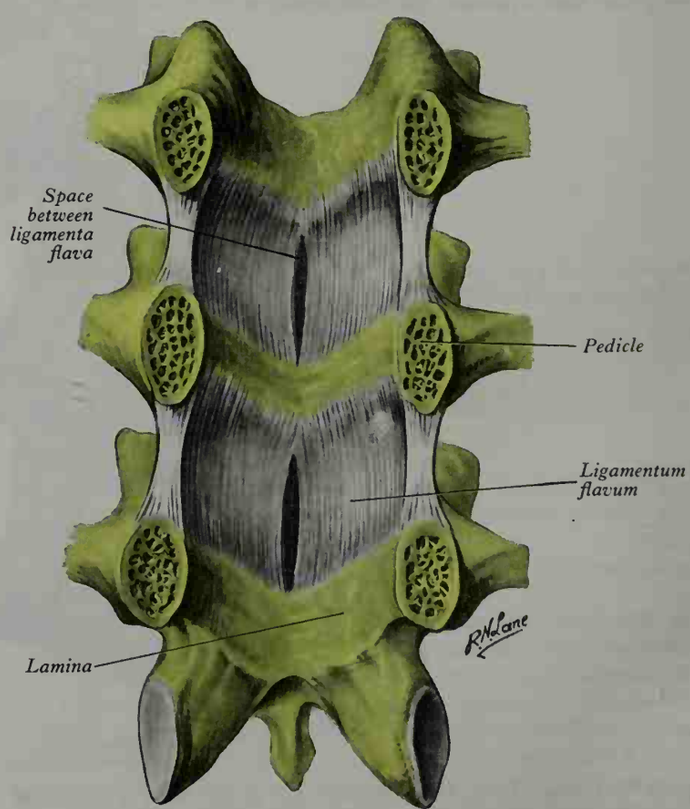
4.23A A median sagittal section through part of the lumbar region of the vertebral column. For contrasting details concerning the direction of fibre bundles in the interspinous ligaments *see* text and Heylings (1978).

4.23B A simplified schema of the main structural features of an intervertebral disc. The fibrocellular structure of the nucleus pulposus is omitted. For clarity the number of fibrocartilaginous laminae has been greatly reduced, since they are in fact of microscopic dimensions. Note alternating obliquity of collagen fascicles in adjacent laminae. (Modified after Inoue 1973.)



thence continued downwards to the sacrum; its upper end is continuous with the membrana tectoria (p. 449). It consists of smooth, glistening fibres, attached to intervertebral discs and to the margins of vertebral bodies, but separated between these attachments by emerging basivertebral veins, and by veins which drain these into the anterior internal vertebral plexuses. At cervical and upper thoracic levels the ligament is broad and nearly uniform in width, but in the lower thoracic and lumbar regions (**4**.24A) it is denticulated, being narrow over the vertebral bodies and broad over the discs. It consists of superficial layers bridging the interval between three or four vertebrae, and deeper layers which extend between adjacent vertebrae. These deeper layers, sometimes termed *perivertebral ligaments* (François 1975), are in turn close to and, in adult life, fused with the annulus fibrosus of the adjoining intervertebral disc. The layers are more easily identifiable in immediate post-natal years.

The intervertebral discs (**4**.23A and B) are interposed between adjacent surfaces of vertebral bodies, from the axis to the sacrum, and are the chief bonds of connexion between them. Their shape corresponds with that of the bodies between which they are placed. Their thickness varies in different regions of the column, and in different parts of the same disc. They are thicker in front than behind in the cervical and lumbar regions, and thus contribute to the anterior convexities of these levels, while they are of nearly uniform thickness in the thoracic region, the anterior concavity of this part of the column being almost entirely due to the shape of the vertebral bodies. The discs are thinnest in the upper thoracic and thickest in the lumbar region. They are adherent to thin layers of hyaline cartilage which cover the superior and inferior surfaces of vertebral bodies. Except for their most peripheral parts, which receive a supply from adjacent blood vessels, the discs are avascular and are supported by diffusion through the spongy bone of the adjacent surfaces of the vertebrae. The vascular and avascular parts hence differ in reaction to injury (Smith and Walmsley 1951). The intervertebral discs are connected to the anterior and posterior longitudinal ligaments; in the thoracic region they are joined laterally, by means of the intra-articular ligaments, to the heads of those ribs, which articulate with two vertebrae. The intervertebral discs constitute about one-fifth of the length of the vertebral column, exclusive of the first two vertebrae; but this amount is not equally distributed, the cervical and lumbar portions having, in proportion to their length, a much greater amount than the thoracic region, with the result that they are more pliant (Harris 1939).



Structure of intervertebral discs. Each disc consists of an outer laminated periphery, the *annulus fibrosus* and an inner core, the *nucleus pulposus* (**4**.23A and B).

The *annulus fibrosus* consists of a narrower outer zone of collagenous fibres and a wider inner zone of fibrocartilage. Its laminae are convex from above downwards and form incomplete collars which are connected by strong fibrous bands and overlap or dovetail into one another. In the posterior region of the disc the laminae join with each other in a complex fashion. Within each lamina the majority of the fibres lie in parallel and run obliquely between two vertebrae; the fibres in contiguous laminae run in different directions (**4**.23B) and lie at an obtuse angle to each other, thus exercising control over the rotatory movements in different directions. A predominantly *vertical* direction of fibres in the posterior part of the annulus fibrosus has been described (Zaki 1973) with the suggestion that this predisposes to herniation. The obliquity of such fibres of the deeper zones varies in different concentric lamellae (Inone 1973).

The *nucleus pulposus* is better developed in the cervical and lumbar regions than in the thoracic part of the spine. It lies nearer the posterior than the anterior surface of the disc. At birth it is soft, gelatinous, relatively large and consists of mucoid material containing a few multinucleated notochordal cells, into the

4.24A The lumbar region of the posterior longitudinal vertebral ligament.

4.24B The ligamenta flava of the lumbar region. Anterior aspect.

periphery of which extend cells and fibres from the inner zone of the adjacent annulus fibrosus. The notochordal cells have disappeared by the end of the first decade, after which time there is a gradual replacement of the mucoid material by fibrocartilage (Sylvén 1951), derived mainly from the cells of the annulus fibrosus but also from the cartilaginous plates covering the upper and lower surfaces of the vertebrae. With this transformation the nucleus pulposus, hitherto distinct, becomes more and more difficult to differentiate from the remainder of the disc (Walmsley 1950; Peacock 1952; Tondury 1958). Recent observations on lumbar intervertebral discs showed that the cellularity of the structure (6000 cells/mm^3 taken overall) is highest in the periphery of the annulus fibrosus and in the hyaline cartilage nearest to the vertebral bodies (Maroudas *et al.* 1975). The same study recorded a glucose diffusion coefficient for these structures of about 2·5 cm^2 per second, comparable to the values for cartilage elsewhere in the body. It was, however, concluded that nutritional conditions in the intervertebral discs might be more critical. This is especially likely in the large discs of the lumbar region.

With these structural changes the nucleus pulposus alters in appearance and becomes amorphous and sometimes discoloured. Its water-binding capacity diminishes and its elasticity is reduced (Püschel 1930), these physical properties of the nucleus pulposus being related in particular to its mucopolysaccharide and protein component (Inman and Saunders 1947; Hendry 1958). When the disc is not loaded, the pressure in the nucleus pulposus is low at all ages (Nachemson 1960).

Applied Anatomy. In the young adult the intervertebral discs are so strong that when violence is applied to the vertebral column the bones always give way first, provided that the discs are healthy. It is impossible to damage a healthy disc except through a fracture of a vertebral body passing through the upper region, where, as the result of forcible flexion, rupture of the disc may occur without fracture of a vertebral body.

After the second decade, however, degenerative changes are liable to occur in the discs, and these may result in necrosis, and sequestration of the nucleus pulposus, and in softening and weakening of the annulus fibrosus. Under these circumstances a comparatively minor strain may cause *either* an internal derangement of the joint tissues with eccentric displacement of the nucleus pulposus *or* an external derangement in which the nucleus pulposus bulges or actually bursts through the annulus fibrosus, usually in a posterolateral direction. In the former the unequal tension within the joint is responsible for muscle spasm and for the sudden violent pain of an acute attack of lumbago; in the latter the projecting nucleus may press upon and irritate the adjacent nerve roots with resulting referred pain, such as sciatica. Derangements of this kind occur most commonly in the lower lumbar region, especially at the lumbosacral joint, and not infrequently in the cervical region at the levels of C. 5–7, but they may occur at any level. Motor effects, with loss of power and reflexes, may also ensue.

The Joints of the Vertebral Arches

The joints between the articular processes of the vertebrae are synovial and vary in shape (p. 446); the laminae, spines and transverse processes are connected by ligamenta flava, interspinous, supraspinous and intertransverse ligaments, and the ligamentum nuchae, which can all be regarded as accessory ligaments of these joints. Each has also an articular capsule.

The articular capsules, thin and loose, are attached just peripheral to the margins of the articular facets of adjacent articular processes; they are longer and looser in the cervical than in the thoracic and lumbar regions.

The ligamenta flava (4.23, 25) connect the laminae of adjacent vertebrae, and are best seen from the interior of the vertebral canal. Their attachments extend from the articular capsules to the regions where the laminae fuse to form the spine; here their posterior margins come into contact and are to a certain extent united, small intervals being left for the passage of veins from the internal to the posterior external vertebral venous plexuses. The predominant component of a ligamentum flavum is yellow elastic tissue, the fibres of which, almost perpendicular in direction, are attached to the lower part of the anterior surface of the lamina above and the posterior surface and upper margin of the lamina below. The ligaments are thin, but broad and long in the neck; thicker in the thoracic region, and thickest at lumbar levels. They permit separation of the laminae in flexion and at the same time brake the movement so that its limit is not reached abruptly. In this way they assist in restoring the vertebral column to the erect attitude after it has been flexed and may protect the discs from injury.

The supraspinous ligament (4.23) is a strong fibrous cord which connects together the apices of the spines from the seventh cervical vertebra to the sacrum. It is thicker and broader in the lumbar region than in the thoracic, and intimately blended in both situations with the neighbouring fascia. The most superficial fibres of this ligament extend over three or four vertebrae; those more deeply seated pass between two or three vertebrae; while the deepest connect the spines of neighbouring vertebrae and are continuous with the interspinous ligaments. Between the spine of the seventh cervical vertebra and the external occipital protuberance it is much expanded and called the ligamentum nuchae. Heylings (1978) has described the supraspinous ligaments as ceasing at the fifth lumbar spinous process.

The ligamentum nuchae is a fibro-elastic membrane or intermuscular septum, which, in the neck, is homologous with the supraspinous and interspinous ligaments of other levels. Its superficial part extends from the external protruberance and external occipital crest to the spine of the seventh cervical vertebra. From this a fibrous lamina is given off which is attached to the median part of the squamous occipital bone below the external occipital protuberance, to the posterior tubercle of the atlas and to the spines of the cervical vertebrae, forming a septum for attachment of muscles of the two sides of the neck. In bipedal man it is the reduced representative of a much thicker elastic ligament which, in quadrupedal mammals, is an important factor suspending the head and modifying its flexion, functioning in the same way as the ligamenta flava in man.

The interspinous ligaments (4.23), thin and almost membranous, connect adjoining spines, and their attachments extend from the root to the apex of each process. They meet the ligamenta flava in front and the supraspinous ligament behind. They are narrow and elongated in the thoracic region, broader, thicker and quadrilateral in form in the lumbar region, and only slightly developed in the neck. The direction of fibres in these ligaments has commonly been described as obliquely dorso-caudal. In a recent study of 28 cadavers Heylings (1978) found their direction to be obliquely dorsocranial at lumbar levels.

The intertransverse ligaments are between the transverse processes. In the cervical region they consist of a few, irregular, scattered fibres and are largely replaced by intertransverse muscles; in the thoracic region they are rounded cords intimately connected with the deep muscles of the back; in the lumbar region they are thin and membranous.

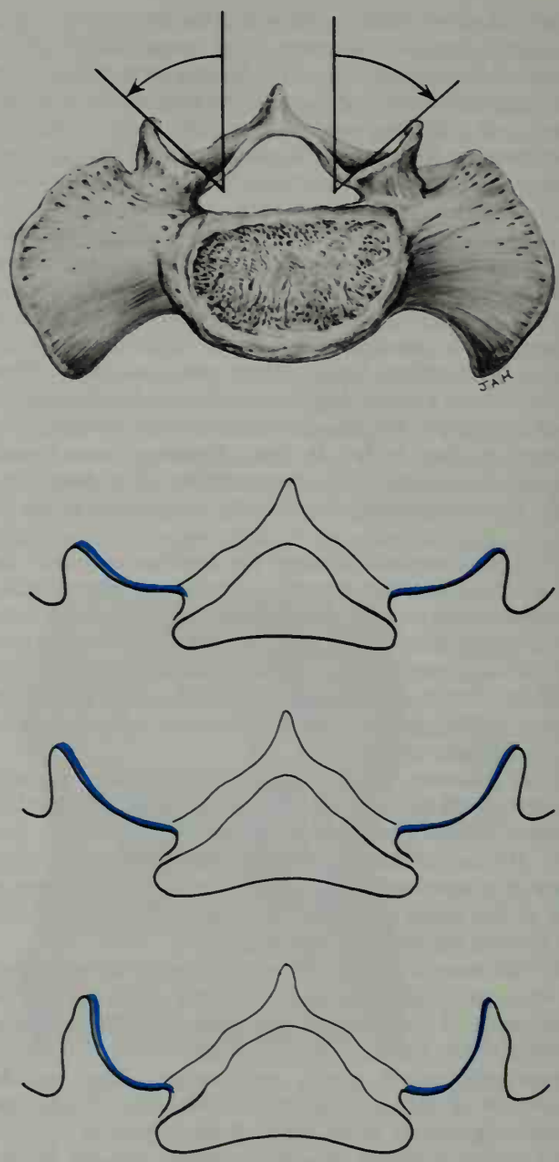
Movements of the Vertebral Column

The range of movement possible between any two adjoining vertebrae is restricted, due to the limited range of deformation of the intervertebral disc connecting the vertebral bodies. The greater thickness of the discs in the cervical and lumbar regions as compared with the thoracic region is associated with the greater individual ranges of movement occurring in those regions. But, although movement between adjoining vertebrae is small, the summation of these movements gives a relatively wide range to the vertebral column as a whole.

Flexion, or forward bending, extension, or backward bending, bending to one or other side (usually termed lateral flexion), rotation and circumduction are all possible in the vertebral column.

In *flexion* the anterior longitudinal ligament is relaxed and the anterior parts of the intervertebral discs are compressed; at the limit of the movement the posterior longitudinal ligament, the ligamenta flava, and the interspinous and supraspinous ligaments are stretched, as well as the posterior fibres of the intervertebral

discs. The intervals between the laminae are widened, and the inferior articular processes glide upwards upon the superior articular processes of the subjacent vertebrae. However, tension of the extensor muscles of the back is an important factor in limiting further movement—e.g. when carrying a load on the shoulders. Flexion is most extensive in the cervical region.



In *extension* an opposite disposition of the parts takes place. This movement is limited by the tension of the anterior longitudinal ligament, and by the approximation of the spines. It is free in the cervical and lumbar regions, but is restricted in the thoracic region, partly because the discs are thinner, perhaps also due to the effects of the thoracic skeleton and its musculature. It has been suggested that in full extension the axis of movement is behind the articular processes and that it moves forwards as the vertebral column straightens and passes into flexion, reaching the centre of the vertebral bodies when flexion is full (Wiles 1935).

In *lateral flexion* the sides of the intervertebral discs are compressed, the extent of motion being limited by the resistance offered by the tension of the antagonist muscles and surrounding ligaments. It is always associated with some degree of rotation. Lateral movements may take place in any part of the column, but are most free in the cervical and lumbar regions.

Circumduction is limited, and is merely a succession of the preceding movements.

Rotation is produced by the twisting of the vertebrae relative to each other with a torsional deformation of the intervening intervertebral discs. Although only slight between any two vertebrae, this allows a considerable extent of movement when it takes place along the length of the column, the upper part being turned to one or other side. This movement occurs to a slight extent in the cervical region, is freer in the upper part of the thoracic region and is least in the lumbar region.

The extent and variety of vertebral movements are influenced by the shape and direction of the articular facets. Though often described as *plane*, these articulations are never truly flat, but are of ovoid type, the opposing surfaces being reciprocally concave and convex. In the *cervical* region the upward inclination of the superior articular facets allows free flexion and extension. Extension can usually be carried further than flexion; at the upper end of the region it is checked by the locking of the posterior edges of the superior atlantal facets in the condylar fossae of the occipital bone; at the lower end it is limited by a mechanism whereby the inferior articular processes of the seventh cervical vertebra slip into grooves behind and below the superior articular processes of the first thoracic vertebra. Flexion is arrested just beyond the point where the cervical convexity is straightened; the movement is checked by the apposition of the projecting lower lips of the bodies of the vertebrae with the shelving surfaces on the bodies of the subjacent vertebrae. Lateral flexion and rotation in the cervical region are always combined; the upward and medial inclinations of the superior articular facets impart a rotatory movement during attempts at lateral flexion. In the *thoracic* region, notably in its upper part, all the movements are limited, thus reducing interference with respiration to a minimum. The almost complete absence of an upward inclination of the superior articular facets prohibits any marked flexion, while extension is checked by the contact of the inferior articular margins with the laminae, and the contact of the spines with one another. Rotation is freer in the thoracic region. The axis of rotation lies within the vertebral bodies in the mid-thoracic region but in front of the bodies elsewhere, so that rotation is accompanied by some lateral displacement of them (Davis 1959, 1965). The direction of the articular facets would allow of free lateral flexion, but this movement is considerably limited in the upper part of the region by the resistance of the ribs and sternum. Rotation is usually associated with a slight degree of angulation or flexion towards the same side as the rotation. In the *lumbar* region extension is free and wider in range than flexion. A considerable amount of lateral flexion and a small amount of rotation can also occur. The range of rotation is in part limited by the fact that right and left articular facets do not have a common centre of curvature (Putz 1976). The functional transition between the thoracic and lumbar regions occurs most frequently between the eleventh and twelfth thoracic vertebrae (p. 277). At this transition the joints of the vertebral arches usually fit very intimately, as in a carpenter's mortice and tenon joint, and a small amount of compression locks the joint, preventing all movement other than flexion.

4.25 The method employed by Čihák (1970), to measure the inclinations of articular surfaces of the lumbosacral zygapophysial joints (above). The lower profiles depict three degrees of increasing curvature and inclination. For quantitative data derived from 132 human sacra consult the original paper.

Muscles producing vertebral movements. The spinal column may be moved by muscles attached to it and acting directly on it, and by muscles attached to other bones and acting indirectly on the column. Gravity also plays a part.

Flexion. Longus cervicis, scaleni, sternocleidomastoid and rectus abdominis of both sides.

Extension. Erector spinae, splenius and semispinalis capitis of both sides.

Lateral flexion. Longissimus and iliocostocervicalis components of erector spinae, the oblique muscles of abdominal wall, and the muscles concerned in *flexion* of the side towards which lateral flexion is occurring.

Rotation. Rotatores, multifidus and splenius cervicis.

Extension, principally of the lumbar spine, occurs when raising the body from a stooping position. In the initial phase, extension is mainly at the hip and knee joints. There is a delay in the onset of continuous lumbar extension during which there is little or no activity in the erector spinae. When lifting heavy weights in the initial phase there is considerable compression of the lumbar intervertebral discs with large rises in pressure in the thoracic and abdominal cavities which may resist flexion (Davis 1963; Davis *et al.* 1965).

THE LUMBOSACRAL JOINTS

The articulations between the fifth lumbar vertebra and the first segment of the sacrum resemble the joints between any two typical vertebrae. The bodies of the fifth lumbar and first sacral vertebra are united by a very large intervertebral disc which is thicker ventrally. Its anterior margin is at the sacrovertebral angle (p. 279) and the anterior and posterior longitudinal ligaments are adherent to it. The right and left zygapophyseal joints between the inferior articular processes of the fifth lumbar vertebra and the superior articular processes of the sacrum are separated by a wider interval than those of the vertebrae above. Associated with them are ligamenta flava, interspinous and supraspinous ligaments. In addition the fifth lumbar vertebra is attached to the ilium and sacrum by the iliolumbar ligament. Marked variation occurs in the geometry of these joints (*see* p. 279). Examples of the range of variation are shown in **4**.25.

The iliolumbar ligament (**4**.56) is attached to the tip and to the lower and front part of the transverse process of the fifth lumbar vertebra, and occasionally has an additional, weak attachment to the transverse process of the fourth. It radiates as it passes laterally and is attached by two main bands to the pelvis. The lower band, which is often termed the *lumbosacral ligament*, runs from the inferior aspect of the fifth lumbar transverse process to the anterior part of the upper surface of the lateral part of the sacrum, blending with the ventral sacro-iliac ligament; the upper, which gives partial origin to the quadratus lumborum, is attached to the crest of the ilium immediately in front of the sacro-iliac joint and is continuous above with the thoracolumbar fascia.

THE SACROCOCCYGEAL JOINT

The sacrococcygeal joint is a symphysis between the apex of the sacrum and the base of the coccyx, the bones being united by a disc of fibrocartilage and by ventral, dorsal and lateral sacrococcygeal ligaments.

The fibrocartilage is a thin disc interposed between the contiguous surfaces of the sacrum and coccyx; it is somewhat thicker in front and behind than at the sides. Occasionally the coccyx is freely movable and articulates with the sacrum by a synovial joint.

The ventral sacrococcygeal ligament (**4**.56) consists of a few irregular fibres which descend along the pelvic surfaces of the sacrum and coccyx, resembling the anterior longitudinal ligament in its attachments.

The superficial dorsal sacrococcygeal ligament is a flat band which passes from the margin of the sacral hiatus and descends to the dorsal surface of the coccyx (**4**.57). This ligament completes the lower part of the sacral canal.

The deep dorsal sacrococcygeal ligament extends from the back of the fifth sacral vertebra to the back of the coccyx, corresponding to the posterior longitudinal ligament.

A lateral sacrococcygeal ligament exists on each side and, like an intertransverse ligament, connects the transverse process of the coccyx to the inferior lateral angle of the sacrum; it completes the foramen for the fifth sacral nerve.

The intercornual ligaments connect the cornua of the sacrum and coccyx on each side. A fasciculus also passes from the sacral cornu on each side to the transverse process of the coccyx.

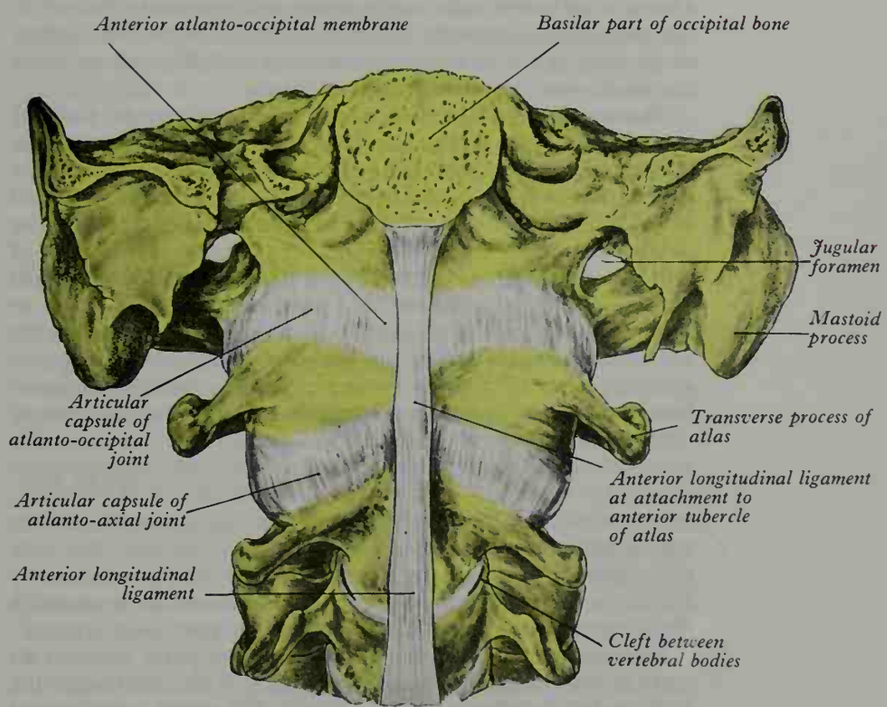
THE INTERCOCCYGEAL JOINTS

These also are symphyses, thin discs of fibrocartilage being interposed between the segments in the young subject. The segments of the coccyx are further connected together by the extension downwards of the ventral and dorsal sacrococcygeal ligaments. In the adult male all the pieces become ossified together at a comparatively early period, but in the female this does not commonly occur until a later period of life. At a more advanced age the joint between the sacrum and coccyx is obliterated. Occasionally the joint between the first and second pieces of the coccyx is synovial. The tip of the last piece of the coccyx is connected to the overlying skin by a bundle of white fibrous tissue.

The Craniovertebral Joints

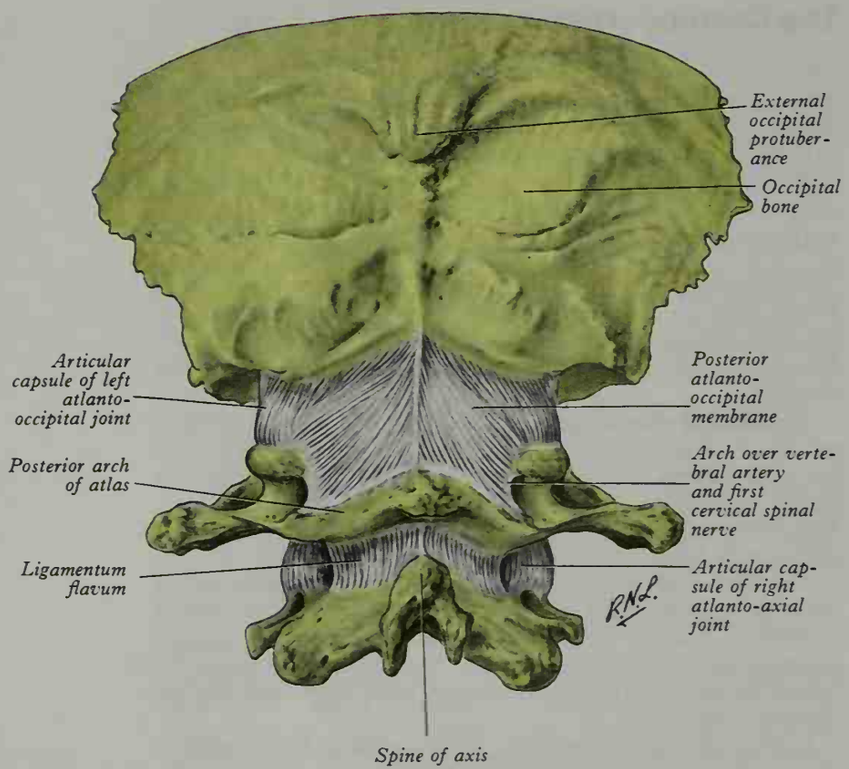
The articulation of the vertebral column with the cranium involves not only the paired atlanto-occipital joints but also ligaments connecting the axis and occipital bone. It is appropriate to include as well the joints between atlas and axis, since it is here that most rotation of the head on the neck occurs.

THE ATLANTO-AXIAL JOINTS



The articulation of atlas and axis comprises three synovial joints, one on each side between the inferior facet of the lateral mass of the atlas and the superior facet of the axis, the other median, between the dens and the anterior arch and transverse ligament of the atlas.

The lateral atlanto-axial joints are often classified as plane, but when covered with cartilage, the *articular surfaces* involved are, in fact, ovoid, the atlantal facets being slightly concave, those of the axis convex and reciprocal in form (pp. 273, 274). According to Kapandji (1974), however, both facets are transversely cylindrical, engaging like two wheels.



The fibrous capsules are thin and loose; they are attached at the articular margins and are, of course, lined with synovial membrane. Each is strengthened posteromedially by an *accessory ligament*, which is attached below to the body of the axis near the base of the dens, and above to the lateral mass of the atlas near the transverse ligament.

In front the two vertebrae are connected by a continuation of the anterior longitudinal ligament (**4**.26). In this position it is a strong and wide band, fixed above to the lower border of the anterior arch of the atlas, and below to the front of the body of the axis. It is thickened in the median plane into a rounded cord which connects the tubercle on the anterior arch of the atlas to the body of the axis.

Behind, the atlas and axis are joined by a broad, thin membrane (**4**.27) attached above to the lower border of the posterior arch of the atlas, below to the upper edges of the laminae of the axis; it is in series with the ligamenta flava and is pierced near its lateral extremity by the second cervical nerve.

4.26 The atlanto-occipital and atlanto-axial joints. Anterior aspect. On each side a small cleft has been opened between the lateral part of the upper surface of the body of the third cervical vertebra and the bevelled, inferior surface of the body of the axis. (See also p. 272.)

4.27 The atlanto-occipital and atlanto-axial joints. Posterior aspect.

The median atlanto-axial joint is a pivot joint between the dens of the axis and the ring formed by the anterior arch and the transverse ligament of the atlas; in a sense it is a double joint, as it consists of two separate 'articulations' and synovial cavities. The latter, clearly, can only act in concert.

Anteriorly, the facet on the anterior surface of the dens articulates with that on the posterior aspect of the anterior arch of the atlas; this articulation is surrounded by a fibrous capsule which is weak and loose and lined with synovial membrane. Posteriorly a second and larger synovial cavity (sometimes termed a bursa), lies between the cartilage-covered anterior surface of the transverse ligament of the atlas and the posterior grooved surface of the dens (4.30): it is often continuous with the joint cavity of one or other of the atlanto-occipital joints.

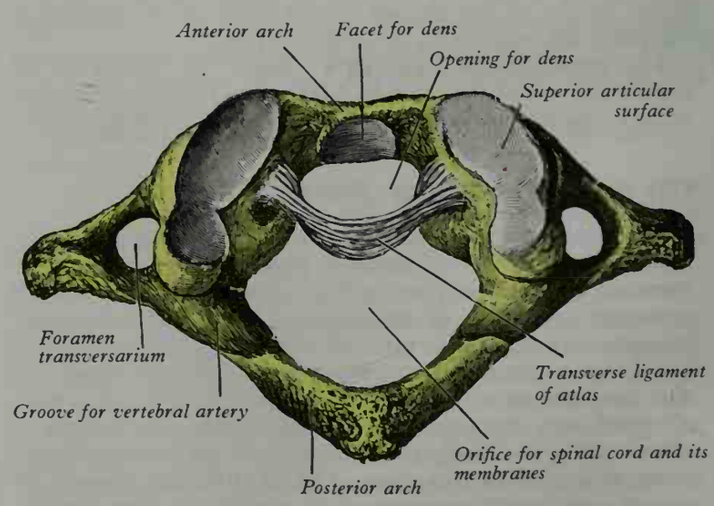
The transverse ligament of the atlas (4.28, 29, 30) is a thick strong band which arches across the ring of the atlas and retains the dens in contact with the anterior arch. It is broader in the middle than at the ends, and firmly attached on each side to a small tubercle on the medial surface of the lateral mass of the atlas. The median part of its anterior surface is covered by a thin layer of articular cartilage. As it crosses the dens, a small longitudinal band is prolonged upwards, and another downwards, from its superficial or posterior fibres. The upper band is attached to the upper surface of the basilar part of the occipital bone between the apical ligament of the dens and the membrana tectoria; the lower band, which may be absent, is attached to the posterior surface of the body of the axis; hence the whole ligament forms a cross and is named the *cruciform ligament of the atlas*. The transverse ligament divides the ring of the atlas into two unequal parts (4.28): of these, the posterior and larger surrounds the spinal cord and its membranes; the anterior and smaller contains the dens. The neck of the process is constricted where it is embraced posteriorly by the transverse ligament, so that this ligament suffices to retain the dens in position after all the other ligaments have been divided.

Movement at the atlanto-axial joints must occur at all three at the same time, consisting largely of the rotation of the atlas (and with it the skull) upon the axis, the extent being limited by the alar ligaments (p. 449).

The opposed articular facets of the atlas and axis are both slightly convex in their anteroposterior axes. When, therefore, the upper facet glides forwards or backwards on the lower it also descends. The stretching of the fibres of the fibrous capsule that would result from this forward movement is diminished owing to the contemporaneous descent of their upper attachments, and in this way excessive laxity of the capsule is obviated. The lateral atlanto-axial joints support the weight of the head via the atlas; the pivot joint guides the rotatory movement. For the most elaborate analysis of these and other cervical movements consult Kapandji (1974), who emphasizes the slight helical component in movements of the lateral atlanto-axial joints, as described above.

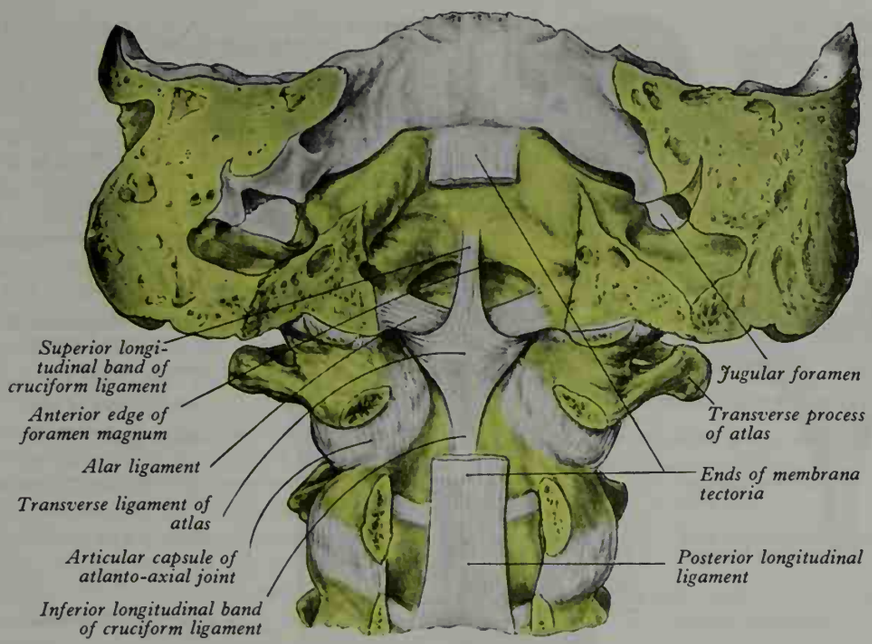
Muscles producing the movements. Obliquus capitis inferior, rectus capitis posterior major and splenius capitis of one side, acting with the opposite sternocleidomastoid.

THE ATLANTO-OCCIPITAL JOINTS



Each of the paired atlanto-occipital joints involves a superior articular facet of the lateral mass of the atlas and a condyle of the occipital bone: it is ellipsoid in type. The *articular surfaces* are reciprocally curved. Each atlantal facet is concave and tilted somewhat medially. The shape of the facet varies but it is usually constricted about its middle; the articular surface is thus partially, sometimes completely, divided (Singh 1965). The bones are united by the articular capsules and the anterior and posterior atlanto-occipital membranes.

Fibrous capsules surround the condyles of the occipital bone and the superior articular facets of the atlas. They are thickened posteriorly and laterally, but are very thin and sometimes deficient medially, where the synovial cavities frequently communicate with the synovial bursa between the dens and the transverse ligament of the atlas (Cave 1934).



The anterior atlanto-occipital membrane (4.26) is broad and composed of densely woven fibres which pass between the anterior margin of the foramen magnum above, and the upper border of the anterior arch of the atlas below; laterally it is continuous with the capsular ligaments; in front, it is strengthened in the median plane by the continuation of the anterior longitudinal ligament, a strong, rounded cord which connects the basilar part of the occipital bone to the tubercle on the anterior arch of the atlas (4.26).

The posterior atlanto-occipital membrane (4.27), broad but thin, is connected above to the posterior margin of the foramen magnum, below, to the upper border of the posterior arch of the atlas. On each side it arches over the groove for the vertebral artery, and with this groove bounds an opening for the entrance of the artery and the exit of the first cervical spinal nerve. The free border of the membrane, arching over the artery and nerve, is sometimes ossified.

In movements at the atlanto-occipital joints their long axes are set obliquely and run from behind forwards and medially. As a result of this obliquity and of the curvature of the occipital condyle, the corresponding articular surfaces of the two sides are in reality portions of the surface of one ellipsoid, the long axis of

4.28 The atlas vertebra, with the transverse ligament.

4.29 Posterior aspect of the atlanto-occipital and atlanto-axial joints, after removal of the posterior part of the occipital bone and the laminae of the upper cervical vertebrae. The atlanto-occipital joint cavities have been opened.

which is set transversely. The two joints therefore act as one, and movement may occur around transverse and anteroposterior axes, but not round a vertical axis. The movements permitted therefore are (*a*) flexion and extension (nodding of the head), and (*b*) a slight lateral tilting motion to one or other side. (Consult Kapandji 1974.)

Muscles producing the movements.

Flexion. Longus capitis and rectus capitis anterior.

Extension. Recti capitis posteriores major et minor, obliquus capitis superior, semispinalis capitis, splenius capitis, and trapezius (upper part).

Lateral flexion. Rectus capitis lateralis, semispinalis capitis, splenius capitis, sternocleidomastoid and trapezius (upper part).

LIGAMENTS CONNECTING THE AXIS WITH THE OCCIPITAL BONE

The membrana tectoria, paired alar ligaments and the apical ligament extend between axis and occipital bone.

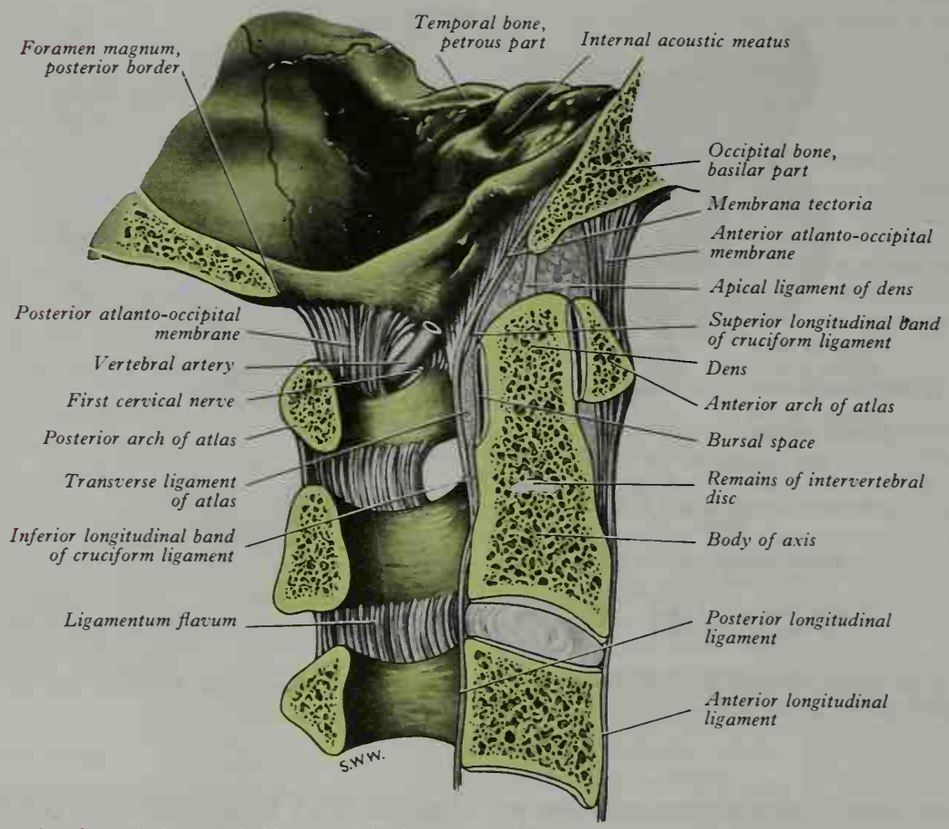
The membrana tectoria (4.29, 30) is situated within the vertebral canal. It is a broad, strong band, which covers the dens and its ligaments and appears to be a prolongation upwards of the posterior longitudinal ligament of the vertebral column. It consists of superficial and deep lamellae, both of which are attached below to the posterior surface of the body of the axis. The superficial lamella expands as it ascends and is attached above to the upper surface of the basilar part of the occipital bone, in front of the foramen magnum, blending with the cranial dura mater. The deep lamella consists of a median band which extends to the basilar part of the occipital bone and two lateral bands which ascend on the medial sides of the atlanto-occipital joints to the margins of the foramen magnum.

The alar ligaments (4.29), two strong, rounded cords, start on each side of the upper part of the dens, and, passing obliquely upwards and laterally, are attached to rough impressions on the medial sides of the condyles of the occipital bone. The alar ligaments are relaxed on extension of the head but become taut on flexion and help to limit the movement. They are so disposed that they would render free rotation of the head impossible, were it not that rotation is accompanied by a slight descent of the atlas. This descent causes sufficient relaxation of the alar ligaments to compensate for the tension brought about by rotation. Rotation to the right is eventually checked by the tension of those fibres of the right alar ligament which are attached to the dens in front of the axis of movement, and by tension of those fibres of the left alar ligament which are attached to the process behind the axis of movement. Rotation to the left is checked by the opposite fibres on each side.

The apical ligament of the dens (4.30), which extends from the tip of the process to the anterior margin of the foramen magnum, lies between the alar ligaments, being intimately blended with the deep portion of the anterior atlanto-occipital membrane and with the upper longitudinal band of the cruciform ligament of the atlas. It is said to represent the core of the centrum of the pro-atlas vertebra and contains traces of the notochord in its substance (Ganguly and Roy 1964).

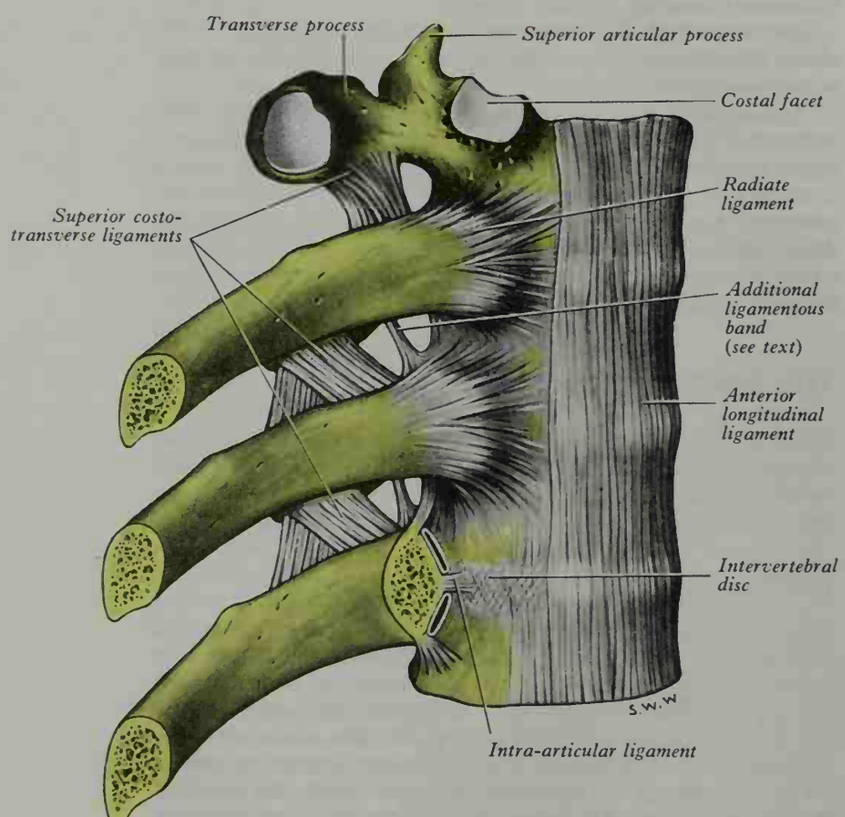
In addition to the ligaments which unite the atlas and axis to the skull, the ligamentum nuchae (p. 445) connects the cervical vertebrae with the cranium.

Applied Anatomy. Dislocation of the atlas from the axis, with rupture of the transverse ligament of the atlas and consequent injury to the spinal cord, is the mode by which death is produced in many cases of execution by hanging. Hanging may, however, produce a fracture through the axis, or a separation through the disc between the axis and the third cervical vertebra. Occasionally a pathological dislocation of the atlas on the axis may result from softening of the cruciform ligament.



The Costovertebral Joints

The articulations of ribs with vertebral column are divisible into two groups, one connecting the heads of ribs with the bodies of vertebrae, the other, the costotransverse joints, uniting the necks and tubercles of the ribs with the transverse processes.



THE JOINTS OF THE HEADS OF THE RIBS

These are formed by the articulation of the heads of the typical ribs with the facets on the margins of the bodies of adjacent thoracic vertebrae, and with the intervertebral discs between them (4.31). They are customarily classed as plane joints, though the surfaces of many are in fact curved. The first, tenth, eleventh, and twelfth ribs each articulate with a single vertebra; in each of the other joints, an intra-articular ligament divides the joint into two distinct parts. The ligaments of each joint are capsular, radiate, intra-articular.

The fibrous capsules connect the heads of the ribs with the circumference of the articular cavities formed by the intervertebral discs and the adjacent vertebrae. Some of their upper

4.30 A median sagittal section through the occipital bone and the first to third cervical vertebrae.

4.31 The costovertebral joints. Right anterolateral aspect. In the lowest joint shown most of the radiate ligament and the anterior part of the head of the rib have been excised to show the two joint cavities and the intra-articular ligament between them.

fibres pass through the intervertebral foramen to the back of the intervertebral disc, while the posterior fibres are continuous with the costotransverse ligament.

The radiate ligament connects the anterior part of the head of each rib with the sides of the bodies of two vertebrae and the intervertebral disc between them. It is attached to the anterior part of the head of the rib, just beyond the articular surface. The superior fibres ascend and are connected with the body of the vertebra above; the inferior fibres descend to the body of the vertebra below; the middle fibres, the shortest and least distinct, are horizontal and attached to the intervertebral disc.

In the articulation of the first rib, the radiate ligament is attached to the body of the last cervical vertebra as well as the first thoracic. In the joints of the tenth, eleventh and twelfth ribs, each of which articulates with a single vertebra, the radiate ligament is connected to this vertebra and also to the one above.

The intra-articular ligament is a short band, flattened from above downwards, attached laterally to the crest separating the two articular facets on the head of the rib and medially to the intervertebral disc; it divides the joint completely. In the joints of the first, tenth, eleventh and twelfth ribs intra-articular ligaments do not exist; consequently these are single synovial joints.

THE COSTOTRANSVERSE JOINTS

The articular part of the tubercle of a rib articulates with a reciprocal facet on the transverse process of the vertebra to which it corresponds numerically (**4**.32). In the eleventh and twelfth ribs this articulation is absent. In the upper six (or five) joints the articular surfaces are reciprocally curved, but in the lower joints the surfaces are more flattened (**4**.33).

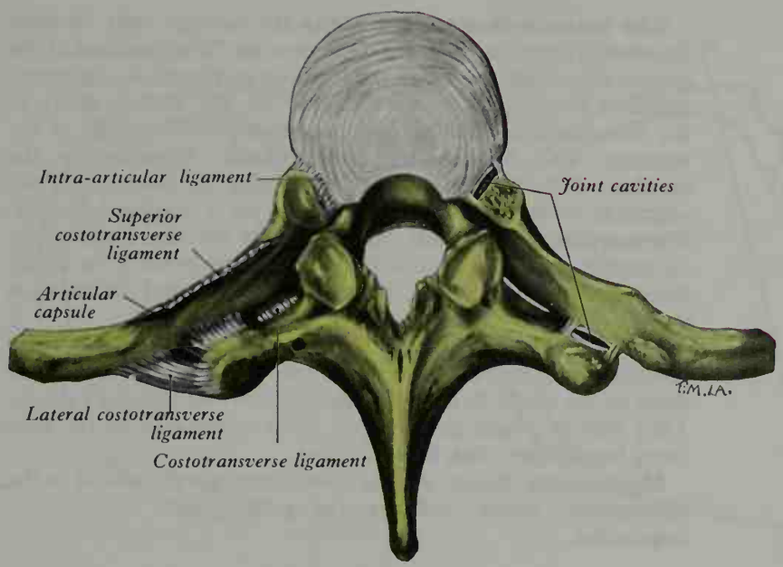
The ligaments of these joints are costotransverse, superior and lateral costotransverse, and the fibrous capsule.

The fibrous capsule is a thin membrane attached to the circumference of the articular surfaces, and lined with synovial membrane.

The superior costotransverse ligament has an anterior layer attached between the crest of the neck of a rib and the lower aspect of the transverse process above it (**4**.31); laterally it is continuous with the internal intercostal membrane and it is crossed by the corresponding intercostal vessels and nerve. The

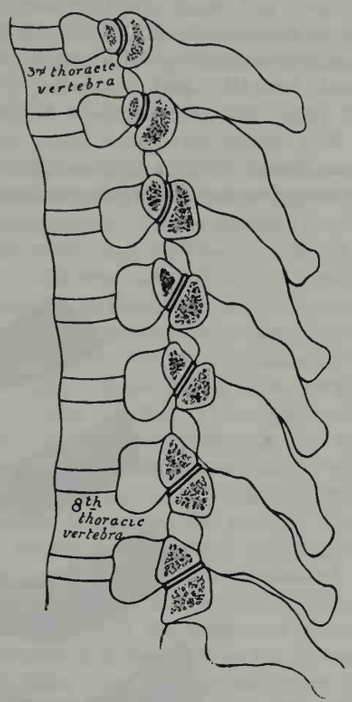
posterior layer is attached to the dorsal aspect of the neck of the rib and passes up medially behind to reach the transverse process above. Laterally it forms a continuous layer with the external intercostal muscle.

The first rib has no superior costotransverse ligament. The shaft of the twelfth rib, close to its head, is connected to the base of the transverse process of the first lumbar vertebra by a *lumbocostal ligament* in series with the superior costotransverse ligaments.



An accessory ligament is usually present medial to the superior costotransverse, and separated from it by the dorsal ramus of a thoracic spinal nerve and accompanying vessels (**4**.31). Somewhat variable in attachments, such bands commonly extend from a depression medial to the tubercle of a rib to the inferior articular process immediately above; some fibres may pass to the base of the transverse process.

The costotransverse ligament occupies the *costotransverse foramen*, the interval between the neck of the rib and the anterior surface of the corresponding transverse process. Its short but numerous fibres are attached in front to the rough surface on the back of the neck of the rib and behind to the anterior surface of the adjacent transverse process. In the case of the eleventh and twelfth ribs the ligament may be rudimentary or absent.



The lateral costotransverse ligament is a short, thick, strong fasciculus, passing obliquely from the apex of a transverse process to the rough nonarticular portion of the tubercle of the adjacent rib. The ligaments attached to the upper ribs ascend from the transverse processes; they are shorter and more oblique than those attached to the lower ribs, which descend slightly.

Movements at the costotransverse joints. The heads of ribs are so closely connected to the bodies of the vertebrae by the radiate and intra-articular ligaments that only slight gliding movements of the articular surfaces on one another can take place. Similarly, the strong ligaments binding the necks and tubercles of the ribs to the transverse processes limit the movements of the costotransverse joints to slight gliding, guided by the shape and direction of the articular surfaces (**4**.33). The articular surfaces on the tubercles of the upper six ribs are oval in shape and convex from above downwards; they fit into corresponding concavities on the anterior surfaces of the transverse processes, so that upward and downward movements of the tubercles are associated with rotation of the rib-neck on its long axis. On the seventh to tenth ribs the articular surfaces of the tubercles are almost flat, and face obliquely downwards, medially and backwards. The surfaces with which they articulate are on the upper aspects of the transverse processes; when, therefore, the tubercles are drawn up they are at the same time carried backwards and medially. The joints of the heads of the ribs and the costotransverse joints move simultaneously and in the same directions, the total effect being that the neck of the rib moves as if on a single joint, of which the two articulations form the ends. In the upper six ribs the neck of the rib moves but slightly upwards and downwards; its chief movement is one of rotation round its own long axis, rotation downwards of the front of the neck of the rib being associated with depression, rotation upwards with elevation of the anterior end of the rib and its costal cartilage. In the seventh to tenth ribs the neck of the rib moves upwards, backwards and medially, or downwards, forwards and laterally, with resultant increase or diminution of the infrasternal angle; a small degree of rotation accompanies these movements.

The muscles involved in the movements of respiration are considered on p. 550.

The Sternocostal Joints

The costal cartilages are received into small concavities on the lateral sternal borders (*chondrosternal articulations* (**4**.34)). The perichondrum and periosteum are continuous. The first costal cartilage is directly united to the sternum by a synchondrosis. The cartilages of the second to seventh ribs articulate with the lateral border of the sternum at synovial joints. The articular cavity is, however, frequently absent, particularly in the lower members of this series of joints. The articular surfaces are covered with *fibrocartilage* which also unites the costal cartilages to the sternum when joint cavities are absent (Gray and Gardner 1943). The ligaments involved are capsular, radiate sternocostal, intra-articular and costoxiphoid (*see* Sick and Koritke 1976, for variations of the seventh costosternal joint, which may be synovial or 'symphysial').

The fibrous capsules surround the joints between the sternum and the second to the seventh costal cartilages. They are very thin, intimately blended with the sternocostal ligaments, and strengthened above and below by a few fibres which connect the cartilages to the side of the sternum.

The radiate sternocostal ligaments are broad, thin, membranous bands which radiate from the front and back of the sternal ends of the cartilages of the true ribs to the anterior and posterior surfaces of the sternum. Their superficial fibres intermingle with the fibres of the ligaments above and below them, with those of the opposite side, and on the front of the sternum with the tendinous fibres of origin of the pectoralis major, forming a thick fibrous membrane which envelops the bone, and is more distinct at its lower part than at its upper part.

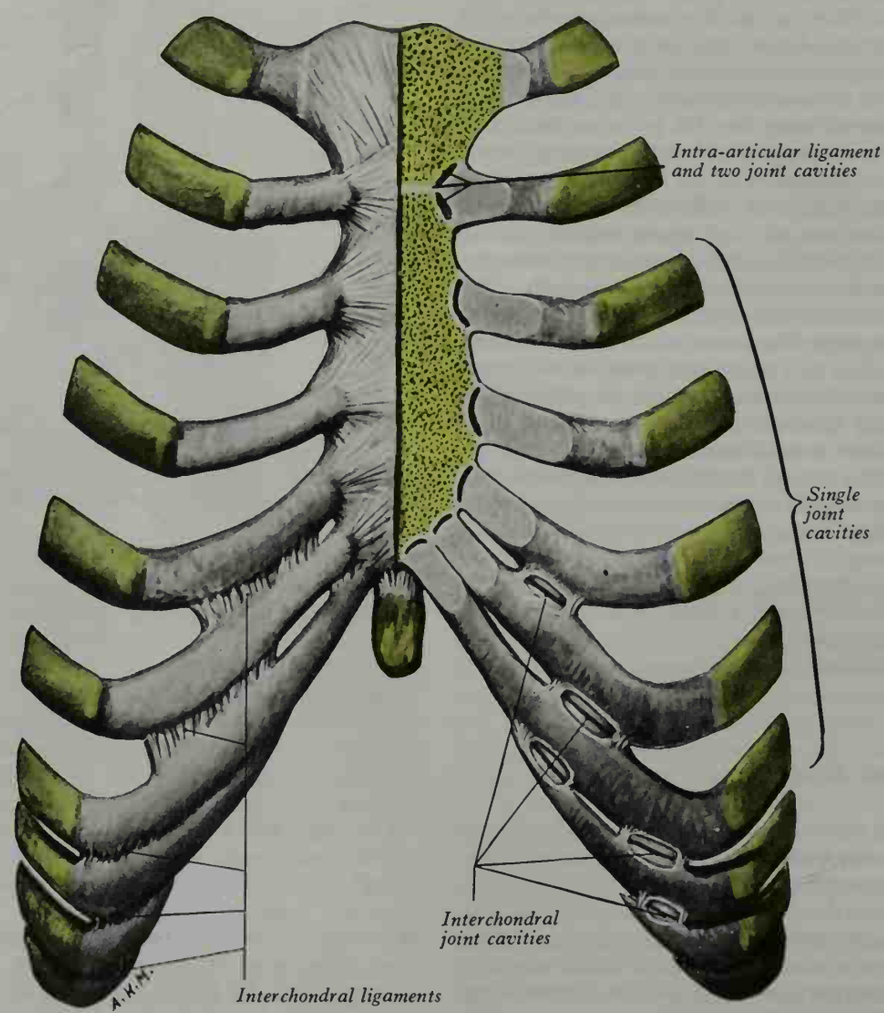
The intra-articular ligaments are constant only between the second costal cartilages and the sternum. The cartilage of the second rib is connected with the sternum by means of a ligament, attached laterally to the cartilage of the rib, and medially to the fibrocartilage which unites the manubrium and body of the sternum, and is therefore intra-articular. Occasionally the cartilage of the third rib is connected with the first and second segments of the body of the sternum by a similar ligament. Fibrocartilaginous strands connecting the articular surfaces are frequently present in the third and succeeding joints of the series. Articular cavities between the costal cartilages and the sternum may be absent at all ages.

The costoxiphoid ligaments connect the anterior and posterior surfaces of the seventh costal cartilage, and sometimes those of the sixth, to the front and back of the xiphoid process. They vary in length and breadth, those on the back of the joint being less distinct than those in front.

Movements. Slight gliding movements are permitted in the sternocostal joints, sufficient to permit easy mobility in respiration.

THE INTERCHONDRAL JOINTS

The contiguous borders of the sixth and seventh, the seventh and eighth, and the eighth and ninth costal cartilages articulate with each other by small smooth, oblong facets. Each articulation is enclosed in a thin *fibrous capsule*, lined with synovial membrane and strengthened laterally and medially by *interchondral ligaments*, which pass from one cartilage to the other (4.34). Sometimes the fifth costal cartilages, more rarely the ninth, articulate by their lower borders with adjoining cartilages by small oval facets; more frequently this connexion is made by a few ligamentous fibres. The articulation between the ninth and tenth cartilages is never synovial and sometimes it is absent (p. 290).



THE COSTOCHONDRAL JUNCTIONS

The costal cartilages are, of course, the persistent, unossified anterior parts of the cartilaginous models which precede the fully developed ribs. When artificially separated from its rib a costal cartilage displays a rounded end and the rib a depression. The junction is covered by periosteum, continuous with the adjoining perichondrium. No movement occurs at these junctions.

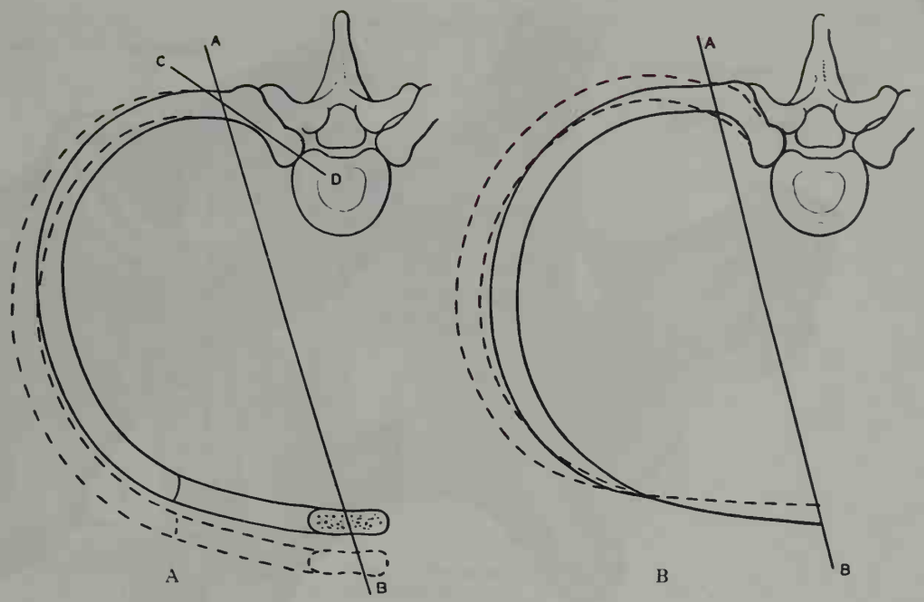
THE STERNAL JOINTS

The manubriosternal joint, between the manubrium and the body of the sternum, is usually a symphysis, the bony surfaces being coated with the hyaline cartilage and connected by a disc of fibrocartilage, which may become ossified in the aged. In rather more than 30 per cent of people the central part of the disc undergoes absorption and the joint *resembles* a synovial one; the same change may occur in the symphysis pubis. The two segments of the bone are also connected by the fibrous membrane which envelops the bone. In 10 per cent of all aged over 30 years the manubrium is joined to the body of the sternum by bone; when this occurs only the superficial part of the intervening cartilage may be ossified, and only in the aged is this complete. Early synostosis has been attributed to the persistence of a synchondrosis in place of a symphysis at this junction (Ashley 1954). In the newborn the union of the manubrium and body of the sternum is by collagenous and elastic fibres without obvious chondrocytes.

Movements. The manubriosternal symphysis permits a small

4.34 The sternocostal and interchodral joints. Anterior aspect.

range of angular change between the longitudinal axes of the manubrium and corpus sterni, and also a limited degree of anteroposterior displacement between these two sternal elements. A detailed study (Constantinesco 1974) of these movements in 62 male athletes yielded (in the standing position) mean values of 162·7° (full inspiration) and 164·7° (full expiration) for the manubriosternal angle. The angular movement and the displacement both contribute to the ventral movement of the sternum in inspiration and its reversal in expiration (*vide infra*).



The xiphisternal joint is between the xiphoid process and the body of the sternum and is also a symphysis; it usually becomes a synostosis by the fortieth year, but the xiphoid process may remain separate even in old age.

The Mechanism of the Thorax

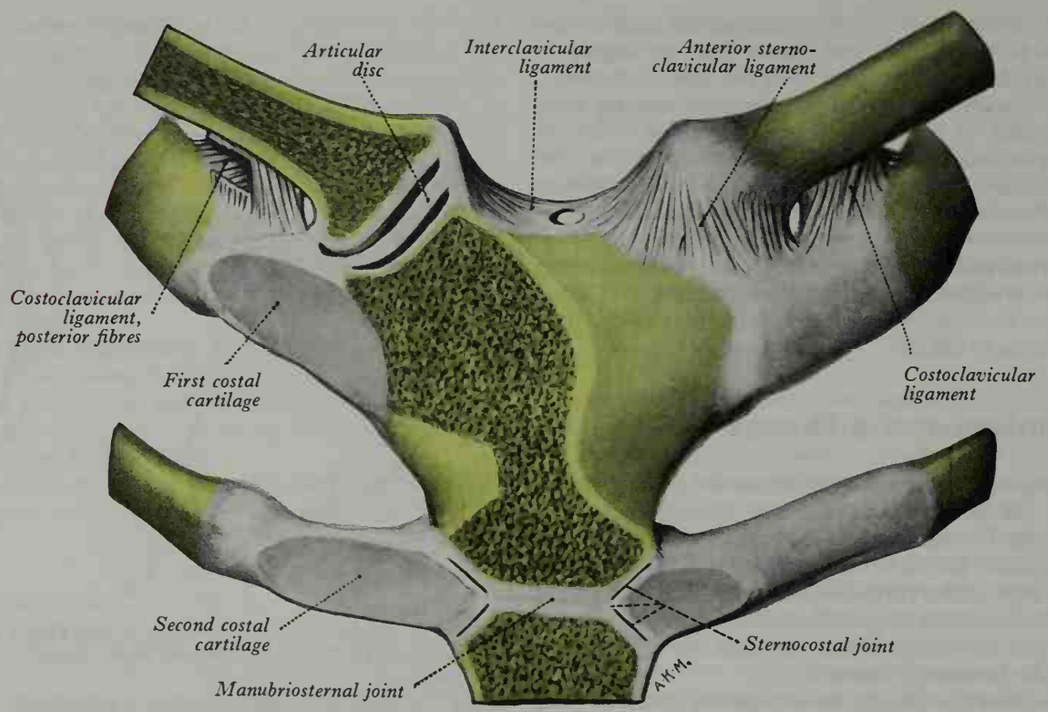
Each rib possesses its own range and direction of movement, contributing to the combined respiratory excursions of the thorax. Each rib may be regarded as a lever, the fulcrum of which is situated immediately lateral to its costotransverse articulation, so that when the shaft of the rib is elevated the neck is depressed, and vice versa; because of the large difference in length of the arms of this lever a slight movement at the vertebral end of the rib is much magnified at the anterior extremity.

The anterior ends of the ribs are lower than the posterior, and therefore, when the shaft of the rib is elevated, they rise in a forward direction. Again, the middle of the shaft of the rib lies in a plane below that passing through the two extremities, so that when the shaft is elevated relatively to its ends it is at the same time carried outwards from the median plane; further, each rib forms the segment of a curve which is greater than that of the rib immediately above. Therefore the elevation of a rib increases the transverse diameter of the thorax in the plane to which it is raised. The modifications of the rib movements at their vertebral ends have already been described (p. 451). Further modifications result from the attachments of their anterior extremities, and it is convenient therefore to consider separately the movements of the ribs in three groups, vertebrosternal, vertebrochondral and vertebral.

Vertebrosternal ribs (**4**.35A). The first rib moves little, except in deep respiration. Its movement occurs about an oblique axis through the neck; the shaft is displaced upwards and laterally in inspiration and the under surface comes to face more directly downwards. This movement is impossible if the costal cartilage is calcified, as it sometimes is; the first rib on each side and the manubrium sterni then move as a single unit about a transverse axis through the costotransverse joints. Movement of the second rib is slight also in quiet respiration. Elevation of the third to sixth ribs raises and thrusts forwards their anterior extremities, the greater part of the movement being effected by the rotation of their necks backwards. The thrust of the anterior extremities carries forwards and upwards the body of the sternum, which moves on the joint between it and the manubrium, and thus the anteroposterior thoracic diameter is increased. This movement, however, is soon arrested, and the elevating force is then expended in raising the middle part of the shaft of the rib and everting its lower border; at the same time the costochondral angle is opened out. By these latter movements a considerable increase in the transverse diameter of the thorax is effected. Measurements of sternal movements during respiration reveal extensive excursions, especially in physically fit adult males (Constantinescu 1974). Between full inspiration and expiration the suprasternal notch may show an excursion of 31 mm; the excursions at the superior (34 mm) and the inferior (37 mm) extremities of the corpus sterni being greater, due to changes in the sternal angle.

4.35A A diagram showing the axes of movement (AB and CD) of a vertebrosternal rib. The interrupted lines indicate the position of the rib in inspiration.
4.35B A diagram showing the axes of movement (AB) of a vertebrochondral rib. The interrupted lines indicate the position of the rib in inspiration.

Vertebrochondral ribs (**4**.35B). The seventh rib is included with this group, as it conforms more closely to their type of motion. While the movements of these ribs assist in enlarging the thorax for respiratory purposes, they are also concerned in increasing the upper abdominal space for viscera displaced by the action of the diaphragm, although relaxation of the abdominal wall can account at least in part for this. The costal cartilages articulate with one another, so that each pushes up that above it, the final thrust being directed to pushing forwards and upwards the lower end of the body of the sternum. The amount of elevation of the anterior extremities is limited on account of the very slight rotation of the necks of these ribs. Elevation of the shaft is accompanied by an outward and backward movement; the outward movement everts the anterior end of the rib and opens up the infrasternal angle, while the backward movement pulls back the anterior extremity and counteracts the forward thrust due to its elevation; this latter is most noticeable in the lower ribs, which are the shortest. The total result is a considerable increase in the transverse and a diminution in the median anteroposterior diameter of the upper part of the abdomen; at the same time, however, the lateral anteroposterior diameters of the abdomen are increased.



Vertebral ribs. Since these ribs have free anterior extremities and only costovertebral articulations with no intra-articular ligaments, they are capable of slight movements in all directions. When the other ribs are elevated these are depressed and fixed by the quadratus lumborum muscles to form fixed points of action for the diaphragm.

The muscles producing these movements are discussed on p. 550.

THE JOINTS OF THE UPPER LIMB

The Sternoclavicular Joint

Entering into the formation of the sternoclavicular joint are the sternal end of the clavicle, the clavicular notch of the manubrium sterni, and the cartilage of the first rib (**4**.36). The *articular surface* of the clavicle is much larger than that of the sternum and is covered with a layer of *fibrocartilage*, which is considerably thicker than that on the sternum. It is convex vertically, and slightly concave anteroposteriorly and is therefore a type of sellar (saddle) joint; the clavicular notch of the sternum is reciprocally

4.36 The sternoclavicular joints. Anterior aspect.

curved, but the two surfaces are not perfectly congruent. (These two joint surfaces show some variation, particularly in their peripheral shape but also in their degrees of curvature—*see* p. 358). The joint is completely divided by an articular disc. Its ligaments are capsular, anterior and posterior sternoclavicular, interclavicular and costoclavicular.

The fibrous capsule surrounds the articulation; in front and behind, it is thickened, but above, and especially below, it is thin and partakes more of the character of loose areolar tissue.

The anterior sternoclavicular ligament is a broad band, covering the anterior surface of the joint; it is attached above to the anterosuperior area of the sternal end of the clavicle, and, passing obliquely downwards and medially, is attached below to the front of the upper part of the manubrium sterni and more laterally to the first costal cartilage.

The posterior sternoclavicular ligament is a weaker band which covers the posterior aspect of the joint. It is attached to the posterior aspect of the sternal end of the clavicle and passes obliquely downwards and medially to be attached to the back of the upper part of the manubrium sterni.

The interclavicular ligament is continuous above with the deep cervical fascia; it unites the upper part of the sternal ends of both clavicles but some of its fibres are attached to the upper margin of the manubrium. When present, the *suprasternal ossicles* (p. 288) are in this ligament.

The costoclavicular ligament is short, shaped like an inverted cone and flattened anteroposteriorly. It consists of anterior and posterior laminae, which are attached below to the upper surface of the first rib and the adjacent part of its cartilage, and above to the margins of the impression on the inferior surface of the medial end of the clavicle. The fibres of the anterior lamina are directed upwards and laterally and those of the posterior lamina, which are shorter, upwards and medially (4.36). Laterally the laminae fuse with each other and medially they merge with the fibrous capsule of the sternoclavicular joint. Between the laminae is a bursa, an indication that they have discrete functions (Cave 1961). It seems probable that each of these two laminae is tensed towards the opposite extremes of clavicular axial rotation.

The articular disc, flat and nearly circular, is interposed between the articulating surfaces of the sternum and clavicle. It is attached, above, to the upper and posterior border of the articular surface of the clavicle, below, to the cartilage of the first rib, near its junction with the sternum, and by the rest of its circumference to the fibrous capsule. It is thicker peripherally—especially at its upper and posterior part—than at its centre, and divides the joint into two parts, the larger above and laterally and the smaller below and medially. The capsule around the former is more lax, and movements between the clavicles and the discs are more extensive than those between the discs and the sternum and first costal cartilages. Movement at the joint is further considered below (p. 455), but it should be noted here that the sellar shape of the joint surfaces permits not only *angulation* in approximately anteroposterior and vertical planes but also a small range of rotation (about the clavicular long axis) or *spin* (30° according to Kapandji 1970). This spin is conjunct. The close-packed position of the joint probably coincides with maximum posterior spin associated with full rotation of the scapula (*vide infra*). Some anteroposterior gliding (translation) also occurs.

The *arteries* supplying the joint are branches from the internal thoracic and suprascapular arteries; the *nerves*, from the anterior supraclavicular nerve and the nerve to the subclavius. For details of vascularization consult Sick and Ring (1976).

Applied Anatomy. The strength of this joint depends upon its ligaments, and especially on the articular disc. Owing to this, and to the fact that the force of a blow is usually transmitted along the long axis of the clavicle, dislocation is rare, and the clavicle is usually broken rather than displaced.

The Acromioclavicular Joint

The acromioclavicular articulation (4.40, 42), between the acromial end of the clavicle and the medial margin of the acromion of the scapula, is of approximately plane type; but both surfaces are not quite flat, either of them being sometimes slightly convex, the other reciprocally concave. Both *articular surfaces* are covered with *fibrocartilage*; on the acromial end of the clavicle is a narrow, oval area, directed downwards and laterally to overlap a corresponding area on the medial border of the acromion. The long axis of the joint is anteroposterior. Its ligaments are capsular, acromioclavicular and coracoclavicular.

The fibrous capsule completely surrounds the articular margins, and is strengthened above by the acromioclavicular ligament.

The acromioclavicular ligament is quadrilateral and covers the superior part of the joint, extending between the upper

part of the acromial end of the clavicle and the adjoining part of the upper surface of the acromion. It is composed of parallel fibres, which interlace with the aponeuroses of trapezius and deltoid.

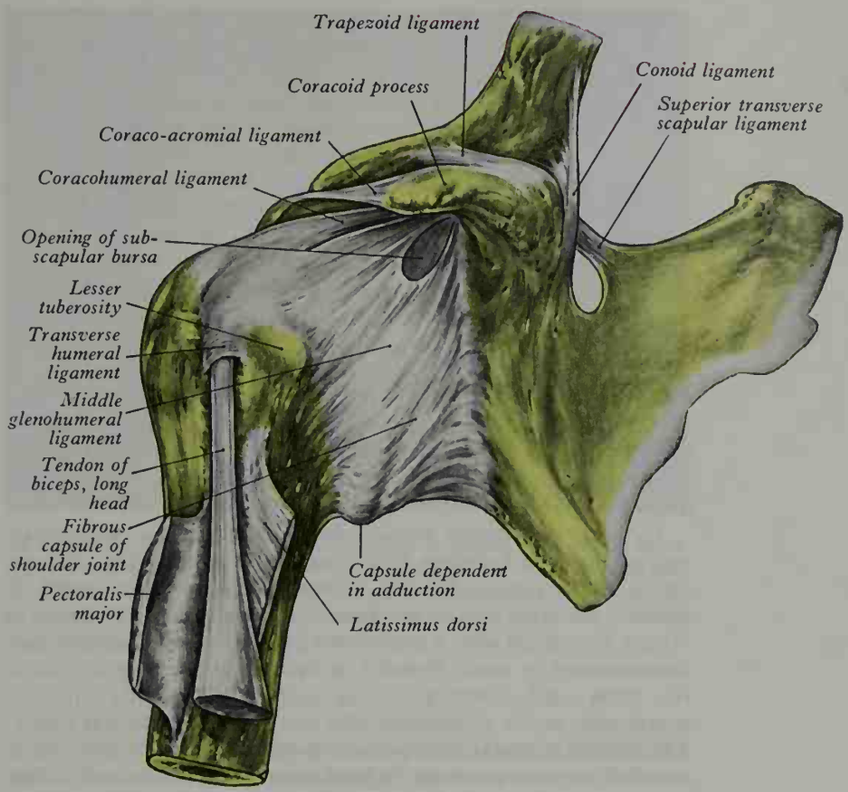
An articular disc is often found in this joint; when present, it occupies the upper part of the articulation, and only partially separates the articular surfaces (de Palma 1957). More rarely, it divides the joint completely.

Movements at the acromioclavicular joint (see also below) are like those of the sternoclavicular articulation. The range of axial rotation of the clavicle here is said to be about 30° (Kapandji 1970). The two joints working together, therefore, permit some 60° rotation of the scapula. Angulation between scapula and clavicle can occur in any direction. Both spin and angulation tense the coracoclavicular ligament (*vide infra*) as extremes are reached, and spin tightens the capsular ligament by spiralization. According to MacConaill and Basmajian (1977) the close-packed position of the joint is achieved in forward rotation of the scapula (*vide infra*), when the angle between the superior scapula border and clavicular shaft becomes about 90°. This 'opening' or *ouverture* of the angle leads to tension of the conoid part of the coracoclavicular ligament (Kapandji 1970). When this position is reached, further rotation of the scapula is permitted by rotation at the sternoclavicular joint.

The coracoclavicular ligament (4.37) connects the clavicle with the coracoid process of the scapula. Though separated by an interval from the acromioclavicular joint it forms a most efficient means of preventing the clavicle from losing contact with the acromion. It consists of two parts, viz. *trapezoid* and *conoid*, which are usually separated by fat or, frequently, a bursa. This bursa thus intervenes between the medial end of the horizontal part of the coracoid process and the lateral end of the groove for the subclavius on the clavicle. These bony regions may be closely apposed and covered with cartilage to form a coracoclavicular joint (Lewis 1959)

The *trapezoid part*, the anterolateral fasciculus, is broad, thin and quadrilateral. It is attached below to the upper surface of the coracoid process and above to the trapezoid line on the inferior surface of the coracoid process and above to the trapezoid line on the inferior surface of the clavicle. The ligament is almost horizontal. Its anterior border is free, its posterior is joined with the conoid part, the two forming, by their junction, an angle projecting backwards.

The *conoid part*, the posteromedial fasciculus, is a dense band above, triangular in form, its base superior. Its apex is attached to the medial and posterior edge of the root of the coracoid process just in front of the scapular notch; its base is fixed to the conoid tubercle on the inferior surface of the clavicle, and to a line proceeding medially from it for a short distance.



The *arterial supply* to the acromioclavicular joint is derived from the suprascapular and thoraco-acromial arteries; the *nerve* supply from the suprascapular and lateral pectoral nerves.

Applied Anatomy. In dislocation of the acromioclavicular joint the coracoclavicular ligament is torn and the scapula falls away from the clavicle. Owing to the flatness and orientation of the joint surfaces, the dislocation readily recurs.

Movements of the shoulder girdle. The clavicular movements which occur at the sternoclavicular and acromioclavicular joints must always be associated with movement of the scapula, and movements of the scapula are usually accompanied by movements of the humerus at the shoulder joint. Therefore this account should be read in association with the description of movements of the shoulder joint (p. 458), and scapular musculature (p. 569).

The acromioclavicular joint allows the acromion, and hence the whole scapula, to glide forwards and backwards, and to rotate on the clavicle, but the range of scapular movement is greatly increased by associated movements at the sternoclavicular joint. The analysis of all these movements can be best made clear by a study of the movements of the scapula.

The movements of the scapula can be primarily analysed as (1) elevation and depression, (2) forward and backward movement round the chest wall, (3) rotation forwards or upwards, using the inferior angle as a reference point, and the reverse movement.

4.37 The right shoulder joint. Anterior aspect.

1. *Elevation and depression of the scapula*, picturesquely exemplified by shrugging of the shoulders, do not necessarily imply movement at the shoulder joint.

During elevation a slight degree of angulation or swing occurs at the acromioclavicular joint, but the sternal end of the clavicle, which rotates round an anteroposterior axis passing through the bone above the attachment of the medial end of the costoclavicular ligament, slides downwards over the surface of the articular disc (*translation*). This movement at the joint is checked by tension of the antagonist muscles, the costoclavicular ligament and the lower part of the capsule. It is brought about by the trapezius (upper part) and the levator scapulae, and, since these muscles tend to rotate the scapula in opposite directions, a purely upward movement can be effected.

In the reverse movement a little angular movement occurs at the acromioclavicular joint, but at the sternoclavicular joint the clavicle slides upwards on the disc, and this is checked by tension of the antagonist muscles, and by the interclavicular and sternoclavicular ligaments and the articular disc. This particular role of the interclavicular ligament in suspension of the clavicle in the depressed position has been confirmed by experiment (Bearn 1967). As a rule this movement is carried out with the help of gravity, but it can be performed actively by the serratus anterior (lower part) and the pectoralis minor.

2. *Forward movement of the scapula (protraction)* round the chest wall occurs in all forward-pushing , thrusting and especially reaching movements, and is usually accompanied by some degree of forward rotation. The acromion moves forwards over the clavicular facet to the limit of its range of movement, and at the same time the point of the shoulder is advanced further by a forward movement of the lateral end of the clavicle, associated with a backward glide of the sternal end of the bone, which moves backwards over the sternal facet, carrying the articular disc with it. Tension of antagonist muscles, of the anterior sternoclavicular ligament and posterior lamina of the costoclavicular ligament checks backward slide of the sternal end of the clavicle. The serratus anterior and the pectoralis minor are the prime movers, and this combination ensures the continuous apposition of the scapula, especially its medial border, in a smooth glide over the chest wall. In addition, the upper part of the latissimus dorsi acts

like a strap to keep the inferior angle in close contact with the thoracic wall, both in this movement and in forward rotation.

In *backward movement of the scapula (retraction)*, such as occurs when the shoulders are braced back, the reverse movements take place and are checked at the sternoclavicular joint by tension of the posterior sternoclavicular ligament and the anterior lamina of the costoclavicular ligament. Trapezius and the rhomboids are the prime movers, but gravity may also produce backward scapular movement, when the weight of the trunk is taken by the arms in leaning forwards; the degree of 'retraction' permitted is controlled through the protraction musculature.

It may be noted here that when force is applied at the extremity of the outstretched arm, e.g. by a fall on the hand, the pressure transmitted to the glenoid cavity tends to drive the sloping acromial facet below the acromial end of the clavicle, but at the same time it causes tension of the trapezoid ligament, which serves to resist the displacement. It must also be noted that, unless the fall is unexpected and sudden, even more extensive forces are available to prevent such dislocation.

3. *Forward rotation of the scapula* serves to increase the range of movement of the humerus, by turning the bone so that the glenoid cavity faces almost directly upwards, the position which it assumes when the arm is raised above the head. This movement is always associated with a degree of elevation of the humerus and accompanied by some forward movement of the scapula round the chest wall. Rotation of the scapula necessarily involves movements at the sternoclavicular and acromioclavicular joints. The sternoclavicular joint permits elevation of the lateral end of the clavicle; this movement is almost complete when the arm has been abducted to 90°. Movement at the acromioclavicular joint occurs in the first 30° of abduction at which point the conoid ligament becomes taut; thereafter abduction is accompanied by a rotation of the clavicle at the sternoclavicular joint around the longitudinal axis of the bone, accompanied by further depression, as its lateral end continues to rise. Some acromioclavicular movement occurs also in the final stages of abduction of the arm (Inman *et al.* 1944). In this important movement the upper part of the trapezius and the lower part of the serratus anterior are the prime movers.

The opposite or *return rotation* is usually effected mainly by gravity, the gradual lengthening of the trapezius and serratus anterior being sufficient to bring it about in a controlled manner. When force is necessary the levator scapulae, rhomboids, and, in the initial stages at least, pectoralis minor are the prime movers in rotating the scapula to its position of rest.

Attention should be drawn to the fact that muscles which are antagonists for one type of movement may nevertheless combine together and act as prime movers for another. Movements and not individual muscles are represented in the cerebral motor centres, and, more significantly, muscles are not associated, in their nervous control, in unalterable partnerships, but can be combined with great plasticity as the demands of movement dictate. Thus the serratus anterior and the trapezius are opposed in forward and backward movements of the scapula round the chest wall, but combine together as prime movers for forward rotation of the bone.

In all the movements of the scapula the subclavius probably serves to steady the clavicle by drawing it medially and downwards, though it is naturally difficult to be certain of its role, due to its relative inaccessibility.

The movements of the scapula on the thoracic wall are greatly facilitated by the loose connective tissue which intervenes between the subscapularis and serratus anterior and between the latter muscle and the costal structures. When the upper limb is pendant, the maintenance of the normal position of the shoulder girdle relative to the trunk involves a comparatively small degree of activity in the trapezius and serratus anterior (Basmajian 1962), which obviously must increase as the weight of the limb is increased by loading.

THE LIGAMENTS OF THE SCAPULA

The ligaments of the scapula (**4**.37) are the coraco-acromial and transverse scapular.

The coraco-acromial ligament is a strong triangular band, extending between the coracoid process and the acromion. Its apex is attached to the edge of the acromion just in front of the articular surface for the clavicle; and its base to the whole length of the lateral border of the coracoid process. This ligament, together with the coracoid process and the acromion, forms an arch above the head of the humerus. It sometimes consists of two strong marginal bands and a thinner intervening portion. When the pectoralis minor is inserted, as it is occasionally, into the capsule of the shoulder joint instead of into the coracoid process, the tendon of the muscles passes between the two bands of the coraco-acromial ligament (p. 568). The subacromial bursa (p. 458 and **4**.39) facilitates movement between the coraco-acromial arch and the subjacent supraspinous muscle and shoulder joint, acting thus almost as a secondary articulation.

The superior transverse scapular (suprascapular) ligament converts the scapular notch into a foramen, and is sometimes ossified. It is a flat fasciculus, narrowing toward its extremities, which are attached to the base of the coracoid process and the medial end of the scapular notch. The suprascapular nerve runs through the foramen; the suprascapular vessels cross over the ligament.

A weak, membranous band, the *inferior transverse (spino-glenoid) ligament*, stretches from the lateral border of the spine of the scapula to the margin of the glenoid cavity. It forms an arch under which the suprascapular nerve and vessels enter the infraspinous fossa. It is frequently absent.

The Humeral (Shoulder) Joint

The shoulder joint is a multi-axial spheroidal joint (**3**.140, **4**.37, 38A, B, C, 41, 42). The bones involved are the roughly hemispherical head of the humerus and the shallow glenoid cavity of the scapula, a construction which permits of very considerable movement but reduces the security of the joint. Skeletally the shoulder joint is weak, since, for such strength as it possesses, it is dependent on the support given by the muscles which surround it and not on its bony conformation or the presence of any strong ligaments. It is, however, covered above by an arch, formed by the coracoid process, the acromion and the coraco-acromial ligament.

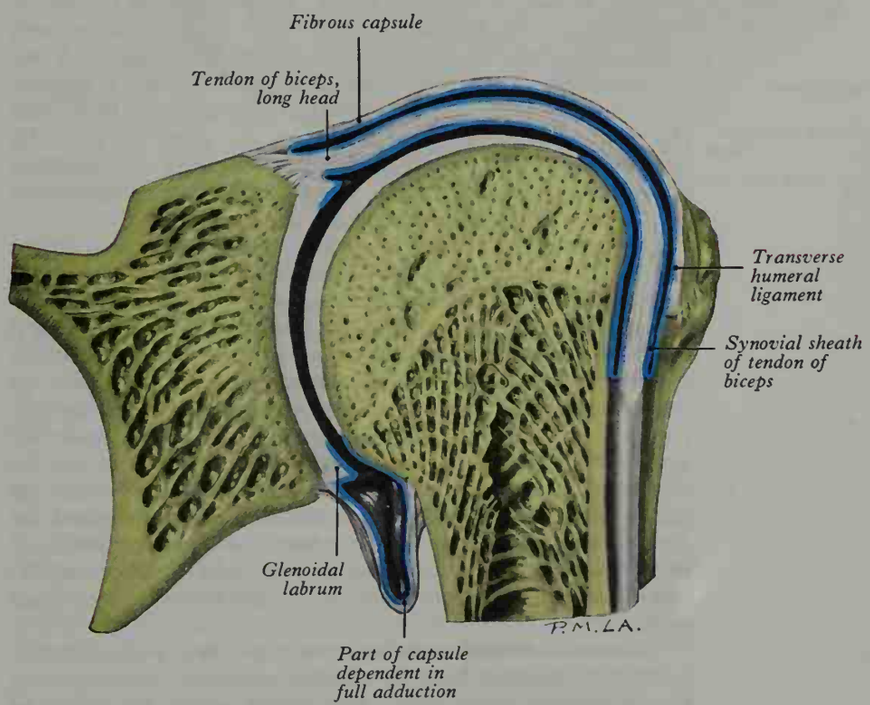
The *articular surfaces* are reciprocally curved and are in fact not sections of true spheres but *ovoids* (*see* p. 432). Here, and in the hip joint, where the ovoid surfaces approximate to a spherical form, as indicated above, they are often classed as *spheroidal*. As the convexity of the humerus is much larger than the glenoid concavity (**4**.38A and B) only a minor part of it can be in contact with the cavity in any given position of the joint and the remainder of its articular surface is in contact with the inner aspect of the capsule. The glenoid cavity (**4**.38A, C, 39) is deepened somewhat by a fibrocartilaginous rim attached to its margins, the *glenoidal labrum*. Both articular surfaces are covered with a layer of hyaline cartilage; that on the head of the humerus is thickest at its centre and thinner peripherally, while the reverse is the case in the glenoid cavity. However, in most positions of the joint, the curvatures of the adjacent parts of the surfaces are not precisely the same, i.e. they are not congruent and the joint is loose-packed (Saha 1961). Full congruence and the close-packed position is reached when the humerus is abducted and laterally rotated (*see* pp. 438, 459; and **4**.5, 17). When the arm is by the side the anterior edge of the glenoid cavity can be represented on the front of the shoulder by a line, 3 cm long, drawn downwards from a point just lateral to the tip of the coracoid process. This line, which should be very slightly concave laterally, lies over the lower half of the joint.

The ligaments of the articulation are the *glenoidal labrum*, *fibrous capsule*, *glenohumeral*, *coracohumeral*, and *transverse humeral*.

The fibrous capsule (**4**.37, 38) envelops the joint, and is attached, medially, to the circumference of the glenoid cavity beyond the glenoidal labrum; above, it encroaches on the root of the coracoid process so as to include the origin of the long head of biceps within the joint. Laterally it is attached to the anatomical neck of the humerus, that is to say close to the articular margin,

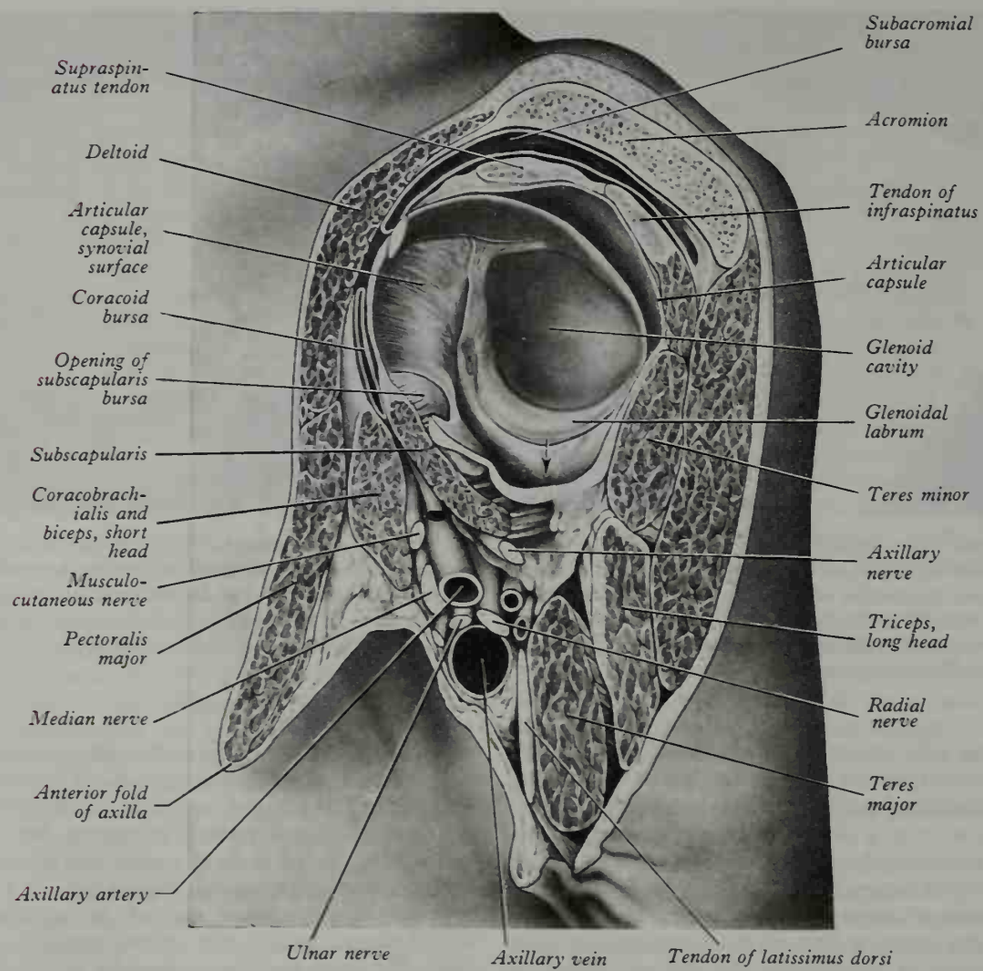
4.38A and B Dissections from a preserved cadaver showing the articular surfaces and periarticular structures of the glenohumeral joint. A shows the glenoid cavity covered by articular cartilage and the glenoidal labrum; note the intracapsular part of the tendon of the long head of the biceps sectioned near the supraglenoid tubercle, the fibrous capsule intimately blended with 'rotator cuff' musculature, the subacromial bursa, and the superjacent coraco-acromial arch complex. B displays the much more extensive spheroidal articular surface of the head of the humerus, and also the pendant inferior part of the fibrous articular capsule. (Preparation by Dr. M. C. E. Hutchinson and photography by Mr. Kevin Fitzpatrick, Guy's Hospital Medical School, London.)

except on the medial side where the attachment descends for rather more than 1 cm on the shaft of the bone. It is so remarkably loose and lax that the bones may even be separated from each other for a distance of 2 or 3 cm by a distractive force. This considerable laxity is obviously to be correlated with the great range of movement which is possible at the shoulder articulation. However, this degree of unphysiological separation can be affected only after the superior part of the ligament has been relaxed by some degree of abduction. The fibrous capsule is supported superiorly, by the supraspinatus; inferiorly, by the long head of the triceps; posteriorly, by the tendons of the infraspinatus and teres minor; anteriorly, by the tendon of the subscapularis. The tendons of the subscapularis, supraspinatus, infraspinatus, and teres minor are all intimately blended with the fibrous capsule forming a cuff, sometimes termed the *rotator cuff*; they reinforce the capsule and provide active support for the joint during movement, and indeed at all times unless fully relaxed. The relationship of the long head of the triceps is not so close, for it is separated from the inferior part of the capsule by the axillary nerve and the posterior circumflex humeral vessels as they pass backwards on leaving the axilla (**4**.41). It is the inferior part of the capsule, therefore, which is least supported, and it is just this part which is subjected to the greatest strain, because it is stretched tightly across the rounded head of the humerus when the arm is fully abducted.



There are usually two, occasionally three, openings in the capsule. One situated anteriorly, below the coracoid process, establishes a communication between the joint and a bursa behind the tendon of the subscapularis; another, placed between the tuberosities of the humerus, gives passage to the long tendon of the biceps and its synovial sheath; the third, which is not constant, is posterior and between the joint and a bursal sac under the tendon of infraspinatus.

Three thickenings, the *glenohumeral ligaments* (**4**.40), reinforce the capsule. These are best seen by opening the joint from behind and removing the head of the humerus. At their scapular ends they are all attached to the upper part of the medial margin of the glenoid cavity and are blended with the glenoidal labrum. The superior band passes along the medial edge of the tendon of biceps and is attached to a small depression above the lesser tubercle of the humerus; the middle band reaches to the lower part of the lesser tubercle; the inferior band extends to the lower part of the anatomical neck of the humerus. In addition to these, the capsule is strengthened in front by extensions from the tendons of pectoralis major and teres major.



The *synovial membrane* lines the inner surface of the fibrous capsule, and covers the lower part and sides of the anatomical neck of the humerus as far as the articular cartilage on the head of the bone. The tendon of the long head of the biceps passes through the joint and is enclosed in a tubular sheath of synovial membrane, which is continued round the tendon into the intertubercular sulcus as far as the surgical neck of the humerus (**4**.37, 38).

The coracohumeral ligament (**4**.37), a broad band strengthening the upper part of the capsule, is attached to the lateral border of the root of the coracoid process, and passes obliquely downwards and laterally to the front of the greater tubercle of the humerus, blending with the tendon of supraspinatus. The posterior and lower border of the ligament is united to the fibrous capsule; its anterior and upper border is free, and overlaps it.

The transverse humeral ligament (**4**.37) is a broad band passing from the lesser to the greater tubercle of the humerus; it converts the intertubercular sulcus into a canal, and its

4.38C A section through the shoulder joint. The synovial membrane is in blue.

4.39 An obliquely coronal section through the left shoulder and shoulder joint, dissected after removal of the upper limb. The arrow points to the dependent part of the articular capsule. *Note*—The relations of the axillary vessels to each other and to the branches of the brachial plexus as displayed in this dissected section may be misleading, and the reader is referred to **6**.69 for the usual view.

attachment lies above the epiphysial line. The ligament functions simply as a retinaculum for the tendon of the long head of biceps.

The glenoidal labrum (**4**.39) is a fibrocartilaginous rim attached round the margin of the glenoid cavity. It is triangular on section, the base being fixed to the circumference of the cavity, while the free edge is thin and sharp. It is continuous above with the tendon of the long head of the biceps, which gives off two fasciculi to blend with the fibrous tissue of the labrum. It deepens the articular cavity, may protect the edges of the bone, and probably assists in the lubrication of the joint (p. 424). Its attachment to the margin of the glenoid cavity is sometimes deficient in parts, and a small fringe of the synovial membrane occasionally protrudes through such gaps.

The bursae in the neighbourhood of the shoulder joint are the following: (1) one between the tendon of the subscapularis and the joint capsule (**4**.40), communicating with the joint through an opening between the superior and the middle glenohumeral ligaments; (2) one sometimes separates the tendon of infraspinatus and the capsule; it occasionally opens into the joint; (3) the *subacromial bursa* (**4**.39) lies between deltoid and the capsule; it does not communicate with the joint, but is prolonged under the acromion and coraco-acromial ligament, between them and the supraspinatus; (4) one on the upper surface of the acromion; (5) one is frequently found between the coracoid process and the capsule; (6) one sometimes exists behind the coracobrachialis; (7) one between the teres major and the long head of the triceps; (8) one in front of, and another behind, the tendon of the latissimus dorsi.

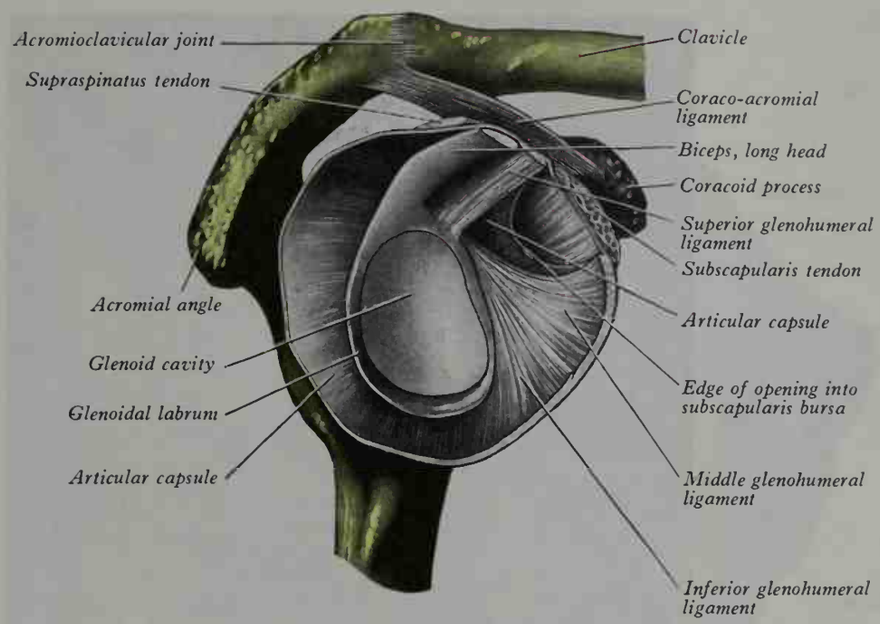
The *muscles* related to the joint are, superiorly, supraspinatus; inferiorly, the long head of triceps; anteriorly, subscapularis; posteriorly, infraspinatus and teres minor; within, the tendon of the long head of biceps. Deltoid covers the joint in front, behind and laterally (**4**.39).

The *arteries* supplying the joint are derived from the anterior and posterior circumflex humeral and suprascapular arteries.

The *nerves* of the joint are derived mainly from the posterior cord and from the suprascapular, axillary and the lateral pectoral nerves. The suprascapular supplies the superior and posterior parts of the articular capsule, the axillary, the inferior and anterior parts, and the lateral pectoral, the anterior and superior parts (Gardner 1948).

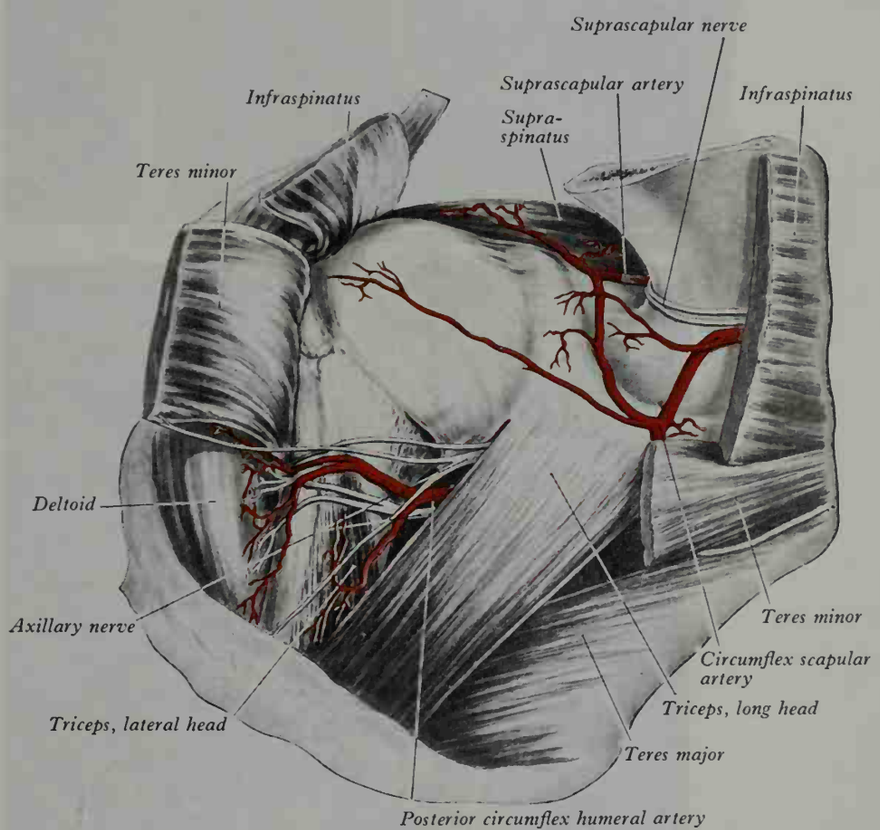
Movements. The shoulder is a multi-axial spheroidal joint, and therefore is capable of an infinite variety of combinations of swinging and spinning movements (p. 435) but these may all be described as rotations of the moving bone about three mutually perpendicular axes, i.e. it possesses three degrees of freedom (p. 429). Classically the joint is considered to permit the movements of flexion-extension, abduction-adduction, circumduction, and medial and lateral rotation (p. 430). The laxity of its articular capsule and the large size of the head of the humerus compared with that of the shallow glenoid cavity give to the shoulder a wider range of movement than is possible at any other joint. Notwithstanding this, however, when the arm is dependent, even when it carries a moderate load, the supraspinatus, combined with tension in the upper part of the fibrous capsule, suffices to prevent downward displacement of the humerus in relation to the glenoid cavity (Basmajian 1962).

When the movements at the shoulder joint are being analysed, it is preferable and easier to consider the movements of the humerus in relation to the scapula rather than to the sagittal and coronal planes, and the relevant axes are illustrated in **4**.5A, B, C. When the arm is by the side in the resting position, the glenoid cavity faces almost equally forwards and laterally, and the position of the humerus corresponds to that of the scapula, although relative to the anatomical position it is rotated medially (p. 431). As a result *flexion* carries the arm forwards and medially



across the front of the chest, and the movement takes place around an axis which passes through the head of the humerus at right angles to the plane of the glenoid cavity at (approximately) its centre. *Abduction and adduction* occur in a vertical plane at right angles to the plane of flexion and extension, and the axis passes horizontally through the head of the humerus parallel to the plane of the glenoid cavity (Flecker 1929). Pure abduction therefore carries the arm anterolaterally away from the trunk, and *the movement occurs in the plane of the body of the scapula.* If, however, the movements of the humerus are considered in relation to the *trunk* and not to the scapula, flexion and extension occur in the paramedian plane and abduction and adduction in the coronal plane. Then the deltoid and supraspinatus produce a combination of flexion and extension, and raising the arm towards the vertical from a position of flexion (in this sense) involves medial rotation of the humerus; raising it to the vertical from the position of abduction (in this sense) is accompanied by lateral rotation of the humerus. Whether 'scapular' or any other form of abduction is described, it must be emphasized that these are merely selected planes in an infinite series. In pure (scapular) abduction points on the humeral surface pursue vertical chords, whereas in rotation the chords are horizontal. In 'pure' flexion-extension, in a plane orthogonal to the scapular plane movement is around a notional mechanical axis projected from the centre of the glenoid cavity.

At the glenohumeral joint the limit of abduction is about 90° (Kapandji 1970), but figures as high as 120° have been stated (Inman *et al.* 1944). About 60° further abduction is contributed by the sterno- and acromio-clavicular articulations. Contralateral flexion of the vertebral column aids in bringing the arm to a vertical position. It must be emphasized, however, that during active elevation of the arm the movement at the shoulder joint and the separate movements of the scapula and clavicle occur simultaneously—except in the initial stages (25°–30°), when most and in some cases the whole of the movement takes place at the shoulder joint. For every 15° of elevation the glenohumeral joint is said to contribute 10° and the scapular movement 5°.



In flexion, however, the humerus moves in a plane at right angles to the plane of the body of the scapula, and no amount of rotation of the scapula can increase the degree of elevation (120°) obtained in full flexion. If the fully flexed humerus is gradually abducted, the degree of elevation increases *pro rata*, until, when the humerus comes to lie in the plane of the body of the scapula, i.e. when the position of true abduction is reached, the full 180° of elevation may be obtained. In *rotation*, which may be medial or lateral, the humerus revolves for about one-quarter of a circle about a vertical axis. The range of rotatory movement is greatest when the arm is by the side, and least when it is raised to the vertical. In practice, when assessing the range of medial and lateral rotation of the humerus at the glenohumeral joint, it is advisable to do so with the forearm bones flexed to a right angle at the elbow joint—this prevents misinterpretation due to superadded movements of either pronation or supination which may occur with the dependent limb. In *circumduction*, which results from a succession of the foregoing movements, the lower end of the humerus describes the base of a cone, the apex of which is at the head of the bone, but this movement at the shoulder joint can be increased very substantially by the movements of the scapula, and the combination is well exemplified in the arm movements of a fast bowler in cricket.

In the newer terminology, it will be realized that because of the offset position of the articular head of the humerus in relation to the long axis of its shaft, the flexion-extension movements of the bone are accompanied by almost pure 'spins' of the head in relation to the glenoid cavity (p. 434). The remaining movements possible at the joint are an infinite variety of cardinal or arcuate swings or successions of these—some of the general consequences of such movements are discussed on pp. 434, 436.

The peculiar relation of the tendon of the long head of the biceps to the shoulder joint appears to subserve various purposes. By its connexion with both the shoulder and elbow the muscle harmonizes the action of the two joints, and acts as an elastic ligament during all the movements which occur at these articulations. It strengthens the upper part of the shoulder joint, and helps to prevent the head of the humerus from being pressed

4.40 Interior of the right shoulder joint. Anterolateral aspect.

up against the acromion when the deltoid contracts (*vide infra*). By its passage along the intertubercular sulcus it assists in steadying the head of the humerus in the various movements of the arm.

Owing to the shallowness of the glenoid cavity and the laxity of the capsule, a wide range of *accessory movements* (p. 429) is possible at the shoulder joint. The head of the humerus can be moved backwards, forwards, upwards and downwards in relation to the glenoid cavity and, when the arm is abducted—the position in which the accessory movements are most free—it can be separated from the cavity by traction.

Muscle producing the movements. The muscles moving

the shoulder may be divided into: (*a*) those acting on the shoulder girdle itself and (*b*) those acting on the shoulder joint.

(*a*) **Muscles acting on the shoulder girdle**. These muscles have already been considered in connection with the movements of the girdle (p. 455).

(*b*) **Muscles acting on the shoulder joint**. The principal muscles concerned—the deltoid, pectoralis major, latissimus dorsi and teres major all converge on the humerus and act to considerable mechanical advantage on a joint which, owing to the shallowness of the glenoid cavity and the laxity of the articular capsule, is less stable than it would otherwise be. This is counteracted by the influence of the short muscles inserted close to the upper end of the humerus, viz. the subscapularis, supraspinatus, infraspinatus and teres minor, for they function frequently as postural muscles to retain the head of the humerus in its correct alignment relative to the glenoid cavity, and to resist the tendency to uncontrolled skid during active movements.

Flexion. Pectoralis major (clavicular part) (p. 567), deltoid (anterior fibres) and coracobrachialis, assisted by biceps. The sternocostal part of pectoralis major plays an important part when the arm is drawn forwards to the plane of the trunk from the fully extended position.

Extension. Deltoid (posterior fibres) and teres major, when the movement starts with the arm by the side. When the fully flexed arm is extended against resistance, the latissimus dorsi and the sternocostal part of the pectoralis major are powerful adjuvants until the arm reaches the plane of the body.

Abduction. Deltoid. It should be noted that, in the initial stages, its force is exerted mainly in an upward direction and, unless opposed, would result in upward displacement of the head of the humerus. The subscapularis, infraspinatus and teres minor provide the opposing force by exerting downward traction on the head of the bone and these three muscles and the deltoid constitute a 'couple', the effect of which is to produce true abduction, i.e. elevation of the humerus in the plane of the scapula. The supraspinatus assists in effecting and maintaining the movement, but its precise role is a matter of controversy.

Medial rotation.. Pectoralis major, deltoid (anterior fibres), latissimus dorsi, teres major and, when the arm is by the side, subscapularis.

Lateral rotation. Infraspinatus, deltoid (posterior fibres) and teres minor.

Applied Anatomy. Owing to the adaptation of the shoulder joint to provide a wide range of movement, it is more often dislocated than any other. Dislocation usually occurs when the arm is abducted, when the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rent in the capsule is almost invariably here, and through it the head of the bone escapes, so that the dislocation in most instances is primarily subglenoid. If, after the dislocation has been reduced, abduction of the arm is prevented, the dislocation cannot recur.

When the shoulder joint is ankylosed, the loss of movement in the joint is partly compensated for by increased mobility of the scapula. In treating conditions of the shoulder joint likely to lead to ankylosis, the humerus should be kept in the position it assumes when the palm of the hand is placed on the back of the neck, i.e. abducted, so as to make full use of this compensating mobility of the scapula.

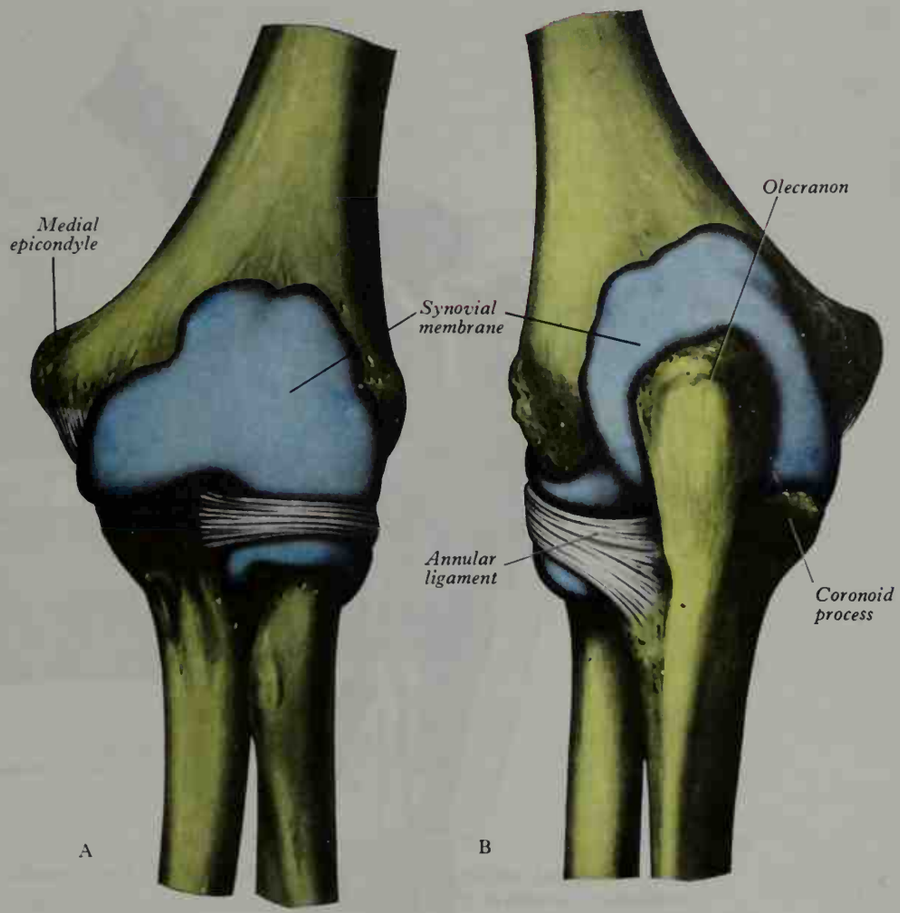
The Cubital (Elbow) Joint

The elbow joint (**3**.149, 150; **4**.48), includes two articulations: (1) *humero-ulnar*, between the trochlea of the humerus and the trochlear notch of the ulna, and (2) *humeroradial*, between the capitulum of the humerus and the facet on the head of the radius. It is hence a *compound* synovial joint. Its complexity is increased further by its continuity with the superior radio-ulnar joint, and the complete articular complex is the *cubital articulation*. The superior radio-ulnar joint will, however, be considered separately.

The *articular surfaces* are the trochlea and capitulum of the humerus, on the one hand, and the trochlear notch of the ulna and

the head of the radius, on the other. The trochlea is not part of a simple pulley, for its medial flange is much more extensive than its lateral flange and projects downwards to a lower level, so that the line of the joint, which is roughly 2 cm below the line joining the two epicondyles, passes downwards and medially. In addition, the trochlea is widest posteriorly and in this position its lateral edge is a sharp rim. The trochlear notch is by no means perfectly congruent with the trochlea. In full extension the medial part of its upper (olecranon) half is not in contact with the trochlea, and a corresponding strip on the lateral side loses contact on flexion. In addition, the description of the trochlea just given should not obscure the fact that it is an asymmetric type of sellar surface—largely concave transversely and convex anteroposteriorly—and that sections of these surfaces show them to be compounded spirals. Consequently the principal swing, or to-and-fro movement of the hinge, is accompanied (as in all hinge joints) by screwing and conjunct rotation (pp. 434, 436). The olecranon and coronoid parts of the trochlear notch are usually separated by a narrow, roughened strip of bone, devoid of articular cartilage and covered with a little fibro-adipose tissue covered by synovial membrane. The capitulum and the head of the radius are reciprocally curved, but the best contact is obtained when the semiflexed radius is in the midprone position. The rim of the head, which is more prominent medially, fits into the groove between the capitulum and the trochlea.

The humero-ulnar and humeroradial articulations together form a largely uni-axial joint, the ligaments of which are the articular capsule, and ulnar and radial collateral ligaments.



The articular capsule (**4**.44, 45). The anterior part of the *fibrous capsule* is a broad and thin layer. It is attached, above, to the front of the medial epicondyle and to the front of the humerus immediately above the coronoid and radial fossae below, to the anterior surface of the coronoid process of the ulna and to the annular ligament (p. 462), being continuous at the sides with the ulnar and radial collateral ligaments. Anteriorly the capsule is related to the brachialis and receives numerous fibres from its deep surface.

The posterior part of the fibrous capsule is thin. Above, it is attached to the humerus immediately behind the capitulum and close to the lateral margin of the trochlea, to all but the lower part of the rim of the olecranon fossa, and the back of the medial epicondyle some distance from the trochlea. Inferomedially it is fixed to the upper and lateral margins of the olecranon, and laterally it is continuous with the capsule of the superior radio-ulnar joint deep to the annular ligament (p. 462). It is related, behind, to the tendon of triceps and to anconeus.

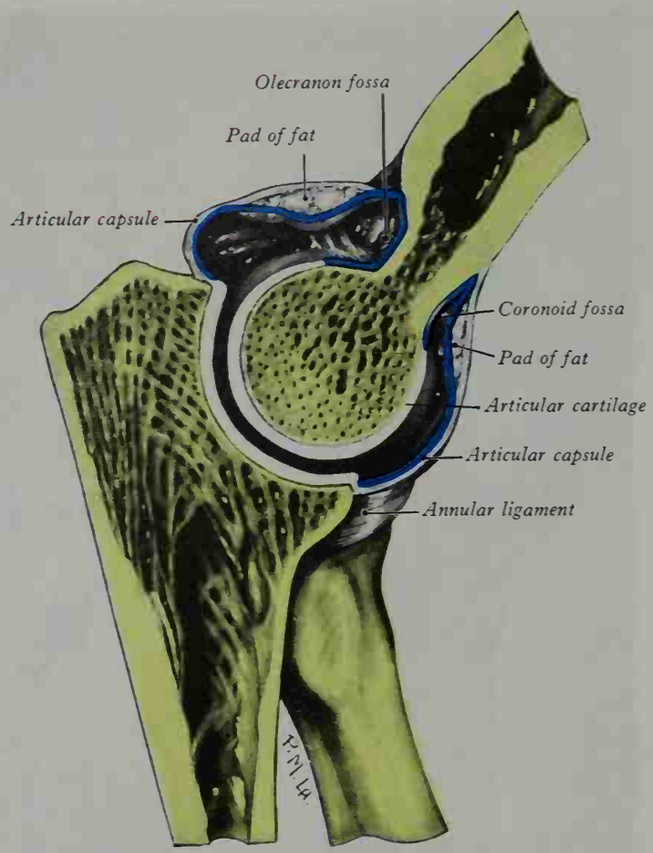
The *synovial membrane* (**4**.43, 44) extends from the margin of the articular surface of the humerus, lines the coronoid, radial and olecranon fossae of that bone and covers the flattened medial surface of the trochlea (**3**.136); it is reflected over the deep surface of the fibrous capsule and lines the deep surface of the lower part of the annular ligament. Projecting into the joint between the radius and ulna from behind there is a crescentic fold of synovial membrane, partly dividing the joint into humeroradial and humero-ulnar parts. This fold is irregularly triangular and contains a variable quantity of extrasynovial fat (**4**.46).

Between the fibrous capsule and the synovial membrane there are three other pads of fat. The largest, over the olecranon fossa, is pressed into this by the triceps during flexion of the joint; the second, over the coronoid fossa, and the third, over the radial fossa, are pressed by the brachialis into their respective fossae during extension. They are, of course, displaced from these fossae during the opposite of these movements. In addition, smaller tags of fat covered with synovial membrane project into the joint cavity opposite to the constrictions on each side of the trochlear notch (p. 367), and cover the small nonarticular areas of the bone in these situations.

The ulnar collateral ligament of the elbow joint (**4**.45A) is a thick triangular band consisting of two parts, an anterior and a posterior, united by a thinner intermediate portion; it is sometimes called the medial ligament. The *anterior part* is attached above, by its apex, to the front of the medial epicondyle of the humerus, and below, by its broad base, to a tubercle on the upper part of the medial margin of the coronoid process. The

4.43A The synovial cavity of the left elbow joint, partially distended. Anterior aspect. (Originally drawn from a specimen prepared by J. C. B. Grant.) The fibrous capsule of the elbow joint has been removed but the annular ligament has been left *in situ*. Note that the synovial membrane descends below the lower border of the annular ligament.

4.43B The synovial cavity of the left elbow joint, partially distended. Posterior aspect of the specimen represented in **4**.43A.



posterior part, also of triangular form, is attached, above, to the lower and back part of the medial epicondyle; below, to the medial margin of the olecranon. Between these two bands a few intermediate fibres descend from the medial epicondyle to an *oblique band*—often feebly developed—which stretches between the olecranon and coronoid processes. This converts the depression on the medial margin of the trochlear notch into a foramen, through which the intracapsular pad of fat is continuous with the extracapsular fat on the medial side of the joint. The ulnar collateral ligament is related to the triceps and flexor carpi ulnaris *and the ulnar nerve*. Along its anterior portion the origin of the flexor digitorum superficialis extends from the medial epicondyle of the humerus downwards and laterally to the medial border of the coronoid process of the ulna.

The radial collateral ligament of the elbow joint (**4**.45B) is attached to the lower part of the lateral epicondyle of the humerus, and below to the annular ligament, some of its most posterior fibres passing over it to the upper end of the supinator crest of the ulna. It is intimately blended with the origins of the supinator and the extensor carpi radialis brevis.

The *muscles* in relation with the joint are, in front, brachialis, behind, triceps and anconeus, laterally, supinator and the common tendon of origin of the extensor muscles, medially, the common tendon of origin of the flexor muscles, and the flexor carpi ulnaris.

The *articular arteries* are derived from the anastomotic network around the joint (**6**.74).

The *articular nerves* are mainly from the musculocutaneous and radial nerves, but the ulnar, median and, sometimes, the anterior interosseous nerves also contribute articular branches. The

4.44 A sagittal section through the left elbow joint. The synovial membrane is shown in blue. Medial aspect.

branch from the musculocutaneous arises from the nerve to brachialis and is distributed to the anterior part of the articular capsule. The articular branches of the radial nerve supply the posterior and anterolateral portions of the articular capsule and are derived both from the nerve to anconeus and from the ulnar collateral branch to the medial head of triceps. The ulnar nerve supplies twigs to the ulnar collateral ligament as it lies behind the medial epicondyle (Gardner 1948). These articular nerves are closely associated with the blood vessels supplying the synovial membrane, fat pads and epiphyses; presumably they contain some vasomotor fibres in addition to afferent fibres subserving the modalities of pain and proprioception.

Movements. The elbow is a uni-axial or hinge joint and its movements consist of flexion and extension, the ulna moving on the trochlea, and the head of the radius on the capitulum of the humerus. However, the flexion-extension movements of the ulna do not constitute a pure swing but are accompanied by a small degree of conjunct rotation—the ulna is slightly pronated during extension, and supinated during flexion. Since the capitulum of the humerus is smaller than the head of the radius, the posterior edge of the head of the radius can be felt projecting at the back of the joint when the forearm is fully extended. The movement of extension is limited by the tension of the fibrous capsule and muscles on the front of the joint (extension constituting the close-packed position of the joint), that of flexion chiefly by apposition of soft parts.

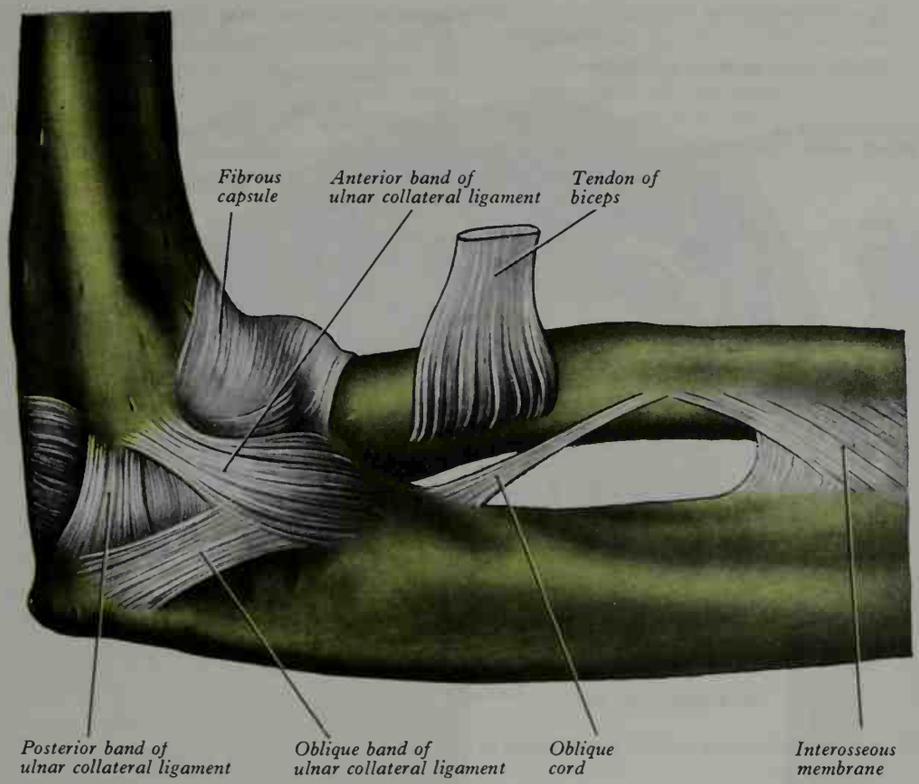
When the forearm is fully extended and the hand supinated, the upper arm and forearm are not in the same line; the forearm is directed somewhat laterally, and, in both sexes, forms with the upper arm the 'carrying angle' of about 163° open to the lateral side (Steel and Tomlinson 1958). Owing to the existence of this angulation the ulnar border of the supinated and extended forearm cannot be brought into contact with the lateral surface of the thigh when the arm is by the side. The 'carrying angle' is caused partly by the medial edge of the trochlea of the humerus, which projects about 6 mm below the lateral edge, and partly by the obliquity of the superior articular surface of the coronoid process, which is not set at right angles to the shaft of the ulna. The angles which the articular surfaces of the humerus and the ulna make with the long axes of the bones are approximately equal, and as a result the carrying angle disappears on full flexion of the forearm and the two bones come to lie in the same plane. When this movement is carried out with the arm by the side, the ulnar border of the little finger lies over the clavicle on account of the position of the resting humerus (p. 459). If the humerus is rotated laterally during the movement, the hand is carried upwards in front of the shoulder. The carrying angle is masked also in pronation of the extended forearm, and this has the effect of bringing the upper arm, the semipronated forearm and the hand into the same straight line. This arrangement increases the precision with which the hand, and any instrument or weapon held in the hand, can be controlled in full extension of the elbow or while the elbow is being extended.

The *accessory movements* of the elbow joint are limited to slight screw action, abduction and adduction of the ulna, and forward and backward movement of the head of the radius on the capitulum of the humerus. In the latter movement, the head of the radius is moved on the radial notch of the ulna also, the annular ligament being slewed backwards and forwards at the same time. The extent of this movement is greater when the elbow joint is half-flexed.

Muscles producing the movements.

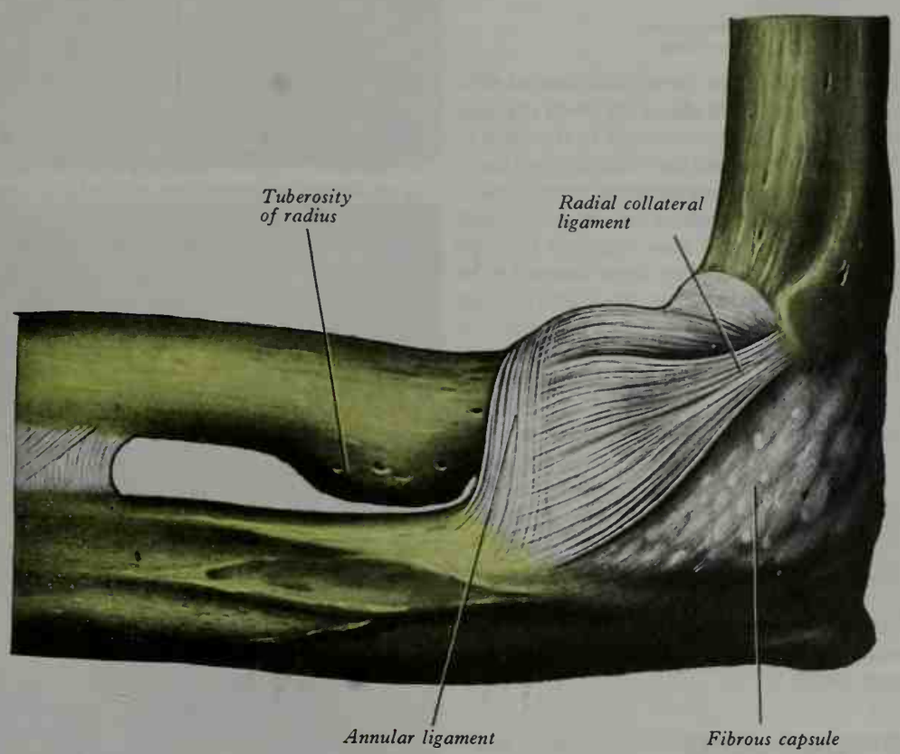
Flexion. Brachialis, biceps and brachioradialis. In slow flexion or in the maintenance of flexion against gravity, even when the forearm carries a moderate load, the brachialis and biceps are principally involved. With increasing speed of movement, activity in brachioradialis becomes increasingly prominent (MacConaill 1949; Basmajian 1959). Owing to the position of its attachments it acts most effectively when the forearm is in the mid-prone position. Against resistance pronator teres and flexor carpi radialis may act.

Extension. Triceps and anconeus. In rapid extension brachioradialis again acts as a shunt muscle (pp. 528, 578).



The Radio-ulnar Joints

The radius and the ulna are connected at their upper and lower extremities by synovial joints, the *proximal* and *distal radio-ulnar joints*. In addition, the shafts of the bones are connected by an interosseous membrane and a ligament, which together are commonly regarded as a non-synovial, *middle radio-ulnar joint*.



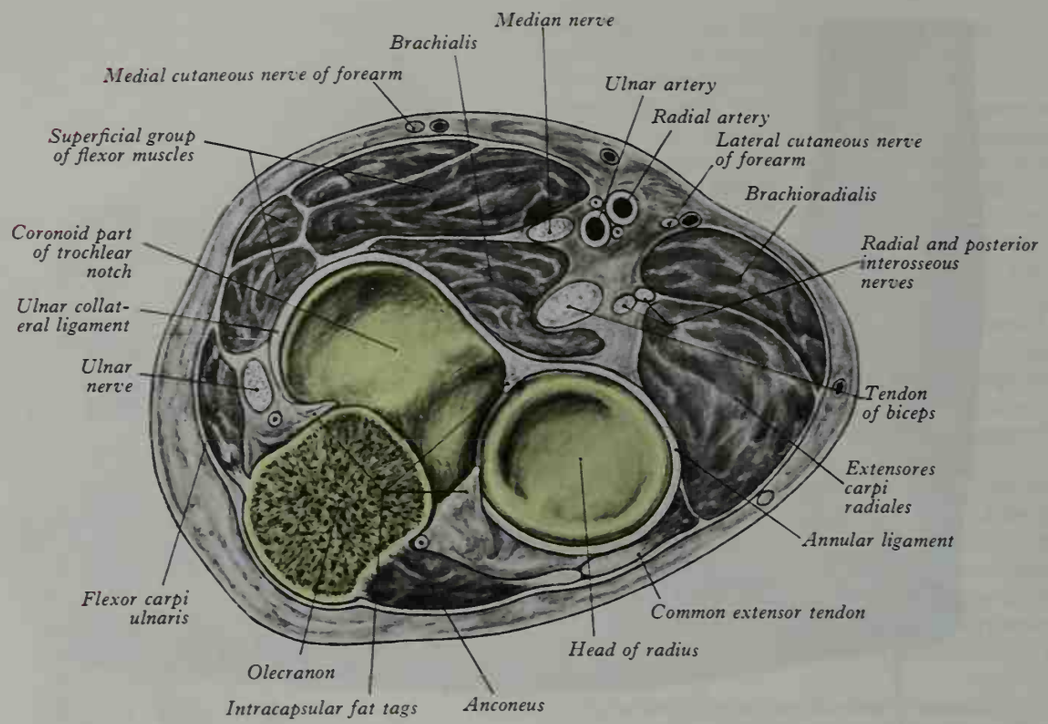
THE PROXIMAL RADIO-ULNAR JOINT

This articulation forms a uni-axial pivot between the circumference of the head of the radius and the osseofibrous ring formed by the radial notch of the ulna and the annular ligament.

The annular ligament (4.45, 46, 47, 49), a strong band, encircles the head of the radius, and retains it in contact with the radial notch of the ulna. It forms about four-fifths of the osseofibrous ring. In front it is attached to the anterior margin of the radial notch. Posteriorly it broadens and may divide into several bands to attach to a rough ridge on the ulna at or just behind the posterior margin of the radial notch; outlying bands may reach the lateral margin of the trochlear notch above and the upper end of the supinator crest below. The upper border of the ligament blends with the fibrous capsule of the elbow joint except posteriorly where the fibrous capsule passes as a separate entity deep to the ligament to be attached around the posterior and inferior margins of the radial notch. From the lower border a few fibres pass over the reflexion of the synovial membrane to be loosely attached to the neck of the radius. A thin fibrous layer, often termed the *quadrate ligament*, covers the synovial membrane which closes the distal aspect of the joint between the radius and ulna (Martin 1958). The *superficial surface* of the annular ligament blends with the radial collateral ligament of the elbow, and affords origin to part of the supinator. It is related posteriorly to the anconeus and the interosseous recurrent artery. On its *internal surface* the annular ligament has a thin coating of cartilage where it

4.45A The left elbow joint. Medial aspect.

4.45B The left elbow joint. Lateral aspect.



comes into contact with the circumference of the head of the radius; its lower part is covered with synovial membrane which is reflected upwards on to the neck of the bone.

THE MIDDLE RADIO-ULNAR UNION

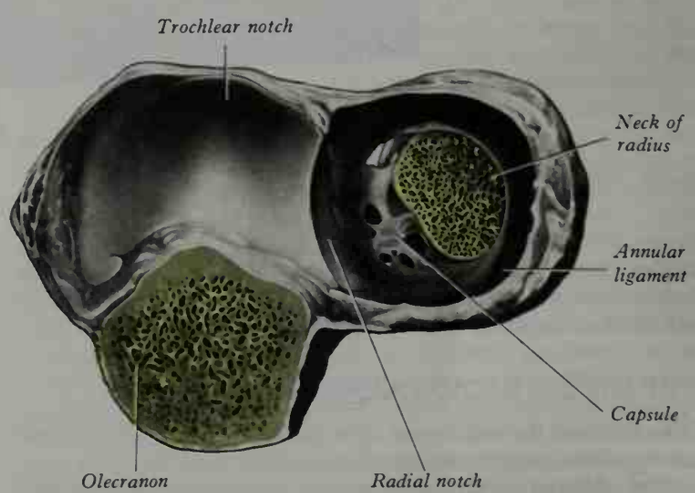
The shafts of the radius and ulna are connected by the oblique cord and the interosseous membrane of the forearm.

The oblique cord (4.49) is a small, inconstant, flattened band or cord formed in the fascia overlying the deep head of supinator and extending from the lateral side of the tuberosity of the ulna to the radius a little below the radial tuberosity. Its fibres run at right angles to those of the interosseous membrane. It is sometimes absent and can scarcely be considered of much functional significance.

The interosseous membrane of the forearm (4.49) is a broad and thin sheet, the fibres of which slant downwards and medially from the interosseous border of the radius to that of the ulna; the lower part of the membrane is attached to the posterior of the two lines into which the interosseous border of the radius divides. Two or three bands are occasionally found on the posterior surface of this membrane; their fibres descend obliquely from the ulna towards the radius, i.e. across the other fibres. The membrane is deficient above, commencing about 2 or 3 cm below

4.46 Transverse section of the right elbow joint to show the relations of the joint. Superior aspect.

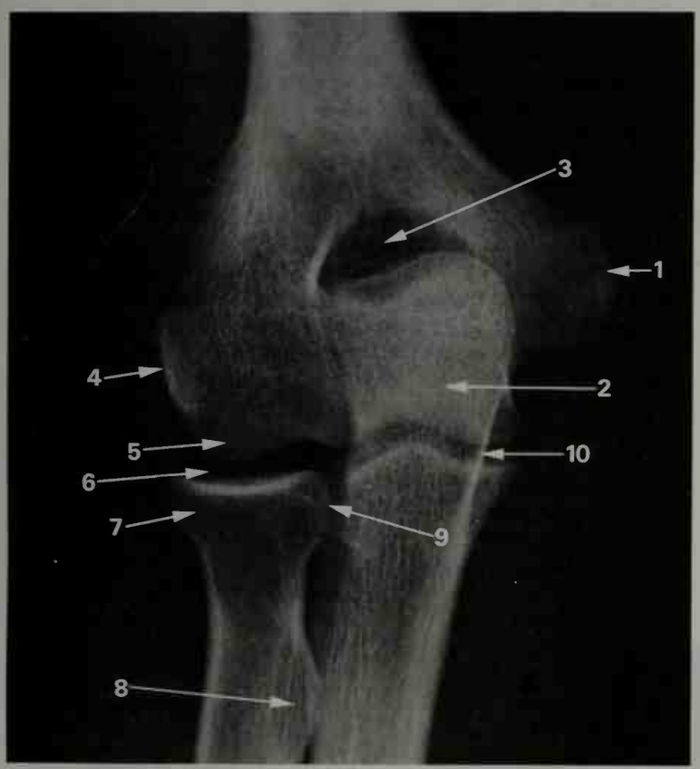
the tuberosity of the radius, is broader in the middle than at each end, and presents an oval aperture a little above its lower margin, for the passage of the anterior interosseous vessels to the back of the forearm. Between its upper border and the oblique cord there is a gap, through which the posterior interosseous vessels pass. The membrane increases the extent of surface for the attachment of the deep muscles of the forearm and also connects the two bones. The arrangement of its fibres has often been claimed to be such as to transmit to the ulna and thence to the humerus any force acting upwards through the hand and radius. However, it is only tense when the hand is midway between the prone and supine positions and is somewhat relaxed in complete pronation and supination, and the hand is usually pronated when subjected to such forces. Further, it has been shown that the radius can itself transmit substantial forces directly to the humerus (Travill 1964). *In front* the membrane is related, in its upper three-fourths, to flexor pollicis longus on the radial side, flexor digitorum profundus on the ulnar side, and between these to the anterior interosseous vessels and nerve, in its lowest quarter with pronator quadratus; *behind* it is related to supinator, abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, extensor indicis and, near the wrist, with the anterior interosseous artery and posterior interosseous nerve.



THE DISTAL RADIO-ULNAR JOINT

This is a uni-axial pivot joint between the convex lower end (head) of the ulna and the concave ulnar notch of the lower end of the radius; the surfaces are enclosed in an articular capsule and are also held together by an articular disc.

The fibrous capsule is slightly thickened in front and behind; above, it is lax and lined with synovial membrane which projects upwards as a pouch (*recessus sacciformis*) in front of the lower part of the interosseous membrane.



The articular disc (4.52), triangular in shape, binds the lower ends of the ulna and radius together. Its periphery is thicker than its centre, which is occasionally perforated. It is attached by a broad apex to a depression between the styloid process and the inferior surface of the head of the ulna, and by its base, which is thin, to the prominent edge which separates the ulnar notch from the carpal articular surface of the radius. Its margins are united to the ligaments of the wrist joint. Its *upper and lower surfaces* are both smooth and concave. The upper articulates with the head of the ulna, whilst the lower forms a part of the radiocarpal joint and articulates with the medial part of the lunate bone; when the hand is adducted, it articulates with the triquetral bone.

Mikić (1978) studied 180 wrist joints from 100 fresh cadavers ranging in age from fetuses to 94 years, and concluded that the triangular fibrocartilaginous disc showed an age-dependent degeneration, consisting of progressively reduced cellularity, loss of elastic fibres, mucoid degeneration of the ground substance, exposure of collagen fibres, fibrillation, ulceration, abnormal thinning, and ultimately disc perforation. No perforations were found in the first two decades, 7·6 per cent in the third, 18·1 per cent in the fourth, 40 per cent in the fifth, 42·8 per cent in the sixth, and 53·1 per cent in those over sixty. Associated with degeneration of the disc, comparable degenerative changes were frequently found in the 'discal' surface of the ulnar head, and the 'discal' area of the proximal articular facet of the lunate bone.

4.47 The annular ligament of the right radius. Superior aspect. The head of the radius has been sawn off and the bone dislodged from the ligament.

Movements. The movements which take place at the radio-ulnar joints result in pronation and supination of the hand. In *pronation* the radius, carrying the hand with it, is turned obliquely across the front of the ulna, its upper end remaining lateral and its lowest end becoming medial to that bone. In *supination* the movement is reversed and the radius lies lateral to and parallel with the ulna. When the movement is limited to the radio-ulnar joints, the hand can be turned through an angle of 140°–150°, but, provided that the elbow joint is extended, the apparent range can be increased to nearly 360° by rotation of the humerus accompanied by forward and backward movements of the shoulder girdle. The power of supination is greater than that of pronation. This point has been appreciated in the industrial design of nuts, bolts and screws, which are tightened or inserted by supinative movements in right-handed persons. Moreover, supination is an anti-gravity movement and in seizing objects for examination (or many other purposes) pronation is merely a preliminary activity, aided by gravity.

4.49 The interosseous membrane of the forearm. Anterior aspect.

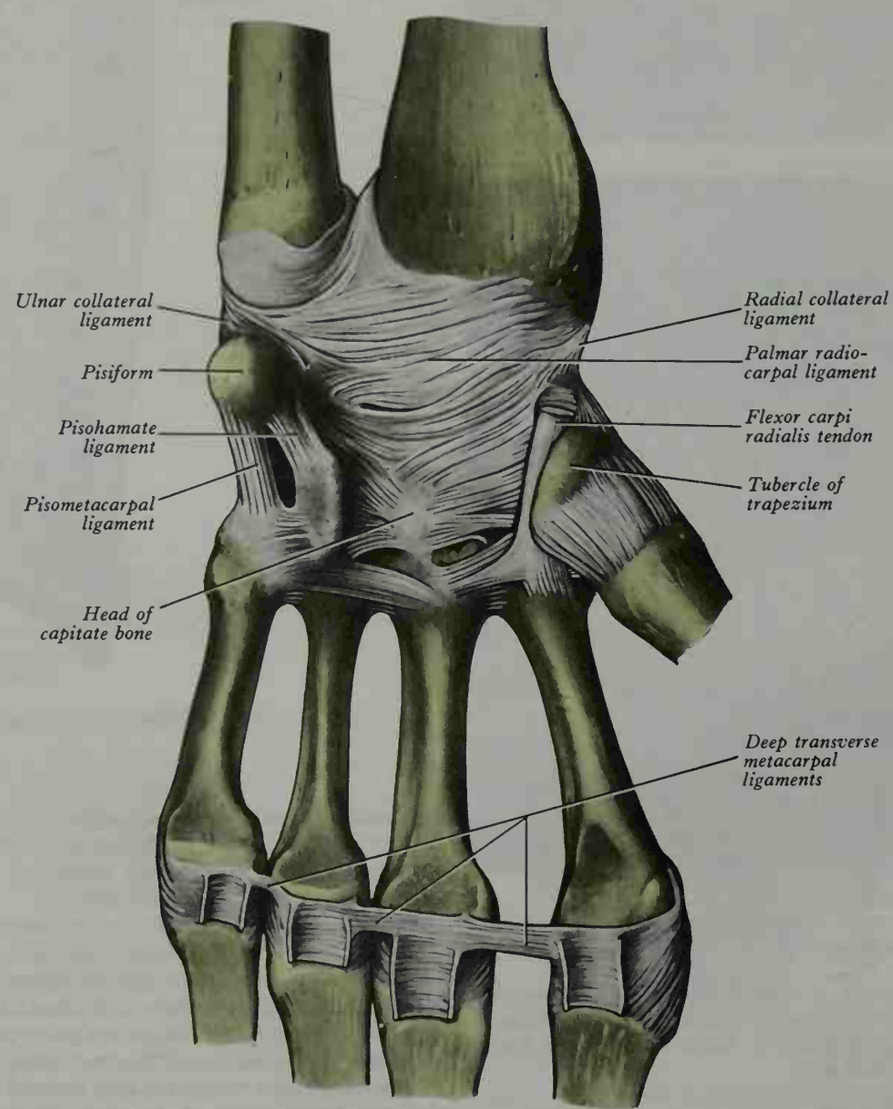
The axis about which the movements of pronation and supination occur is often somewhat inadequately represented by a line drawn through the centre of the head of the radius above, and through the ulnar attachment of the articular disc below. More precisely this is solely the axis of movement of *radius relative to ulna*, and, as we shall see, it *does not remain stationary*. The head of the radius rotates within the ring formed by the annular ligament and the radial notch of the ulna, while the lower end and the articular disc swing on the head of the ulna. During the rotation of

the head of the radius within the osteoligamentous ring, its proximal surface is, of course, spinning in relation to the articular surface of the capitulum of the humerus. However, the lower end of the ulna *is not stationary* during these movements. It moves a variable amount, along a curved course, backwards and laterally during pronation, and forwards and medially during supination. The occurrence of this movement means that the axis, as defined above, becomes displaced laterally in pronation and medially in supination. The axis, around which *supination and pronation* of the *whole forearm and hand* occurs, may therefore be considered as passing *between* the forearm bones at both the superior and inferior radio-ulnar joints, when there is marked ulnar movement, and through the centre of the head of the radius and ulnar styloid when ulnar movement is minimal; below it may run towards any one of the digits depending on the amount of medial or lateral displacement of the lower end of the ulna (Ray *et al.* 1951). It is important to state that this lateral displacement is not a conjunct rotation, for it can be varied at will. For example, the index finger and thumb, in a precision grip (p. 591) can be made to describe an arc of varying radius according to prevailing functional demands. The greatest radius of arc involves minimal ulnar deviation, whereas rotation of the opposed digits around a virtually fixed point (often employed in the manipulation of tools and instruments) involves marked to maximal ulnar displacement. These ulnar movements are permitted by the incongruence of the trochlea and trochlear notch, and may therefore occur *without* any rotation of the humerus at the glenohumeral joint, whether the elbow joint be in a flexed, semi-flexed or extended position. The fact that the trochlear incongruence persists in all positions of the elbow joint perhaps indicates that the 'close-packed position' of the humero-ulnar articulation in relation to terminal elbow extension is more dependent upon the disposition of its ligaments than upon the articular surface geometry.

Accessory movements. In addition to the backward and forward movement of the head of the radius on the radial notch of the ulna (p. 367), the head of the ulna can be moved backwards and forwards on the ulnar notch of the radius.

Muscles producing the movements.

Pronation. Pronator quadratus (p. 578), aided during rapid movement and movement against resistance by pronator teres (Basmajian and Travill 1961). Gravity also assists.



Supination. Supinator, in slow unresisted movement and when the elbow is extended. It is assisted by biceps in fast movements with the elbow flexed, especially when resistance is encountered.

Electromyographic studies have not confirmed activity in brachioradialis during pronation and supination.

Applied Anatomy. Dislocation backwards, and abduction dislocation are the commonest forms at the elbow joint. Owing to the shapes of the bones, dislocation backwards is often complicated by fracture of the coronoid process; owing to the strength of the collateral ligaments, the medial epicondyle is frequently torn away in abduction dislocations.

The elbow joint is occasionally the seat of acute synovitis. The joint cavity then becomes distended with fluid, the bulging showing itself principally around the olecranon, in consequence of the laxness of the articular capsule. Again, there is often some swelling, just above the head of the radius in the line of the humeroradial joint, or the whole elbow may assume a fusiform appearance.

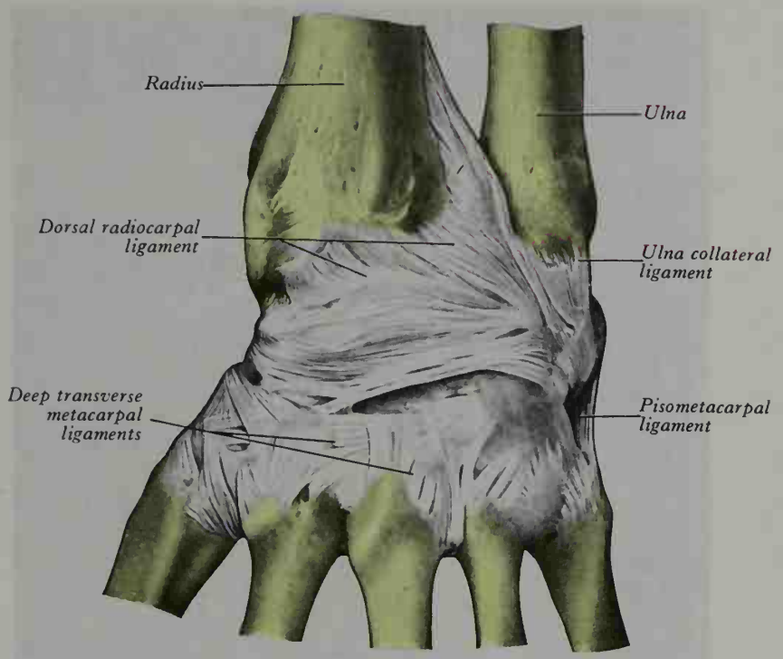
Dislocation of the head of the radius alone is a not uncommon

466 4.50 The ligaments of the left wrist and metacarpus. Palmar aspect.

accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture of the annular ligament. Occasionally a peculiar injury, which is supposed to be a subluxation, occurs in young children. It is believed that the head of the radius is displaced downwards in the annular ligament, the upper border of which becomes folded over the head of the bone, between it and the capitulum of the humerus; the small size of the head of the radius in the child predisposes to this injury. The forearm becomes fixed in a position of semiflexion, midway between supination and pronation, and pain is complained of when any attempt is made to move the joint.

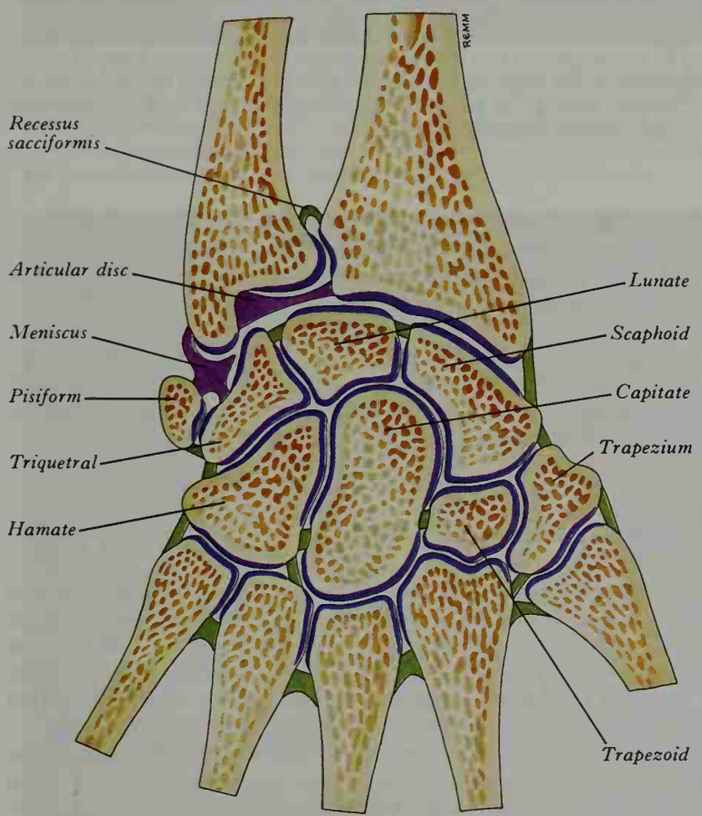
The Radiocarpal or Wrist Joint

The radiocarpal or wrist joint (**4**.50, 51, 52) is a bi-axial joint, commonly classed as ellipsoid (*vide infra*). The parts forming it are the distal end of the radius and lower surface of the articular disc, above, and the scaphoid, lunate and triquetral bones, below. The *articular surface* of the radius and the lower surface of the articular disc form together a roughly elliptical, concave surface with its long axis transversely disposed. However, the radial surface is divided into two by a low ridge and therefore bears two concavities. A similar ridge is usually distinguishable between the medial concavity on the radius and the concave distal surface of the articular disc. The proximal articular surfaces of the scaphoid, lunate and triquetral bones form a fairly smooth convex surface, which is received into the proximal concavity. The line of the joint corresponds to a line, convex upwards, joining the styloid process of the radius to that of the ulna (**4**.53, 54).



The articular capsule is lined by *synovial membrane* which is usually distinct from that of the inferior radio-ulnar joint and from that of the intercarpal joints; but a protrusion of it, ventral to the triangular articular disc, is closely related to the styloid process, the *prestyloid recess*, which is bounded distally by a small fibrocartilaginous meniscus, projecting inwards from the ulnar collateral ligament, between the styloid process and triquetral (**4**.52). Occasionally ossification occurs within this meniscus (Lewis *et al.* 1970). The fibrous capsule is strengthened by ligaments—palmar radiocarpal and ulnocarpal, dorsal radiocarpal, and radial and ulnar collateral.

The palmar radiocarpal ligament (**4**.50) is a broad membranous band, attached above to the anterior margin of the lower end of the radius and to its styloid process; its fibres pass downwards and medially to be attached to the anterior surfaces of the scaphoid, lunate and triquetral bones, some being continued to the capitate. It is partly intracapsular.



The palmar ulnocarpal ligament is a rounded fasciculus which runs from the base of the styloid process of the ulna and the anterior margin of the triangular articular disc of the distal radio-ulnar joint to the lunate and triquetral bones. Lewis, Hamshire and Buckwill (1970) and Mayfield, Johnson and Kilcoyne (1976) regard both palmar carpal ligaments as completely intracapsular. The latter workers also divide the radiocarpal into three parts and the ulnocarpal into two, named according to their attachments, e.g. radiocapitate, ulnolunate, etc. It is not entirely clear in these accounts whether the ligaments are totally intracapsular, i.e. completely separate from the overlying articular capsule. (See also pp. 423 and 468.)

The palmar ligaments of the wrist are perforated by apertures for the passage of vessels and are in relation, in front, with the tendons of the flexor digitorum profundus and flexor pollicis longus.

The dorsal radiocarpal ligament (**4**.51), thinner and weaker than the palmar, as attached, above, to the posterior border of the distal end of the radius; its fibres are directed obliquely downwards and medially, and are fixed, below, to the dorsal surfaces of the scaphoid, lunate and triquetral bones, being continuous with those of the dorsal intercarpal ligaments. It is related behind, with the extensor tendons of the wrist and fingers, their synovial sheaths and the posterior interosseous nerve; in front, it is blended with the articular disc of the inferior radio-ulnar articulation.

4.51 The ligaments of the left wrist. Dorsal aspect.

4.52 A coronal section through the distal ends of the radius and ulna, the carpus and the proximal ends of the metacarpals, showing the general form of the articular surfaces, synovial cavities, interosseous ligaments and fibrocartilages. Partly after Lewis *et al.* (1970).

The ulnar collateral ligament of the wrist joint (**4**.50, 51) is attached to the end of the styloid process of the ulna; it divides into two fasciculi, one of which is fixed to the medial side of the triquetral, the other to the pisiform bone.

The radial collateral ligament of the wrist joint (**4**.50, 51) extends from the tip of the styloid process of the radius to the radial side of the scaphoid bone, some of its fibres being prolonged to the trapezium. It is in relation with the radial artery as it winds round the lateral side of the wrist separating the ligament from the tendons of the abductor pollicis longus and extensor pollicis brevis. Both collateral ligaments are relatively poorly developed.

4.53A Radiograph of the hand and wrist in full flexion. Lateral aspect. The arrows point: (1) to the capitate bone; (2) to the lunate bone; (3) to the tubercle of the scaphoid bone; and, (4) to the tubercle of the trapezium. Compare with 4.53B and note the relative positions of the capitate and lunate, and the lunate and radius.

4.53B Radiograph of the hand and wrist. Lateral aspect. The long axes of the third metacarpal bone, the capitate and the lunate are, approximately, in line with the long axis of the radius. The arrows point to the same structures as in 4.53A. Note the relative positions of the capitate and lunate, and the lunate and radius.

The *arteries* supplying the joint are the anterior interosseous, the anterior and posterior carpal branches of the radial and ulnar, the palmar and dorsal metacarpals, and some recurrent branches from the deep palmar arch. The *nerves* are derived from the anterior and posterior interosseous nerves.

Movements. The movements at this joint are closely associated with those in the intercarpal and midcarpal joints. All these are described together (p. 469). The close-packed position of the radiocarpal joint is in full extension.

The Intercarpal Joints

The intercarpal joints connect the carpal bones to one another and may be subdivided into: (1) joints between the bones of the proximal row of the carpus; (2) joints between the bones of the distal row; (3) a somewhat complicated and extensive joint between the two rows, termed the midcarpal joint. The carpal elements are connected by a most extensive system of ligaments, not all of which are specifically named. In addition to the ligaments described below, the flexor retinaculum (p. 583) is an important accessory ligament of the intercarpal joints. The joint surfaces are either sellar, ellipsoid, or spheroidal.

THE JOINTS OF THE PROXIMAL ROW OF CARPAL BONES

(*a*) The scaphoid, lunate and triquetral bones are connected by dorsal, palmar and interosseous ligaments.

The dorsal and palmar ligaments are placed transversely between the bones of the first row; they connect the scaphoid to the lunate and the lunate to the triquetral. The palmar ligaments are weaker than the dorsal. Mayfield *et al.* (1976) described a distinct capito-triquetral ligament (in 28 dissections), extending from the palmar aspect of the capitate, across the hamate, to the palmar surface of the triquetrum.

The interosseous ligaments (4.52) are two narrow bundles, one connecting the lunate and scaphoid bones, the other the

4.53C Radiograph of the hand and wrist in full extension. Lateral aspect. The arrows point to the same structures as in 4.53A. Compare with 4.53B and note the alterations in the relative positions of the capitate and lunate bones, and the lunate bone and the radius.

lunate and triquetral bones. They are on a level with the proximal surfaces of these bones, and form part of the convex articular surface of the radiocarpal joint.

(*b*) The pisiform articulates with the palmar surface of the triquetral bone and the following are ligaments associated with the joint: fibrous capsule, pisohamate and pisometacarpal.

The fibrous capsule is thin, and surrounds the joint; the synovial membrane is usually distinct from that of the other carpal joints but may communicate with the radiocarpal.

The pisohamate and pisometacarpal ligaments connect the pisiform to the hook of the hamate, and to the base of the fifth metacarpal bone respectively (**4**.50). Both are really continuations of the tendon of flexor carpi ulnaris and are, as such, misnamed.

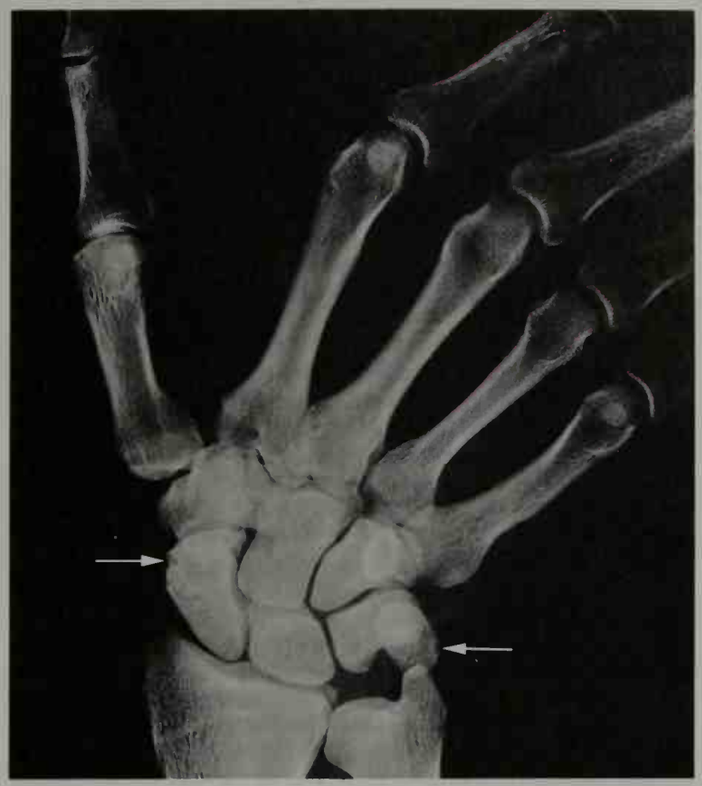
THE JOINTS OF THE DISTAL ROW OF CARPAL BONES

The bones of the distal row of the carpus are connected by dorsal, palmar and interosseous ligaments.

The dorsal and palmar ligaments extend transversely between the trapezium and trapezoid, the trapezoid and capitate, and the capitate and hamate bones.

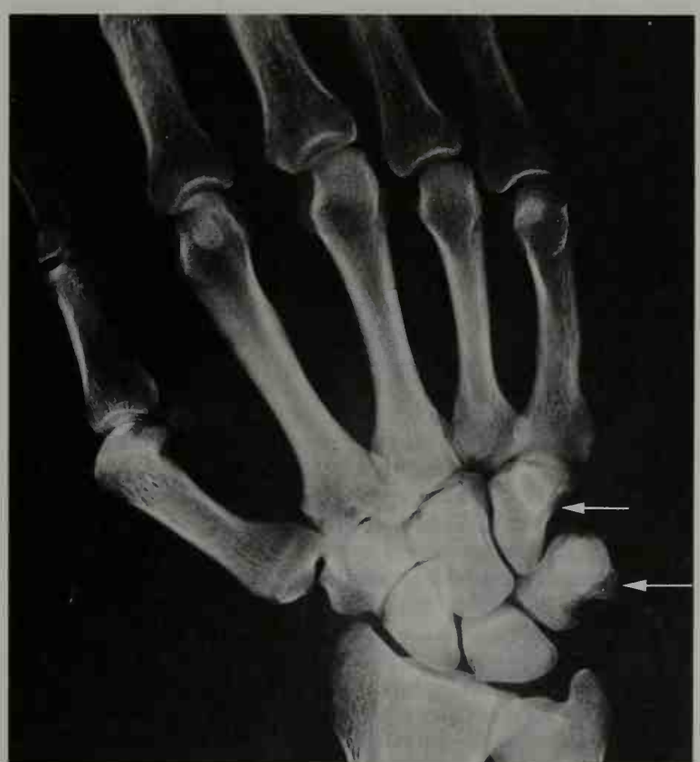
The interosseous ligaments are much thicker than those of the proximal row; one unites the capitate and hamate, a second the capitate and trapezoid, and a third the trapezium and trapezoid. The first is the strongest and rarely missing, while the second and third are frequently absent.

THE MIDCARPAL JOINT



The joint between the scaphoid, lunate and triquetral bones on the one hand, and the second row of carpal bones on the other is a compound articulation, which may be divided for descriptive convenience into medial and lateral parts. On the medial side the head of the capitate and the hamate articulate with the concavity formed by the scaphoid, lunate and triquetral bones, and constitute a compound sellar joint; on the lateral side the trapezium and trapezoid articulate with the scaphoid bone and constitute a second compound articulation, often described as plane, but in fact another sellar joint. The ligaments are dorsal, palmar and collateral.

The dorsal and palmar ligaments consist of short, irregular bundles passing between the bones of the first and second rows. On the palmar surface the fascicles radiating from the head of the capitate to the surrounding bones are termed the *radiate carpal ligament*.



The collateral ligaments, radial and ulnar, are very short. The former, the stronger and more distinct, connects the scaphoid and trapezium, the latter the triquetral and hamate; they are continuous with the corresponding ligaments of the wrist joint. In addition to these ligaments, a slender, interosseous band sometimes connects the capitate and scaphoid bones, but it does not completely divide the midcarpal synovial cavity.

The synovial membrane of the carpus is most extensive (**4**.52), and bounds an articulation of very irregular shape. The proximal part of the cavity intervenes between the distal surfaces of the scaphoid, lunate and triquetral bones and the proximal surfaces of the bones of the second row. It sends two prolongations upwards—between the scaphoid and lunate bones, and between the lunate and triquetral bones—and three downwards between the four bones of the second row. The prolongation between the trapezium and the trapezoid, or that between the trapezoid and capitate bone, is, owing to the absence of the interosseous ligament, often continuous with the cavity of the carpometacarpal joints, sometimes of the second, third, fourth and fifth metacarpal bones, sometimes of the second and third only. In the latter condition the joint between the hamate and the fourth and fifth metacarpal bones has a separate synovial membrane and is separated from the others (**4**.52) by the carpometacarpal interosseous ligament (p. 471). The synovial cavities of the carpometacarpal joints are prolonged for a short distance between the bases of the metacarpal bones. There is usually a separate synovial joint between the pisiform and triquetral bones.

Movements. The movements which occur at the radiocarpal and intercarpal joints are considered together, for the joints concerned form parts of the same mechanism and are acted on by the same muscle groups. The active movements which can be carried out are flexion (*c.* 85°), extension (*c.* 85°), adduction (ulnar deviation), abduction (radial deviation) and circumduction.

4.54A Radiograph of the hand in full adduction. The arrows point to the scaphoid bone on the lateral side and to the pisiform bone on the medial side. Note that the shadow of the pisiform bone overlaps the shadow of the tip of the styloid process of the ulna. Compare with **4**.54B and observe that the movements occur at both the radiocarpal and intercarpal joints.

4.54B Radiograph of the same hand in full abduction. The arrows point to the hamate and pisiform bones. Compare with **4**.54A and note: (1) that the scaphoid and lunate bones have passed medially so that the latter articulates to a large extent with the articular disc of the inferior radio-ulnar joint; (2) that the pisiform is now widely separated from the styloid process of the ulna; (3) that the scaphoid, having rotated round a transverse axis, is much foreshortened; (4) that the apex of the hamate bone has been thrust away from the lunate by the rotation of the capitate around an anteroposterior axis; (5) that a gap has opened up between the distal portions of the hamate and triquetral bones; and (6) that the long axes of the capitate and lunate bones are now almost in the same straight line.

When the wrist is *flexed*, both the radiocarpal and the midcarpal joints are implicated, but the range of movement is greater at the latter. In *extension* the reverse is the case and more of the movement takes place at the radiocarpal joint (4.53). In consequence, the proximal surfaces extend further on the posterior than on the anterior surfaces of the lunate and scaphoid bones. These movements are limited chiefly by the tension of the antagonistic muscles and, in this connexion, it may be noted that the range of flexion is perceptibly diminished when the fingers are flexed, owing to the increased tension of the extensor muscles. It is only when the joints are subjected to violence at the limits of flexion or extension that the dorsal or palmar ligaments, respectively, are fully stretched (but see also below).

The range of *adduction* of the hand (*c.* 45°) is considerably greater than the range of abduction (*c.* 15°), a fact which may be associated with the shortness of the styloid process of the ulna. In adduction, most of the movement occurs at the radiocarpal joint, and the lunate bone, which articulates both with the radius and with the articular disc when the hand is in line with the forearm (4.52), passes off the articular disc and comes to articulate only with the radius (4.54A).

In *abduction* the movement takes place almost entirely at the midcarpal joint and radiographs of the abducted hand show that the capitate bone rotates round an anteroposterior axis so that its head passes medially, and the hamate conforms to the movements of the capitate. As a result, the distance between the lunate bone and the apex of the wedge of the hamate is perceptibly increased (4.54B). The movements are limited by the tension of the antagonistic muscles and, when the extreme limits are reached, by the radial and ulnar collateral radiocarpal ligaments.

Circumduction of the hand does not result from axial rotation but from the movements of flexion, adduction, extension and abduction carried out in that order or in reverse.

It should be noted that abduction-adduction movements are of particular functional importance. The hand is very commonly used with the carpus slightly extended and the forearm in a position intermediate between full pronation and supination. Highly skilled abduction-adduction movements are then used to manipulate a large variety of precision tools, from fine needles to hammers.

The accessory movements are obtained for the most part at the radiocarpal joint. They are relatively free and can be demonstrated more easily in flexion than in extension of the wrist. The carpus can be moved bodily backwards and forwards on the radius and articular disc and *it can be rotated axially to a considerable extent*. A little side-to-side movement is also possible.

ADDITIONAL ANALYSES OF RADIOCARPAL AND CARPAL MOVEMENTS

It has been suggested that the mechanical equivalent of the radiocarpal and the medial part of the midcarpal joint is a 'link' joint, such as exists in its simplest form between the units of the chain of a bicycle (Gilford *et al.* 1943). This type of joint is stable only when it is under tension and 'on centre', i.e. when the links are in line, and unless it is strengthened by the addition of a 'stop' mechanism, it buckles when subjected to a compression force acting in its long axis, especially when it is 'off centre'. Certain advantages, however, are inherent in the 'link' joint. Since the range of movement at each of its constituent parts is appreciably less than the total range, the articular surfaces can be flatter than would be possible in a single joint giving the same total range of movement, and they are therefore better adapted to bearing pressure. Further, there is less tendency for the overlying tissues to be squeezed at the extremes of movement.

Other investigators, however, have made an analysis of carpal movement which contrasts sharply with the foregoing account (MacConaill 1941). Firstly it is pointed out that in most positions of the hand, the carpal bones are loosely packed and relatively mobile, and that they only become a rigid block in full extension which is the close-packed position for both radiocarpal and most carpal joints; further, close packing is achieved in *two* distinct stages (*vide infra*). The carpus is regarded as divisible into four functional parts: (1) trapezium; (2) scaphoid; (3) hamate, capitate and trapezoid; and (4) triquetrum and lunate. When passing from full flexion to full extension the following stages are considered to occur. Initially, the distal row (3) moves on the proximal row (2 and 4) until the hand is approximately in line with the forearm, at which point the hamate, capitate, trapezoid and scaphoid come into a mutual close-pack and form a rigid mass (i.e. 2+3). During the second stage, the rigid mass moves as a whole upon the triquetrum and lunate which themselves move at the radiocarpal joint until full extension is reached, with close-packing of the radiocarpal joint and most of the carpal joints (i.e. except the articulations of pisiform and trapezium). In such a position, which is adopted only when a special effort is to be made, exceptionally large forces may be transmitted across the articular structures. A similar position is often assumed during a fall on the outstretched hand and commonly results in traumatic damage, e.g. a 'supination' (Colles') fracture of the radius, a fracture of the scaphoid, or dislocation of the lunate. Mayfield *et al.* (1976), in a study of the behaviour of carpal ligaments in experimental production of carpal fractures, have corroborated these views of the dorsal 'locking' of the wrist, and have analysed further the role of carpal ligaments in producing the progressive intercarpal slides which terminate in the close-packed position.

It may be noted that during the initial stages of the movement, the scaphoid bone functions as a part of the proximal row of carpals, but in the later stages joins the distal row in its movements. The joint between the scaphoid and trapezium is not considered to be involved in the general close-packing of the rest of the carpus and it is proposed that this is concerned with a continued functional independence of the thumb even when the remainder of the carpus has been converted into a rigid mass.

A more recent analysis of carpal movements (Kauer 1974) continues the concept of articular links or chains, but places particular emphasis upon rotations of the lunate and scaphoid relative to the radius and articular disc. During flexion-extension both rotate relative to each other and to the capitate bone. The curvatures of the proximal aspects of the lunate and scaphoid are different and this dictates some degree of independence of movements, which nevertheless are interdependent as a result of the strong interosseous ligament between the two bones.

Muscles producing the movements.

Flexion. Flexor carpi radialis, flexor carpi ulnaris and palmaris longus, assisted by flexores digitorum superficialis et profundus, flexor pollicis longus and abductor pollicis longus.

Extension. Extensores carpi radiales longus et brevis and extensor carpi ulnaris, assisted by extensor digitorum, extensor digiti minimi, extensor indicis and extensor pollicis longus.

Adduction. Flexor carpi ulnaris in association with extensor carpi ulnaris.

Abduction. Flexor carpi radialis, in association with extensores carpi radiales longus et brevis, abductor pollicis longus and extensor pollicis brevis.

As a result of these combinations of carpal flexors and extensors abduction or adduction can be carried out without simultaneous flexion or extension.

The Carpometacarpal Joints

CARPOMETACARPAL JOINT OF THE THUMB

This is a saddle-shaped (sellar) joint between the base of the first metacarpal bone and the trapezium, and it enjoys a great range of movement on account of the configuration of its articular surfaces. The joint is surrounded by a fibrous capsule, which is thick but loose, and passes from the circumference of the base of the metacarpal bone to the rough edge bounding the articular surface of the trapezium; it is thickest laterally and dorsally. The synovial membrane which lines the fibrous capsule is distinct from that of the other carpometacarpal joints (4.52).

The metacarpal bone of the thumb is connected to the trapezium by lateral, anterior and posterior ligaments in addition to the capsular ligament.

The *lateral ligament* is a relatively broad band, running from the lateral surface of the trapezium to the radial side of the base of

the first metacarpal bone. The *palmar* and *dorsal ligaments* are oblique bands which converge on the ulnar side of the base of the metacarpal bone from the palmar and dorsal surfaces, respectively, of the trapezium. These two ligaments play an important part in connexion with the movements of the thumb (Haines 1944).

Relations of the joint. On the *palmar surface* the joint is covered by the muscles of the thenar eminence. On the *dorsal surface* are the long and short extensors of the thumb. *Medially* is the first dorsal interosseous muscle and the radial artery which is passing from the dorsal to the palmar surface of the hand through the first interosseous space. *Laterally* is the tendon of the abductor pollicis longus.

Movements. In this joint the *active* movements that can be carried out are flexion-extension, abduction-adduction, rotation and circumduction. Owing to the set of the first metacarpal bone in the position of rest (p. 592), flexion and extension take place in a plane parallel to the plane of the palm, while abduction and adduction occur in a plane at right angles to the flexion-extension plane. Except in its early stages, flexion of the metacarpal bone is always associated with medial rotation and, conversely, medial rotation cannot be performed actively apart from flexion. The intimate association of these two movements is largely dependent upon the geometry of the articular surfaces, which are sellar and impose some degree of conjunct rotation, and upon the obliquity of the fibres of the dorsal ligament, which when taut anchors the ulnar side of the base of the metacarpal bone, while its radial side is free to move. Under these conditions contraction of the flexor brevis muscle, assisted by the opponens pollicis, will produce medial rotation combined with flexion (Napier 1955). This combined movement, together with abduction at the carpometacarpal joint, enables the pulp of the thumb to be brought into contact with the palmar surfaces of the pulps of the slightly flexed fingers, a movement which is termed *opposition*.

Full extension of the metacarpal bone of the thumb is conversely associated with slight lateral rotation (Kuczynski 1974). This is attributable, again, to the sellar form of the joint surfaces, and to the fact that the ulnar side of the base of the metacarpal bone becomes anchored by tension of the palmar ligament while the radial side is still free to move, and continued action of the extensors of the thumb produces lateral rotation in addition to further extension.

As indicated, however, these various rotations are conjunct and the inevitable accompaniment of flexion-extension, of spiralization and tautening of the joint capsule, and of balanced conarticular compression, occurring at the extremes of the movements. The position of close-packing has been claimed to occur in powerful, complete opposition, when the greatest forces would be transmitted to the joint. (For interesting analyses of this articulation consult Kapandji 1963, 1970; Kuczynski 1974; MacConaill and Basmajian 1977.)

Accessory movements are limited to axial rotation in the position of rest, and distraction.

Muscles producing the movements.

Flexion. Flexor pollicis brevis and opponens pollicis, aided by flexor pollicis longus when the other joints of the thumb are flexed. Flexion is associated with medial rotation.

Extension. Abductor pollicis longus and extensores pollicis brevis et longus. In full extension the extensor pollicis longus, partly owing to the obliquity of its line of pull and partly also to the disposition of the palmar ligament of the joint, rotates the thumb laterally and draws it dorsally, i.e. slightly adducts it.

Abduction. Abductor pollicis brevis and abductor pollicis longus. When the movement reaches its maximum the digit and its metacarpal bone are not in line, for the thumb is then abducted both at its metacarpophalangeal and at its carpometacarpal joints.

Adduction. Adductor pollicis alone; the first palmar interosseous muscle acts on the metacarpophalangeal joint.

Opposition. Opponens pollicis and flexor pollicis brevis which simultaneously flex and medially rotate the abducted thumb. The pressure which the opposed thumb can exercise on the tips of the fingers is increased by the reinforcing action of the adductor pollicis and the flexor pollicis longus.

Circumduction. The above muscle groups acting consecutively, the extensors, the abductors, the flexors and the adductors following one another in that order.

THE SECOND TO FIFTH CARPOMETACARPAL JOINTS

The joints between the carpus and the second to fifth metacarpal bones, though often classed as plane, are in fact formed by curved articular surfaces often of complex sellar shape. (*See* the description of the relevant facets given on pp. 373–375.) The bones are united by articular capsules, strengthened by dorsal, palmar and interosseous ligaments.

The dorsal ligaments, which are the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surfaces. The second metacarpal bone receives two fasciculi, one each from the trapezium and trapezoid bone; the third metacarpal receives two, one each from the trapezoid and capitate bones; the fourth two, one each from the capitate and hamate bones; the fifth receives a single fasciculus from the hamate, and this is continuous with a similar ligament on the palmar surface, forming an incomplete fibrous capsule.

The palmar ligaments have a somewhat similar arrangement, with the exception of those of the third metacarpal bone, which are three in number: a lateral one from the trapezium, situated superficially to the sheath of the tendon of the flexor carpi radialis; an intermediate one from the capitate; and a medial one from the hamate bone.

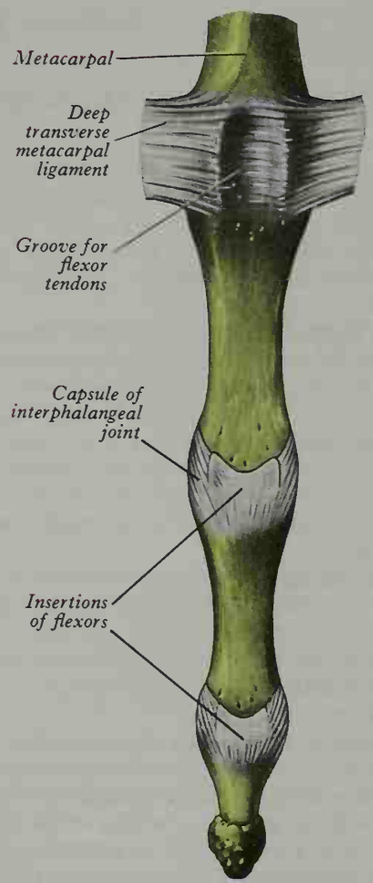
The interosseous ligaments consist of short, thick fibres, and are limited to one part of the carpometacarpal articulation; they connect the contiguous distal margins of the capitate and hamate bones with the adjacent surfaces of the third and fourth metacarpal bones, and they may be united at their proximal ends.

The synovial membrane is often a continuation of that of the intercarpal joints. Occasionally, the joint between the hamate and the fourth and fifth metacarpal bones has a separate synovial membrane, and is then bounded on its lateral side by the more medial of the two interosseous ligaments just described, and by extensions from it to the palmar and dorsal parts of the capsule (**4**.52).

THE INTERMETACARPAL JOINTS

The bases of the second, third, fourth and fifth metacarpal bones articulate with one another by small surfaces covered with cartilage, and are connected together by dorsal, palmar and interosseous ligaments.

The dorsal and palmar ligaments pass transversely from one bone to another on the dorsal and palmar surfaces. **The interosseous ligaments** connect the contiguous surfaces of the bones, just distal to their collateral articular facets.



The synovial membrane of these joints is continuous with that of the carpometacarpal articulations.

Movements. The movements permitted in the carpometacarpal and intermetacarpal articulations of the fingers are limited to slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. They are partly accessory movements of the first type (p. 431) and only come into prominence when the palm of the hand becomes 'cupped' as a solid object is grasped. The metacarpal bone of the little finger is the most movable, then that of the ring finger; the metacarpal bones of the index and middle fingers are almost immovable. The close-packed position probably coincides with extension of carpal articulations as in gripping.

Further accessory movements are limited to spiral twisting of the metacarpus as a whole on the carpus.

The Metacarpophalangeal Joints

These articulations (**4**.55A, B) are usually classified as ellipsoid, but the heads of the metacarpals, fitting into shallow concavities on the bases of the proximal phalanges, are not regularly convex; their articular surfaces are partially divided on their palmar aspect and are almost bicondylar (**3**.162–167). Each joint has a palmar and two collateral ligaments.

4.55A The metacarpophalangeal and digital joints of the middle finger. Palmar aspect.

The palmar ligaments are unusual in that they are thick, dense, fibrocartilaginous structures, placed upon the palmar surfaces of the joints in the intervals between the collateral ligaments, to which they are connected; they are loosely united to the metacarpal bones, but are very firmly attached to the bases of the proximal phalanges. Their palmar surfaces are intimately blended with the deep transverse ligaments of the palm, and are grooved for the flexor tendons, the fibrous sheaths of which are connected to the sides of the grooves. Their deep surfaces form parts of the articular areas for the heads of the metacarpal bones.

The deep transverse metacarpal ligaments consist of three short, wide, flattened bands which connect the palmar ligaments of the second, third, fourth and fifth metacarpophalangeal joints (**4**.55A). They are related, anteriorly, to the lumbricals and the digital vessels and nerves and, posteriorly, to the interossei. Offsets from the digital slips of the central portion of the palmar aponeurosis join the palmar surface (p. 585). On both sides of the metacarpophalangeal joint of the middle and ring fingers (but only on the ulnar side of the index and on the radial side of the little finger) the transverse band of the dorsal digital expansion (p. 580) joins the transverse metacarpal ligament; deep to it is the phalangeal attachment of the dorsal interosseous and superficial to it the remainder of this muscle, the palmar interosseous and lumbrical (p. 589 and **5**.70).

The collateral ligaments are strong, rounded cords, along the sides of the joints; each is attached to the posterior tubercle and adjacent depression on the side of the head of the metacarpal bone, and passes obliquely distally and forwards to reach the side of the ventral aspect of the base of the phalanx (**4**.55B).

On the dorsal surfaces of these joints the fibrous capsule is thin and is separated from the extensor tendon by a bursa (**5**.70).

Movements. The active movements are flexion, extension, adduction, abduction, circumduction, and some limited rotation. However, rotation cannot be instigated voluntarily as an isolated movement; it is accessory to flexion-extension and usually due to resistance of a grasped object.

Extension is limited to a few degrees, while flexion is possible to almost 90°; both are limited chiefly by tension of antagonistic muscles, but flexion is commonly limited by the resistance of a grasped tool or other object. Abduction and adduction are also limited to a few degrees, and in the flexed position of these joints the movements are neglible in range. The pollicial metacarpophalangeal joint has a flexion-extension range limited to about 60° (almost entirely flexion) or even less; other active movements are almost nil apart from slight conjunct rotation accompanying the former. Of the other metacarpophalangeal joints, that of the index is the most mobile in adduction/abduction (*c.* 30°), followed by the minimus, annularis, and with the medius least mobile.

The accessory movements comprise rotation (which in the case of the thumb may be considerable), gliding of the phalanx on the head of the metacarpal bone forwards, backwards and from side to side, and distraction.

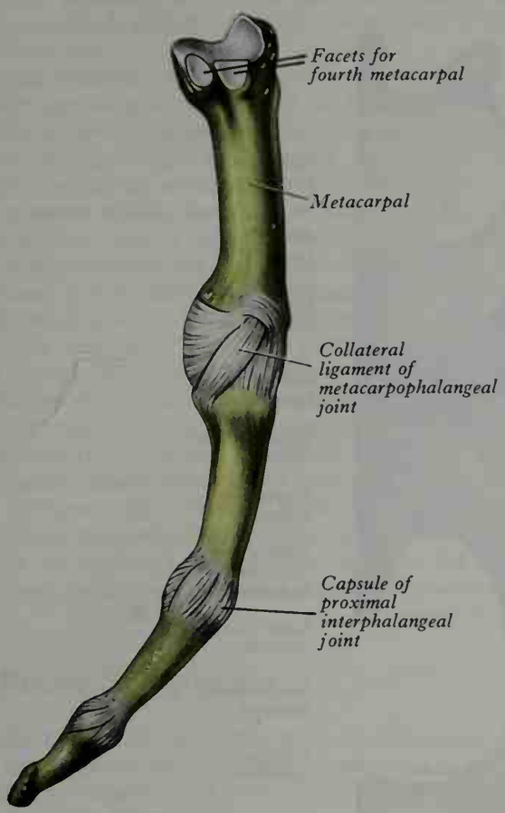
Muscles producing the movements.

Flexion. Flexores digitorum superficialis et profundus, assisted by lumbricals and interossei (Long *et al.* 1961; and *see* p. 591) and, in the little finger, by flexor digiti minimi; in the thumb flexores pollicis longus et brevis and first palmar interosseous. Slight lateral rotation accompanies finger flexion.

Extension. In the middle and ring fingers, extensor digitorum, assisted, in the index and little fingers, by extensor indicis and extensor digiti minimi respectively; in the thumb extensores pollicis longus et brevis only.

Adduction. With extended fingers, palmar interossei. During flexion the long flexors of the fingers play the principal part. The slight degree of this movement in the thumb is attributable to the adductor pollicis and the first palmar interosseous.

Abduction. In the extended fingers, dorsal interossei, assisted by the long extensors except in the case of the middle finger. In the little finger, abductor digiti minimi. Abductor pollicis brevis produces the slight movement possible in the thumb which contributes towards opposition. When the fingers are in the flexed position, abduction cannot be performed actively, but, provided that the long flexors of the fingers are not in active contraction, it can easily be carried out passively. The inability to perform the movement actively in this position may be due to the fact that the dorsal interossei and the abductor digiti minimi are so shortened by flexion that they are unable to function, but the altered relation of the line of pull of the interossei to the axis of movement is probably the determining factor, for whereas in extension of the digits the axis of side to side movements is anteroposterior, in flexion it is proximodistal and the line of pull of the interossei is then nearly parallel to the axis; the inability is certainly not to be ascribed solely to tension of the collateral ligaments.



The Interphalangeal Joints

The interphalangeal articulations are uni-axial hinge joints (**4**.55A, B). In addition to a fibrous capsule, each has a palmar and two collateral ligaments. The arrangement of these ligaments is similar to those in the metacarpophalangeal joints (p. 471). The extensor tendons take the place of dorsal ligaments.

Movements. The only active movements which occur at the interphalangeal joints are flexion and extension; these movements are greater in range between the proximal and middle phalanges than between the middle and distal. The amount of flexion is very considerable, but extension is limited by tension of the digital flexors and, in violent movements, by the palmar ligaments. Full extension is the close-packed position of these joints, and it is utilized whenever the fingers are used as props to transmit the body weight, or powerful thrust, though the fully clenched position is also used under these circumstances.

Finally, careful inspection of a finger during flexion and extension reveals that these principal movements are accompanied by a small amount of conjunct rotation. During flexion, the rotation turns the pulp of the finger slightly laterally, i.e. it faces more fully the pulp of the opposed thumb. An opposite rotation occurs, of course, during finger extension. (*See* also above.)

The *accessory movements* comprise a limited range in each case of rotation, abduction, adduction and gliding forwards and

4.55B The metacarpophalangeal and digital joints of the right third finger. Medial aspect.

backwards. They permit the fingers to adapt themselves to the shape of any object gripped in the hand, and they provide against the stresses and strains which occur during the ordinary use of the hand.

Muscles producing the movements.

Flexion. At the proximal joint, flexor digitorum superficialis and flexor digitorum profundus, at the distal joint, flexor digitorum profundus, at the interphalangeal joint of the thumb, flexor pollicis longus.

Extension. Extensor digitorum and extensor pollicis longus. Extension occurs simultaneously in both joints as in opening the closed fist.

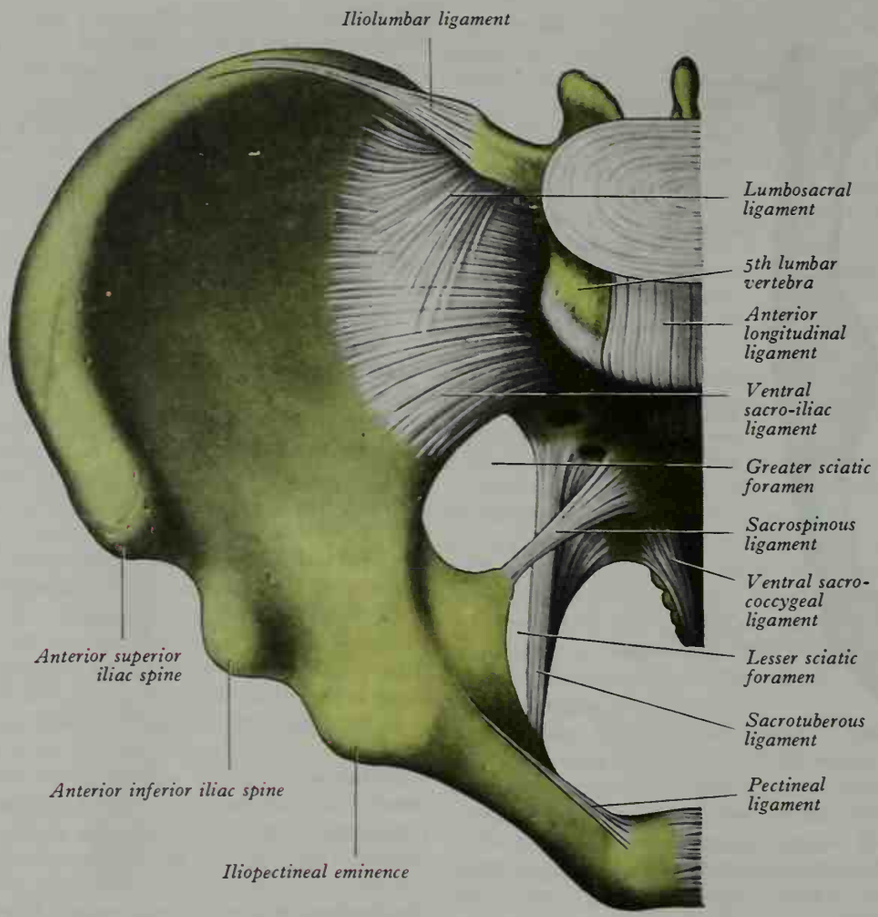
Attention should be drawn at this point to the combined movements of flexion at the metacarpophalangeal joint and extension at the interphalangeal joints, which can be carried out simultaneously and are of such importance in fine movements as executed in writing, drawing and threading a needle. For many years it has been widely taught that the lumbricals and the interossei are not only the active agents in producing flexion at metacarpophalangeal joints, but are also the active agents in extending the interphalangeal joints through their attachments to the dorsal digital expansions (p. 579). It has been urged that, when the lumbricals and interossei flex the metacarpophalangeal joints, the balance between the tone of the digital flexors and extensors is altered in favour of the extensors, and that this factor alone is responsible for the extension of the interphalangeal joints (Braithwaite *et al.* 1948). However, both the lumbricals and interossei alone can extend these joints (Sunderland 1945; *see* also p. 589).

The Flexure Lines of the Wrist and Hand

A number of more or less constant flexure lines or skin creases traverse the flexor surfaces of the wrist and hand (**6**.82). Though not necessarily overlying the bony joints, these result from anchorage of the skin to the underlying deep fascia and mark sites of folding of the skin during movements of the parts. (Here, and of course elsewhere, such flexures have often thus been termed 'skin joints'.) These lines are useful landmarks.

At the wrist there are usually three transverse lines; the proximal marks the upper limit of the synovial sheaths of the flexor tendons, the intermediate overlies the wrist joint, and the distal is placed at the upper margin of the flexor retinaculum.

In the palm a curved longitudinally directed flexure line, often termed the *radial longitudinal line*, encircles the thenar eminence and ends at the lateral margin of the hand. Medial and roughly parallel to it are one or two less constant longitudinal lines. Two transverse lines, proximal and distal, cross the palm. The proximal line begins at the distal end of the radial longitudinal line and runs to the hypothenar eminence; it is placed obliquely across the shafts of the metacarpal bones. The distal line begins in the cleft between the index and middle fingers and runs with a slight convexity upwards across the palm, over the heads of the second, third and fourth metacarpal bones, at a level near the commencement of the fibrous flexor sheaths.



In each of the medial four digits there are three sets of transverse lines, proximal, middle and distal. The proximal lines are placed at the roots of the fingers and lie about 2 cm distal to the metacarpophalangeal joints. The middle digital lines are typically double, the proximal member of the pair lying over the proximal interphalangeal joint. The distal flexure lines, usually single, lie proximal to the distal interphalangeal joint, the level of which may, however, be indicated by a second but fainter line nearer the tip of the finger. In the thumb, the base is partially encircled by a line which starts on the radial side and proceeds distally crossing the metacarpophalangeal joint obliquely to end in the cleft between the thumb and index finger on a level with the base of the proximal phalanx. A second shorter crease lies about 1 cm distal to it. At the interphalangeal joint of the thumb there are two lines which are comparable in position to the middle digital lines on the other fingers.

THE JOINTS OF THE LOWER LIMB

The Sacro-iliac Joint

The sacro-iliac articulation is synovial and between the auricular surfaces of the sacrum and ilium (**4**.59). Although often described as plane, the *articular surfaces* are nearly flat only in the infant; in the adult they exhibit irregular elevations and depressions. These curvatures, more pronounced in the male, fit into one another, restrict movements, and contribute to the strength of the joint, which transmits weight from the vertebral column to the lower limb. According to Putschar (1931) and Schunke (1938) the sacral articular surface is covered by hyaline cartilage, that on the ilium by fibrocartilage, an unusual arrangement, which apparently has not been subsequently confirmed. Fibrous adhesions and gradual obliteration of the synovial cavity occurs in both sexes, earlier in males, and after the menopause in females. A radiological study (Cohen *et al.* 1967) of 94 individuals without demonstrable joint disease, showed such changes in 6 per cent before 50 years and 24 per cent after this. (In old age the joint may become completely fibrosed and even ossified.) The *articular capsule* is attached close to the margins of the articular surfaces of the sacrum and ilium. The ligaments of the joints are ventral, interosseous, and dorsal sacro-iliac.

The ventral sacro-iliac ligament (**4**.56) is a thickening of the anterior and inferior parts of the fibrous capsule. It is particularly well developed at the level of the arcuate line and inferiorly at the level of the posterior inferior iliac spine, where it connects the third piece of the sacrum to the lateral margin of the pre-auricular sulcus, but it is thin elsewhere.

4.56 The joints and ligaments of the right half of the pelvis. Ventral aspect.

The interosseous sacro-iliac ligament is massive and forms the chief bond between the two bones. It fills the irregular space immediately above and behind the joint (4.60) and is covered by the dorsal sacro-iliac ligament. It consists of deeper and more superficial parts. The deeper part has cranial and caudal bands which pass from the depressions behind the auricular surface of the sacrum to depressions on the iliac tuberosity. These bands are covered by and blend with the more superficial part which forms a fibrous sheet connecting the cranial and dorsal margins of the rough area behind the auricular surface on the sacrum to the corresponding margins of the iliac tuberosity. This sheet is often partially divided into cranial and caudal parts. The cranial one unites the superior articular process and lateral crest on the first two pieces of the sacrum to the ilium and is sometimes termed the *short posterior iliac ligament* (4.57).

The dorsal sacro-iliac ligament overlies the interosseous ligament, from which it is separated by the dorsal rami of the sacral spinal nerves and vessels. It consists of several weak fasciculi which arise above from the intermediate and below from the lateral crest of the sacrum and pass with varying degrees of obliquity to the posterior superior iliac spine and inner lip of the dorsal part of the iliac crest. The lower fibres passing from the third and fourth segments of the sacrum to the posterior superior iliac spine may form a separate fasciculus which is sometimes termed the *long posterior sacro-iliac ligament* (4.57) and is continuous laterally with some of the fibres of the sacrotuberous ligament and medially with the posterior layer of the thoracolumbar fascia (Weisl 1954).

It is not uncommon to find accessory synovial articulations between the lateral sacral crest and the posterior superior iliac spine and tuberosity of the ilium (Trotter 1937).

Movements. A small amount of anteroposterior rotatory movement occurs at the sacro-iliac joint around a transverse axis which is usually about 5–10 cm vertically below the promontory of the sacrum (Weisl 1955). These movements occur during flexion and extension of the trunk and the range is the same in the male and non-pregnant female. The range is increased temporarily in pregnancy. The greatest change in position of the sacrum relative to the iliac bones occurs when rising from the recumbent to the standing position (4.61). The sacral promontory moves forwards as much as 5–6 mm as the body weight is taken upon the sacrum. Backward movement of the lower end of the sacrum is considerably less. The movement is not a simple rotation, the axis being dynamic (Weisl 1953); some translation or glide is thus associated with the rotation.

THE VERTEBROPELVIC LIGAMENTS

The ilium is connected to the fifth lumbar vertebra by the *iliolumbar ligament* (p. 272), and the sacrum to the ischium by the *sacrotuberous* and *sacrospinous ligaments*.

The sacrotuberous ligament (4.56, 57) is attached by a broad base to the posterior iliac spines (where it is partly blended with the dorsal sacro-iliac ligament), to the lower transverse tubercles of the sacrum, and to the lateral margin of the lower part of the sacrum and upper part of the coccyx. Its fibres run obliquely downwards and laterally, and converge to form a thick, narrow band; this widens below and is fixed to the medial margin of the ischial tuberosity, continuing along the ramus of the ischium under the name of the *falciform process*, the free concave edge of which blends with the fascial sheath of the internal pudendal vessels (p. 721) and pudendal nerve. To its posterior surface are attached the lowest fibres of the gluteus maximus, and some of the superficial fibres of its lower part are continued into the tendon of the long head of biceps femoris. The ligament is pierced by the coccygeal branches of the inferior gluteal artery, by the perforating cutaneous nerve, and by minute filaments of the coccygeal plexus.

The sacrospinous ligament (4.56) is thin and triangular in form; it attaches to the spine of the ischium and, medially, by its broad base to the lateral margins of sacrum and coccyx in front of the sacrotuberous ligament, with which its fibres are inter-

mingled. It is related in front to the coccygeus, to which it is closely connected, and of which it is often held to represent a degenerated part.

The sacrotuberous and, to a lesser extent, the sacrospinous ligaments oppose upward tilting of the lower part of the sacrum under the downward thrust which is imparted to the upper end of the bone by the weight of the trunk (*vide infra*). These two ligaments convert the sciatic notches into foramina.

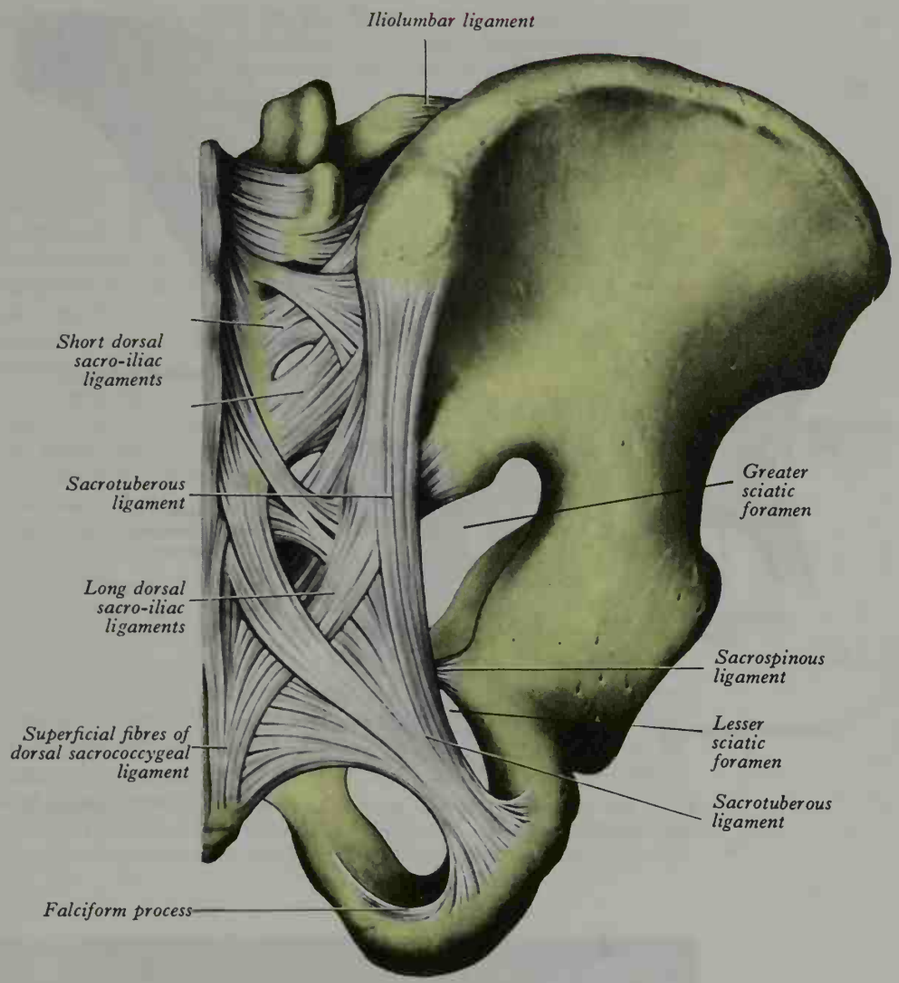
The greater sciatic foramen is bounded in front and above by the greater sciatic notch, behind by the sacrotuberous ligament, and below by the sacrospinous ligament and the spine of the ischium. It is partially filled by the piriformis, which emerges from the pelvis through it. Above this muscle the superior gluteal vessels and nerve pass out of the pelvis; below it, the inferior gluteal vessels and nerve, the internal pudendal vessels and pudendal nerve, the sciatic and the posterior femoral cutaneous nerves, and the nerves to the obturator internus and quadratus femoris make their exit from the pelvis.

The lesser sciatic foramen is bounded in front by the body of the ischium, above, by the spine of the ischium and the sacrospinous ligament, behind, by the sacrotuberous ligament. It transmits the tendon of the obturator internus, the nerve to this muscle, and the internal pudendal vessels and pudendal nerve.

The Pubic Symphysis

The pubic bones meet each other in the median plane, where they form a cartilaginous joint, the *pubis symphysis* (4.2, 58). They are connected by superior and arcuate pubic ligaments, and by an interpubic disc of fibrocartilage.

The superior pubic ligament connects the pubic bones superiorly, and extends as far as the pubic tubercles.

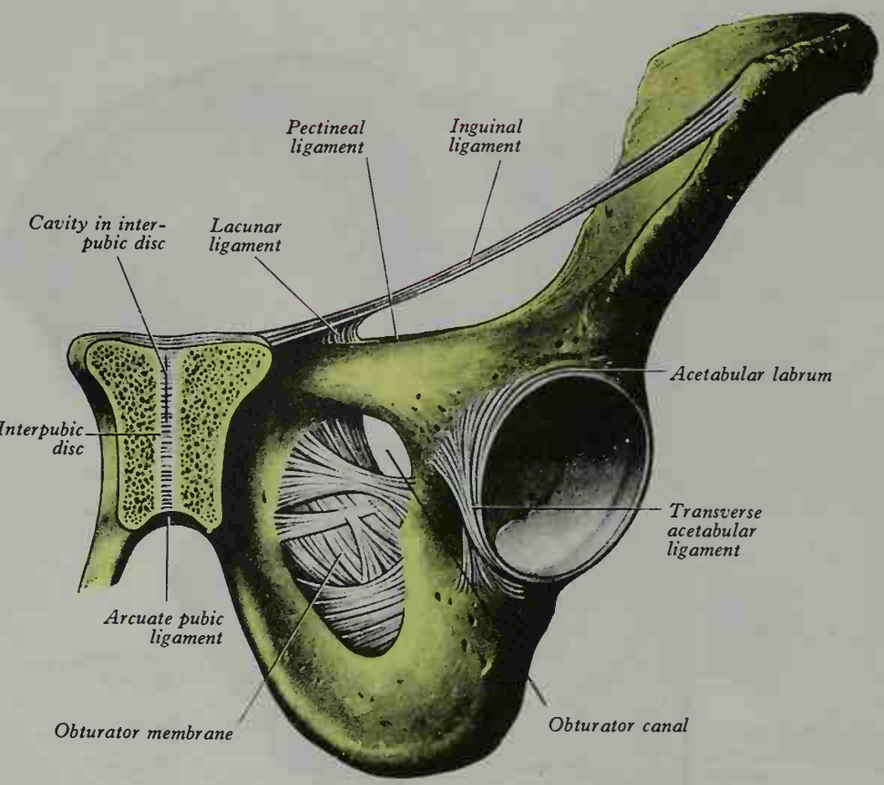


The arcuate pubic ligament is a thick arch of fibres, connecting the lower borders of the symphysial surfaces of the two pubic bones, and forming the upper boundary of the pubic arch. Above, it is blended with the interpubic disc, laterally, it is attached to the inferior rami of the pubic bones; its base is free, and is separated from the free ventral border of the urogenital diaphragm by an opening through which the deep dorsal vein of the penis (or clitoris) enters the pelvis.

The interpubic disc connects the adjacent surfaces of the pubic bones. Each of these surfaces is covered with a thin layer of hyaline cartilage firmly joined to the bone. This junction is not a flat zone (p. 381), being marked by ridges and papilliform elevations, with their reciprocal depressions. This arrangement would, theoretically at least, present a resistance to shearing forces. The opposed surfaces of hyaline cartilage are connected by a lamina of fibrocartilage, which varies in thickness in different subjects. It often contains a cavity, probably formed by softening and absorption since it is rarely seen before the tenth year of life and is not lined with synovial membrane. This cavity, which is better developed in the female, is usually limited to the upper and back part of the joint; it occasionally reaches the front, and may even occupy the whole of the sagittal length of the cartilage (4.58). In front the disc is strengthened by several superimposed layers of fibres, which pass obliquely from one bone to the other, decussating and forming an interlacement with the fibres of the external oblique aponeuroses and the medial tendons of origin of the recti abdominis.

Movements at this articulation have been the subject of little recorded observation. Obviously, as at any symphysis, small degrees of angulation, rotation and displacement are possible, and are likely to occur in activities at the sacro-iliac and hip joints. Some separation between the pubic bones is held to occur late in gestation and particularly during childbirth.

The Mechanism of the Pelvis

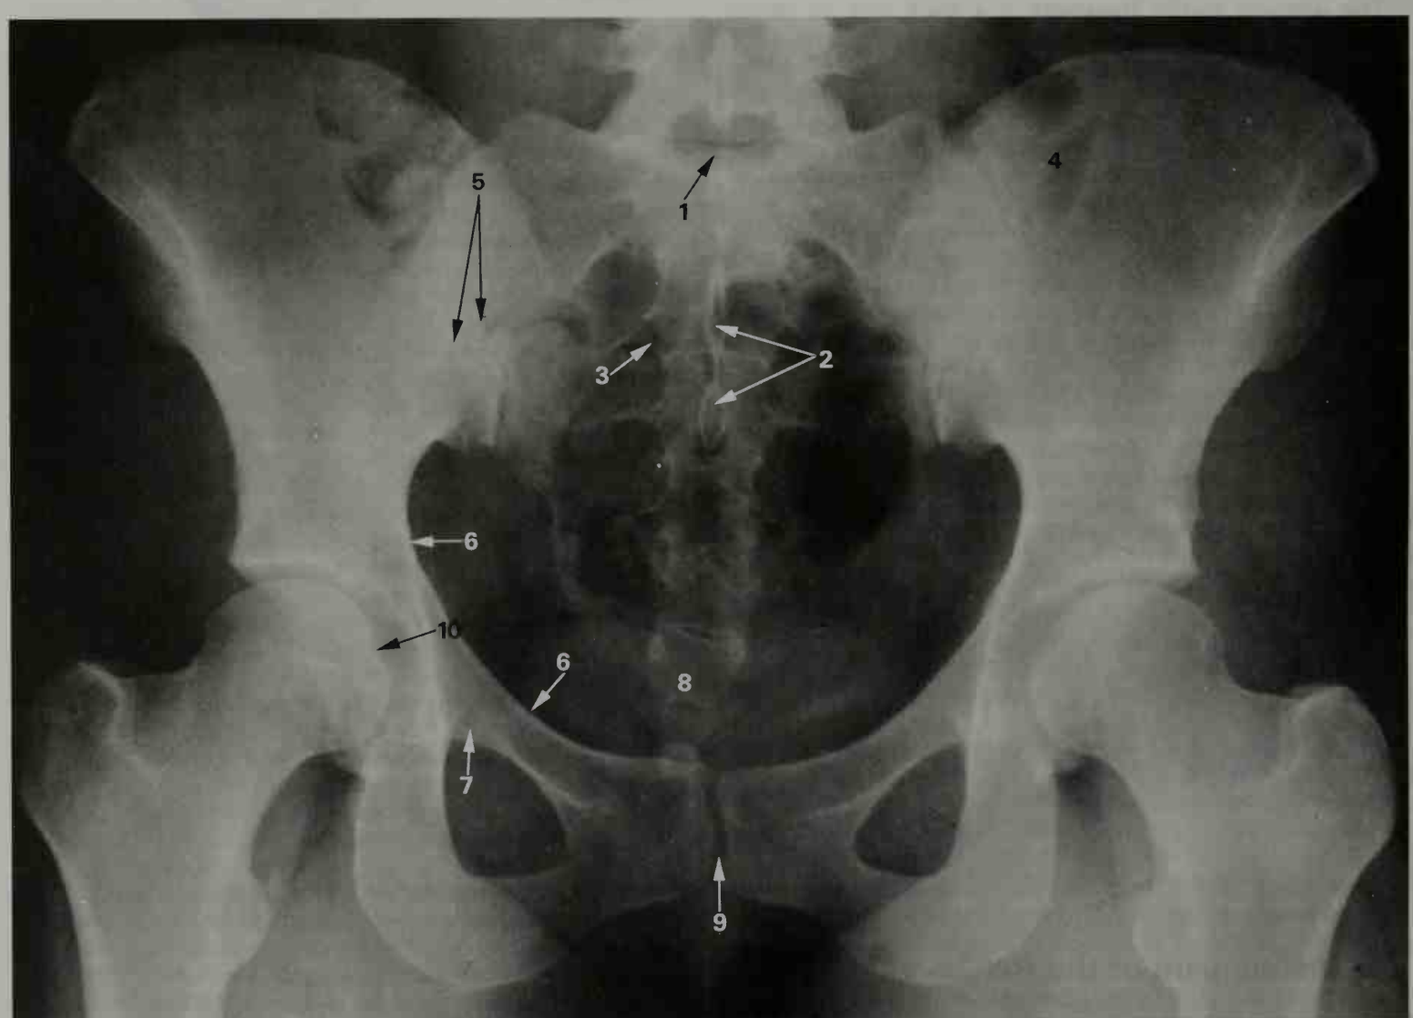


While the skeletal pelvis supports and protects the contained viscera, it is primarily part of the lower limb. It affords surfaces for the attachments of the muscles of the trunk and lower limb. Its most important mechanical function is to transmit the weight of the head, trunk and upper limbs to the lower extremities. It may be divided into two arches by a vertical plane passing through the acetabular cavities; the posterior of these arches is the one chiefly concerned in the function of transmitting the weight of the trunk. Its essential parts are the upper three sacral vertebrae and two strong pillars of bone running from the sacro-iliac joints to the acetabular fossae (p. 384). The anterior arch is formed by the pubic bones and their superior rami. It connects the bases of the lateral pillars of the posterior arch and so acts as a tie-beam to prevent their separation. The anterior arch also acts as a compression strut, resisting the medial thrust of the femoral heads. The sacrum is the summit of the posterior arch; transmitted weight falls on it at the lumbosacral joint and, theoretically, has a component in each of two directions. One component of the force drives the sacrum downwards and backwards between the iliac bones, while the other thrusts the upper end of the sacrum downwards and forwards towards the pelvic cavity.

4.57 The joints and ligaments of the right half of the pelvis and fifth lumbar vertebra. Posterior aspect.

The movements of the sacrum are regulated by its form and ligamentous attachments. Viewed as a whole, it presents the shape of a wedge with its base upwards and forwards. The first component of the force is therefore acting against the resistance of the wedge, and its tendency to separate the iliac bones is resisted by the sacro-iliac and iliolumbar ligaments and by the ligaments of the symphysis pubis.

If a series of coronal sections be made through the sacro-iliac joints, the articular portion of the sacrum may be divided into three segments: anterior, middle and posterior. In the *anterior segment*, which involves the first sacral vertebra, the articular surfaces show slight sinuosities and are almost parallel to one another. In the *middle segment* (4.60) the width between the dorsal margins of the sacral articular surfaces is greater than that between the ventral margins, and in the centre of each surface



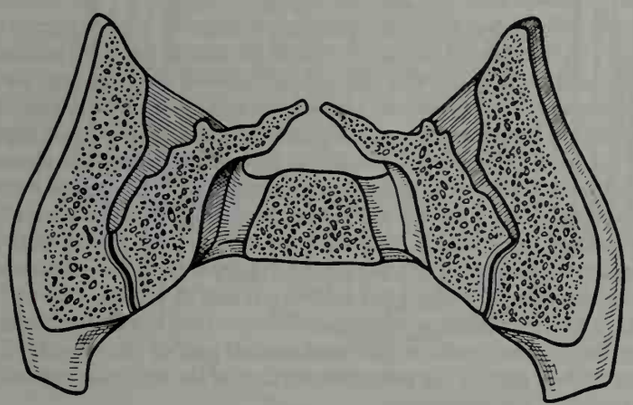
4.58 An obliquely coronal section through the pubic symphysis. Antero-inferior aspect.

there is a concavity into which a corresponding convexity of the iliac surface fits. This forms an interlocking mechanism which relieves the strain of the body weight on the ligaments. In the *posterior segment* the ventral width of the sacrum is greater than the dorsal, and the articular surfaces are only slightly concave.

Dislocation downwards and forwards of the sacrum by the second component of the force applied to it is prevented therefore by the middle segment, which interposes the resistance of its wedge shape and that of the interlocking mechanism on its surfaces; a rotary movement, however, is produced, by which the anterior segment is tilted downwards and the posterior upwards (4.61). The movement of the anterior segment is slightly limited by its wedge form, but chiefly by the dorsal and interosseous sacro-iliac ligaments; that of the posterior segment is checked to a slight extent by its wedge form, but the chief limiting factors are the sacrotuberous and sacrospinous ligaments. In all these movements the effect of the sacro-iliac and iliolumbar ligaments and the ligaments of the symphysis pubis in resisting the separation of the iliac bones must be recognized.

Statistical analysis of the locomotor significance of structural data has been carried out more extensively on the primate, including human, pelvis than any other part of the skeleton, except perhaps the femur. As an example of the application of metrical analysis to the interactions of structure and function consult a paper by Zuckerman, Ashton *et al.* (1973). Muscular gravitational and inertial forces acting on the pelvis have been analysed by means of a mathematical model by Goel and Svensson (1977).

Applied Anatomy. During pregnancy the pelvic joints and ligaments are relaxed and capable of more extensive movements. This relaxation renders the locking mechanism of the sacro-iliac joint less restrictive and permits greater rotation. This change may allow alterations in the diameter of the pelvis at childbirth

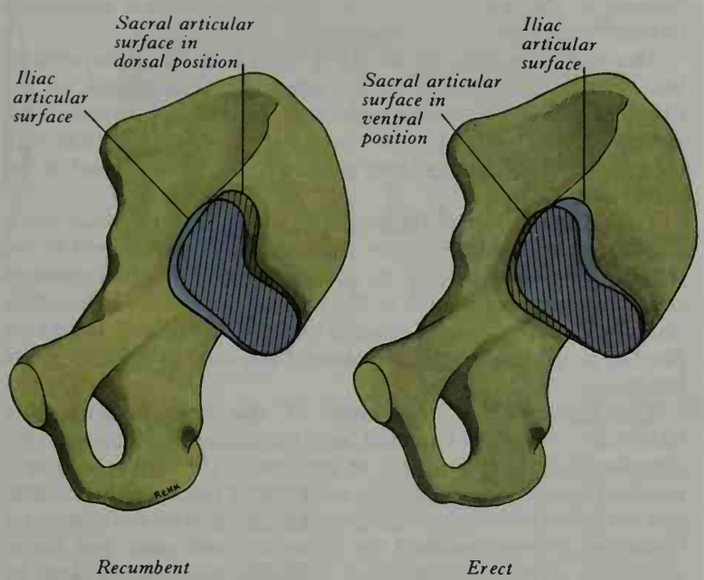


4.59 Anteroposterior radiograph of adult female pelvis. 1. Sacral promontory. 2. Sacral spinous crest. 3. Margin of anterior sacral foramen. 4. Gas in pelvic colon. 5. Sacro-iliac joint. 6. Pelvic brim. 7. Obturator groove. 8. Coccyx. 9. Symphysis pubis. 10. Fovea of femoral head.

but its effect is, at the best, small (Young 1940). The less the locking mechanism, the more the strain of weight-bearing falls on the ligaments, leading to the frequent occurrence of sacro-iliac strain after pregnancy. After childbirth the ligaments become tightened up again and the locking mechanism increases again, but, in some cases, the locking may occur in the position of rotation of the hip bones adopted during the pregnancy. This so-called subluxation of the sacro-iliac joint causes pain by the unusual tension which it imposes on the ligaments, and reduction by forcible manipulation may be attempted. The common position found in this condition is believed to be backward rotation of the innominate bone on the sacrum; it is usually unilateral.

The Hip (Coxal) Joint

The hip joint is multi-axial and of the ball-and-socket type. The head of the femur articulates with the cup-shaped fossa of the acetabulum. Its centre lies some 1·2 cm below the middle third of the inguinal ligament (4.59); this is, of course, an average estimate for an adult male. The articular surfaces are reciprocally curved, but are not co-extensive, nor are they completely congruent, the close-pack position being one of full extension, with some degree of abduction and medial rotation. As in the case of the shoulder joint, the articular surfaces are spheroid rather than spherical. The sphericality of these surfaces has been subject to controversy, and the literature should be consulted, e.g. Hammond and Charnley 1967; Bullough and Goodfellow 1968; Greenwald and Haynes 1972. The weight of evidence favours spheroid (slightly ovoid—p. 432) surfaces, which may become more nearly spherical with advancing age. The head of the femur is completely



4.60 A coronal section passing through the middle of the sacro-iliac joints. The sacrum is in its normal position with the body in the erect attitude.

covered with articular cartilage, except over the small, roughened pit to which the ligament of the head is attached (4.62A). In front, the cartilage extends laterally to cover a small area on the adjoining part of the neck of the femur; it is thickest at the centre of the head and thinner towards its periphery. Kurrat and Oberländer (1978) have measured the thicknesses of the acetabular and femoral articular cartilages in 10 human joints. They find the maximal thickness in the acetabulum to be in its ventrocranial quadrant, whereas that on the femoral head is ventrolateral (4.62C, D). The articular surface of the acetabulum forms an incomplete ring, termed the *lunate surface*, broadest at its upper part where the pressure of the body weight falls in the erect attitude and narrowest where it covers the pubic constituent. It is deficient below opposite the acetabular notch (4.62B). It is covered with articular cartilage which is thickest where the lunate surface is broadest; the floor of the acetabular fossa within this surface is devoid of articular cartilage, lodging a fibroelastic mass of fat largely covered with synovial membrane. The depth of the acetabulum is appreciably increased by a fibrocartilaginous rim, the *acetabular labrum*. The ligamentous structures of the joint are the fibrous capsule, the acetabular labrum, the ligament of the head of the femur, and the iliofemoral, ischiofemoral, pubofemoral and transverse acetabular ligaments.

The fibrous capsule (4.64, 65) is strong and dense. It is attached above to the margin of the acetabulum, 5 or 6 mm beyond the acetabular labrum, in front, to the outer margin of the labrum, and, opposite the acetabular notch, to the transverse acetabular ligament and the edge of the obturator foramen. It surrounds the neck of the femur, and is attached in front to the trochanteric line, above, to the base of the neck, behind, to the neck about 1 cm above the trochanteric crest, below, to the lower part of the neck close to the lesser trochanter (4.64). From its attachment to the front of the femoral neck many of the fibres are reflected upwards along the neck as longitudinal bands, termed *retinacula*; these contain blood vessels supplying the head and neck of the bone (p. 727). The fibrous capsule is much thicker at the upper and fore part of the joint, where the greatest amount of resistance is required, particularly in standing; behind and below, it is thin and only loosely connected to the bone. It consists of two sets of fibres, circular and longitudinal. The circular fibres (*zona orbicularis*) are the deeper (4.63A, B) and form a collar or ring round the neck of the femur; although partially blended with the pubofemoral and ischiofemoral ligaments, these fibres have no direct attachment to bone. The longitudinal fibres are greatest in number at the upper and front part of the capsule, where they are reinforced by the *iliofemoral ligament*. The articular capsule is also strengthened by the *pubofemoral* and the *ischiofemoral ligaments*. The external surface of the capsule is rough, covered by numerous muscles, and separated in front from the psoas major and iliacus by a bursa.

The synovial membrane is extensive. Commencing at the margin of the articular cartilage of the head of the femur, it covers

4.61 This illustrates the changing relation (rotation) of the auricular surface of the sacrum and that of the ilium when changing from a recumbent to an erect posture. (Based upon work by Dr. H. Weisl, 1953, with kind permission of the author.)

the portion of the neck which is contained within the joint capsule; from the neck it is reflected on the internal surface of the capsule, covers both surfaces of the acetabular labrum, ensheathes the ligament of the head of the femur, and covers the mass of fat contained in the acetabular fossa. It is very thin over the deep surface of that part of the iliofemoral ligament which is compressed against the head of the femur in the erect attitude and has even been described as absent in this situation. The interior of the joint communicates sometimes with the subtendinous iliac bursa (p. 594) beneath the psoas major tendon, through a circular aperture between the pubofemoral ligament and the vertical band of the iliofemoral ligament.

4.62A and B The articular surfaces of a cadaveric hip joint. A shows the acetabulum, comprising the articular cartilage-covered lunate surface, the acetabular fossa with its articular pad of fat, the acetabular labrum, the transverse acetabular ligament, and portions of the peri-articular musculature are included in the field of view. B displays the spheroidal articular cartilage covering the femoral head; note the severed ligament of the head of the femur. (Preparation by Dr. M. C. E. Hutchinson and photography by Mr. Kevin Fitzpatrick, Guy's Hospital Medical School, London.)

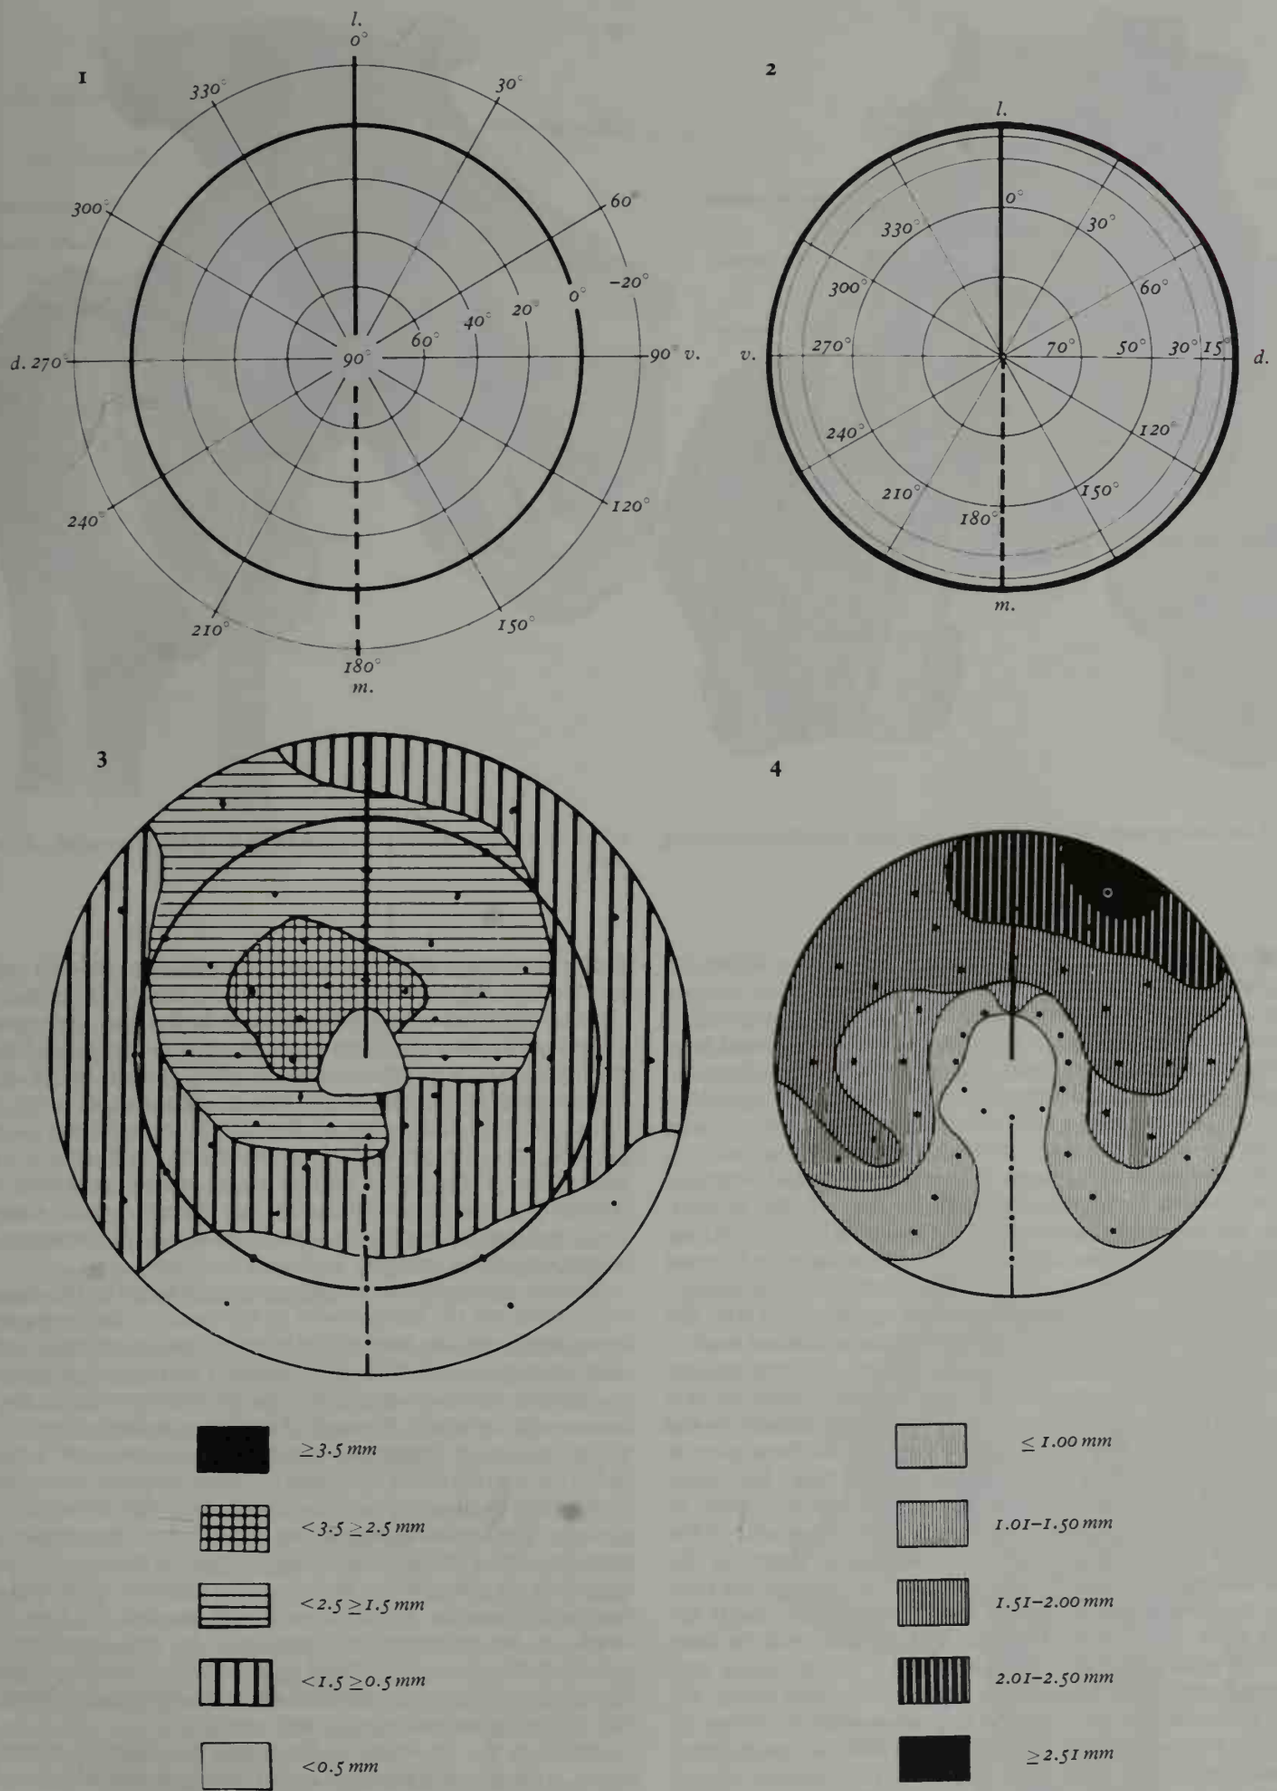
The iliofemoral ligament (4.64), triangular in shape and of great strength, lies in front of the joint and is intimately blended with the capsule. Its apex is attached to the lower part of the anterior inferior iliac spine, its base to the trochanteric line of the femur. The medial and lateral parts of the ligament are strong bands, while the central part is relatively thin and weak; the medial band is vertical in direction and is fixed to the lower part of the trochanteric line; the lateral band is oblique and is attached to the tubercle at the upper part of the same line. The iliofemoral ligament is frequently called the Y-shaped ligament, from its likeness to the inverted letter Y. Its lateral band is sometimes termed the *iliotrochanteric ligament*.

The pubofemoral ligament (4.64) is also triangular, with its base at the innominate bone, where it is attached to the iliopectineal eminence, the superior ramus of the os pubis, the obturator crest and obturator membrane; below, it blends with the capsule and with the deep surface of the medial band of the iliofemoral ligament.

The ischiofemoral ligament (4.65) has a somewhat spiral disposition on the back of the joint. From its attachment to the ischium below and behind the acetabulum it is directed upwards and laterally over the back of the neck of the femur. Some of its fibres are continuous with those of the zona orbicularis, others are fixed to the greater trochanter anterior and deep to the iliofemoral ligament.

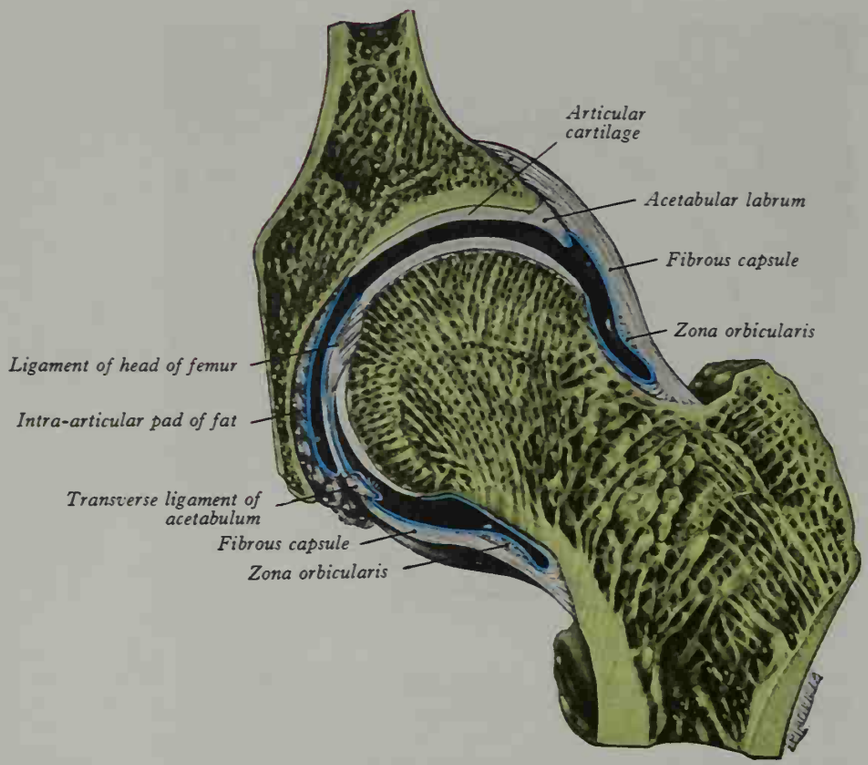
The ligament of the head of the femur (4.66) is a triangular, somewhat flattened band implanted by its apex on the anterosuperior part of the pit on the head of the femur; its base is attached by two bands, one into each side of the acetabular notch, and between these bony attachments it blends with the transverse ligament. It is ensheathed by synovial membrane, and varies greatly in strength in different subjects; occasionally only its synovial sheath exists, and in rare cases even this is absent. From these attachments it can be concluded that the ligament is tense when the thigh is semiflexed and then adducted and relaxed when the limb is abducted.

The acetabular labrum (4.58, 62) is a fibrocartilaginous rim attached to the margin of the acetabulum, the cavity of which it deepens. It bridges the acetabular notch as the *transverse ligament of the acetabulum*, and thus forms a complete circle. It is triangular on cross-section; the base is attached to the edge of the acetabulum, the apex being the free margin of the labrum. The rim of the acetabular cavity is constricted by the free edge of the labrum, which is turned in and embraces the head of the femur closely.



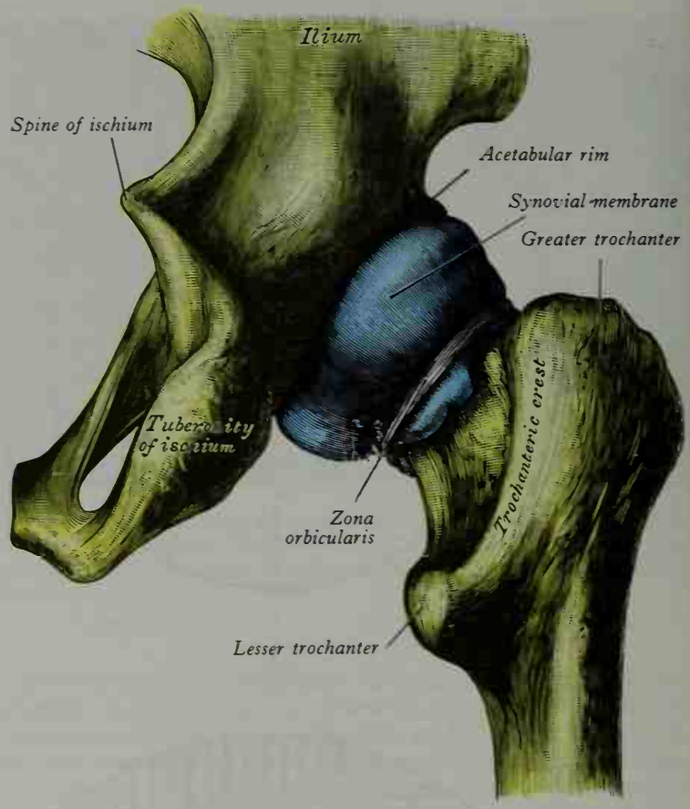
The transverse ligament of the acetabulum (4.58) is in reality a portion of the acetabular labrum, though differing from it in having no cartilage cells among its fibres. It consists of strong, flattened fibres, which cross the acetabular notch, and convert it into a foramen through which vessels and nerves enter the joint.

Relations of the hip joint. The capsule is surrounded by muscles on all sides (4.67). *Anteriorly*, the lateral fibres of the pectineus intervene between the most medial part of the capsule and the femoral vein. Lateral to the pectineus the tendon of the psoas major, with the iliacus on its lateral side, runs downwards across the front of the capsule, partly separated from it by a bursa. Here the femoral artery is on the psoas tendon and the femoral nerve lies deeply in the groove between the tendon and the iliacus. More laterally the straight head of the rectus femoris crosses the joint and, under its lateral border, the deep layer of the iliotibial tract blends with the fibrous capsule. *Superiorly*, the reflected head of the rectus femoris is in contact with the medial part of the capsule; the gluteus minimus covers the lateral part and is closely adherent to it. *Inferiorly*, the lateral fibres of the pectineus lie on the capsule as they incline backwards and, more posteriorly, the obturator externus crosses obliquely to gain the posterior aspect of the joint. *Posteriorly*, the lower part of the capsule is covered with the tendon of the obturator externus, which separates it from the quadratus femoris and is accompanied by the ascending branch of the medial circumflex femoral artery. Above that the tendon of the obturator internus and the two gemelli are in contact with the joint and intervene between it and the sciatic nerve. The nerve to the quadratus femoris lies deep to the obturator internus tendon and descends on the most medial part of the capsule. The uppermost part of the posterior surface of the articular capsule is crossed by the piriformis.



The *arteries* supplying the joint are derived from the obturator, medial circumflex femoral, and superior and inferior gluteal arteries.

The *nerves* are derived from the femoral, directly or through its muscular branches, the obturator, accessory obturator, nerve to quadratus femoris and superior gluteal (Gardner 1948).



Movements. The *active movements* of the hip joint can be categorized as flexion-extension and adduction-abduction, a combination of the foregoing—circumduction, and medial and lateral rotation. These various movements are conveniently considered as rotations occurring around three mutually perpendicular axes (p. 434), but when movements of the whole femur are being considered in relation to the accompanying movements of the articular surfaces, due regard must be paid to the effect of the length and angulation of the neck of the femur in relation to the long axis of its shaft. Thus, when the thigh is flexed or extended, the head of the femur rotates ('spins') within the acetabulum around an approximately transverse axis, and of course conversely, the acetabula rotate around similar axes during flexion and extension of the trunk and pelvis on relatively stationary femoral heads. Medial and lateral rotation of the femur occurs around a vertical axis which passes through the centre of the head of the femur and its lateral condyle, when the foot is *in firm contact with the ground*. Such rotations are an inevitable

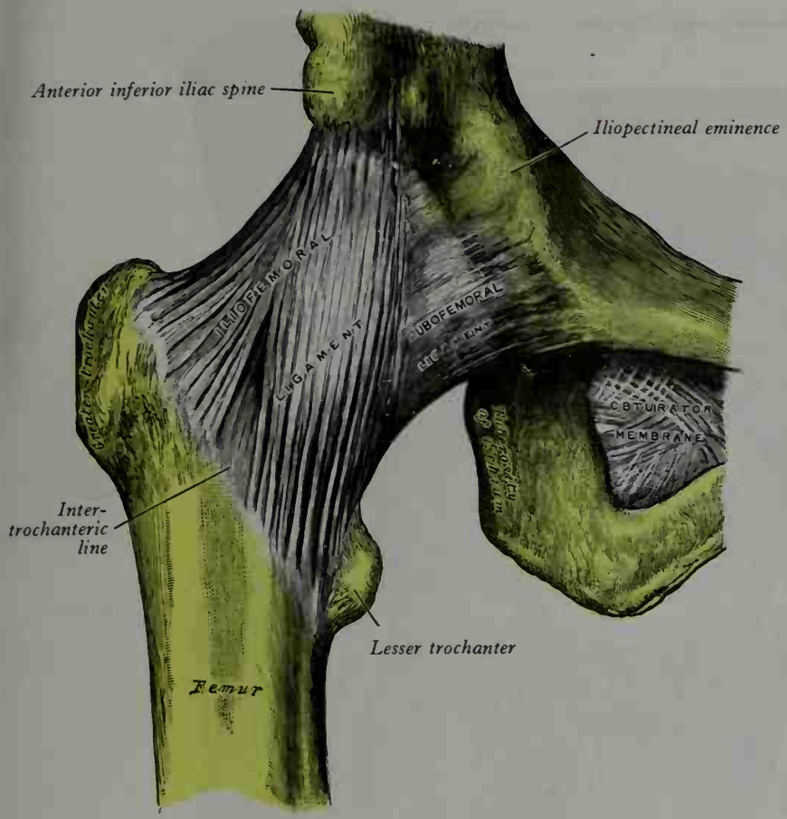
4.62C Diagrams showing variations in the thickness of the articular cartilages of the femoral head (1 and 3) and the lunate surface of the acetabulum (2 and 4). Diagrams 1 and 2 are reference grids by which the distance and angular direction of sampling points are measured from the centres of the femoral head (2) and of the acetabulum (4). Diagrams 3 and 4 show the average contours of the thickness ranges indicated in the shading codes included below. Dorsal and ventral aspects are denoted as '*d*' and '*v*'; '*l*' and '*m*' denote superolateral and inferomedial points on the circumference of the femoral articular surface. The black dots indicate the intersections of lines of 'longitude' and 'latitude' and also represent sampling points. It is immediately apparent that this method does not provide a detailed representation of the graded topology of the articular surfaces (*see* p. 432 for an alternative methodology, recently introduced). (Kindly provided from the paper by Drs. H. J. Kurrat and W. Oberländer, *Journal of Anatomy* 1978, by courtesy of Cambridge University Press.)

4.63A A section through the hip joint. The synovial membrane is shown in blue.

4.63B The synovial cavity of the right hip joint (distended). Posterior aspect.

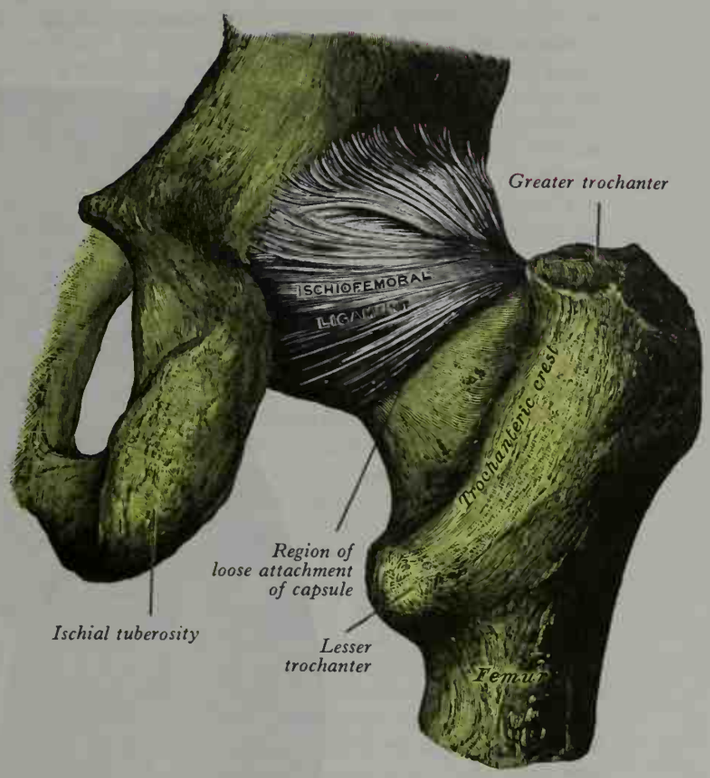
accompaniment of the conjunct rotation which occurs during the terminal stages of extension, or initial stages of flexion, at the knee joint (pp. 434–437). It should be noted that because of the relation of the axis to the remainder of the femur (i.e. the angulated neck and oblique position of its shaft), during such a medial rotation, the medial condyle of the femur moves in an arc *backwards* in relation to the medial tibial condyle, whereas the greater trochanter is simultaneously moving *forwards* along an arc: obviously, converse movements occur during lateral rotation. With the foot in loose contact with, or free of the ground, however, medial and lateral rotation of the whole lower limb may occur around variable axes, all of which pass through the femoral head above but through any part of the foot below. Conversely, with one foot firmly on the ground, and the opposite foot free, the whole trunk and pelvis may rotate about a single femoral head—well instanced by the cross-kick of the footballer. The movements of abduction and adduction occur around an anteroposterior axis which passes through the centre of the head of the femur. As the head of the femur is not truly spherical none of these axes is stationary (Walmsley 1928). When considering hip joint movements, some kinesiologists prefer to consider them in relation to a *mechanical axis* coincident with the long axis of the femoral neck and impinging on the approximate centre of the articular surface of its head (p. 433). In such an analysis it is seen that the movements of extension and flexion of the thigh are relatively pure 'spins' at the hip joint and that they will be most effective in spiralizing and tautening, or in straightening and relaxing the capsule and ligaments, respectively (*vide infra*). All remaining movements are regarded as pure or impure swings (p. 434). While such a simplification permits an analysis much closer to actual functioning than a cardinal tri-axial system, related arbitrarily to the anatomical position, it must be understood that the mechanical axis itself is dynamic, and that 'spin' may occur in many positions of the joint. It makes an angle of about 125° with the long axis of the femoral shaft, the actual angle varying, of course, with age and sex.

Simple flexion of the hip joint is possible to a forward angulation of about 90 to 100° from the *vertical*; extension posteriorly from the *vertical* is highly limited (perhaps 10 to 20°). Both movements are given much greater amplitude by adjustments of the spinal column and pelvis, by flexion of the knee and concomitant medial or lateral rotation at the hip. For example, flexion of the knee (by lessening tension in the posterior femoral muscles) increases coxal flexion to 120°, and the thigh can be drawn passively to the trunk, though this also involves some spinal flexion. Extension of the thigh in walking, running, dancing, etc., is increased by forward bending of the trunk, tilting and rotation of the pelvis, and by lateral rotation at the hip joint. (For analyses of these and other hip movements, consult Kapandji 1965, 1974; and Joseph 1975.) Abduction and, to a lesser extent, adduction can be similarly increased in range.



The hip joint presents a very striking contrast to the shoulder joint as regards the limitation of its movements. In the shoulder, as has been seen, the head of the humerus has an articular surface which much exceeds that of the glenoid cavity, and its ordinary movements are restrained but little by the capsule. In the hip joint, on the contrary, the head of the femur is fairly closely fitted to the acetabulum for an area extending over nearly half a sphere, and at the margin of the bony cup it is embraced still more closely by the acetabular labrum, so that the head of the femur is held in place by that ligament even when the fibres of the capsule have been divided. The iliofemoral ligament is the strongest of all the ligaments in the body, and is progressively spiralized and tautened, when the femur in extension reaches the line of the trunk as in symmetrical standing. In this position the pubofemoral and ischiofemoral ligaments also tighten up, and as the joint approaches its position of close-packing, resistance to any extending torque rapidly increases.

Owing to the structure of the joint, no *accessory movements* occur, with the exception of a very small degree of separation which can be effected by strong traction.



Muscles producing the movements.

Flexion. Psoas major and iliacus, assisted by pectineus, rectus femoris and sartorius. Adductors, particularly adductor longus, participate in the movement, especially in its early stages.

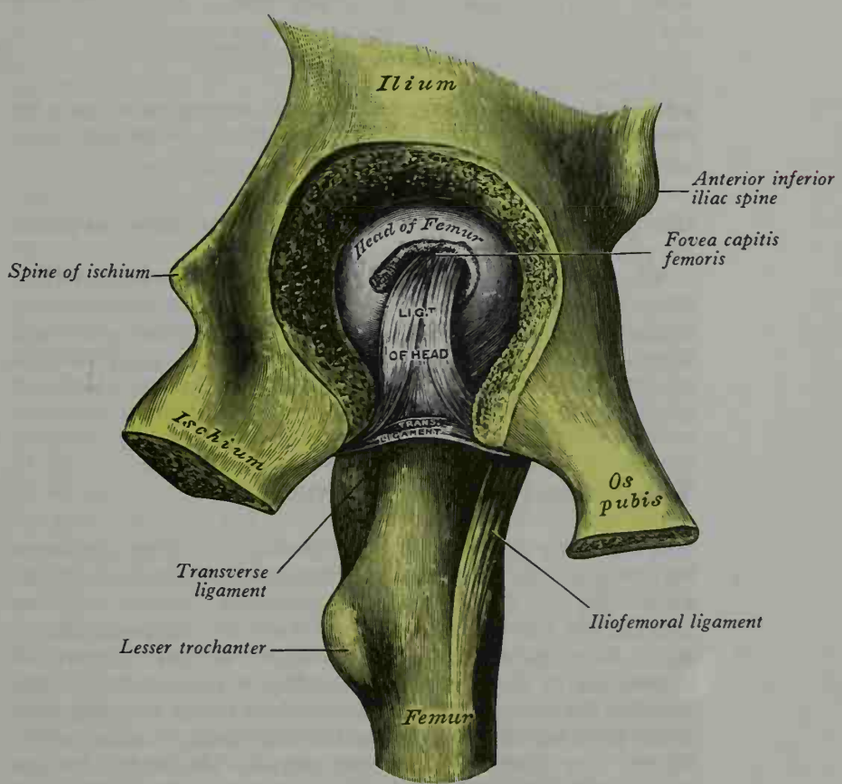
Extension. gluteus maximus and hamstring muscles. In the erect posture a vertical line passing through the centre of gravity of the trunk falls just behind the line joining the centres of the

4.64 The right hip joint. Anterior aspect.

4.65 The right hip joint. Posterior aspect.

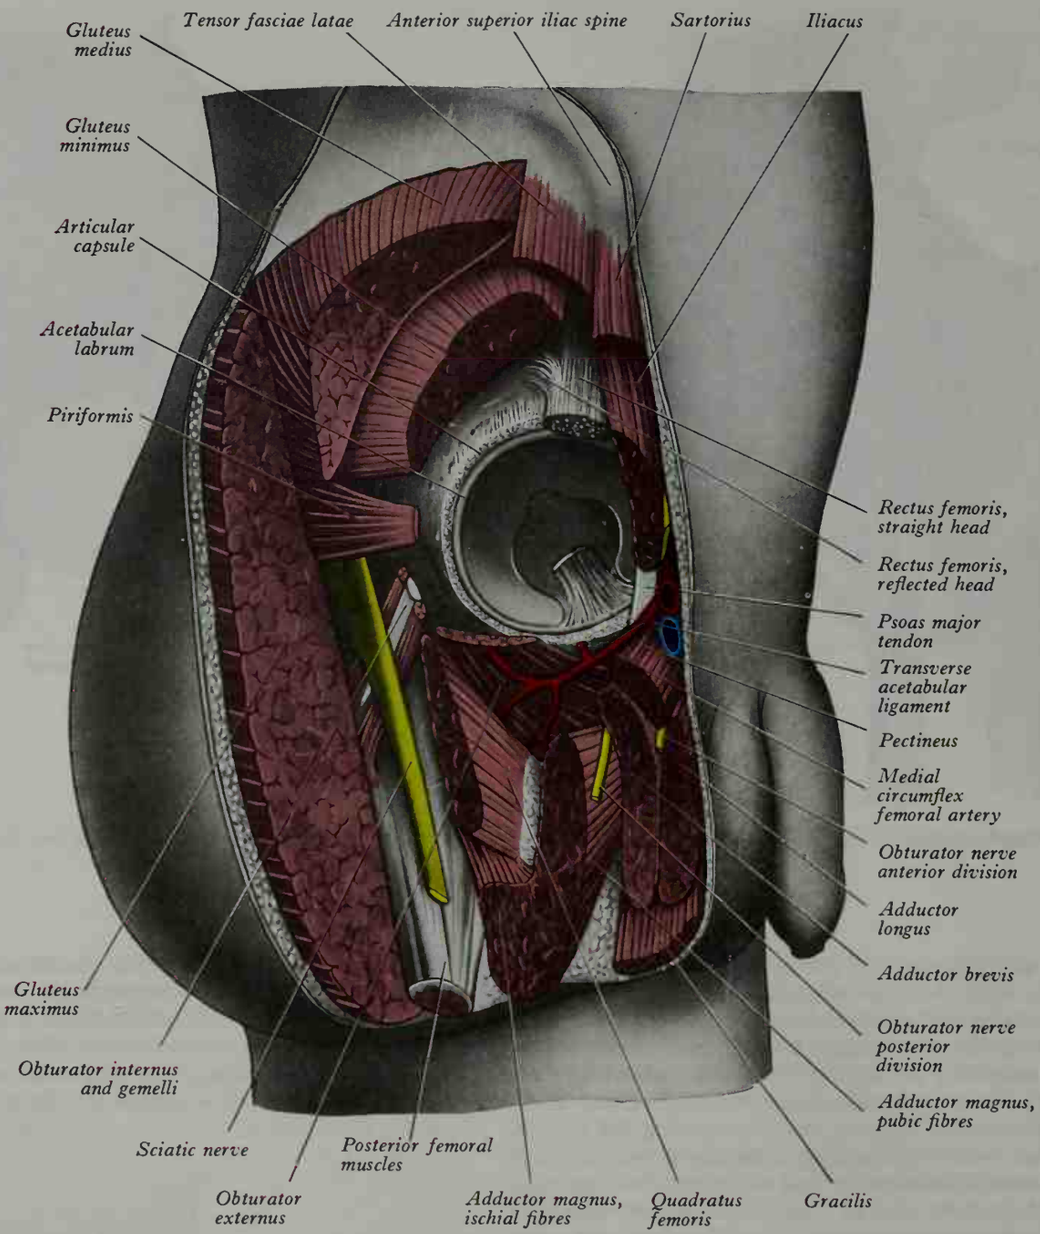
femoral heads and therefore the pelvis (and trunk) tends to fall backwards, but this is counterbalanced by the ligamentous tension, congruence and compression of the articular surfaces which characterize the close-packed position of the joint. Under conditions of increased loading of the trunk or in backward swaying, these passive mechanisms are assisted by contraction of the joint flexors. During forward swaying, holding the arms in front of the trunk, or forward bending at the hip joints, the line of body weight is carried forwards in front of the transverse axis and the posture adopted, or rate of change of posture, is largely controlled by contraction of the hamstrings. The gluteus maximus is active more particularly when the thigh is extended against resistance, as in rising from a bending or sitting position, or when walking upstairs.

Abduction. Glutei medius et minimus (p. 601) assisted by tensor fasciae latae and sartorius. Abduction is a relatively free movement and it is limited by the tension of the adductor muscles, the pubofemoral ligament and the medial band of the iliofemoral ligament. These muscles are most constantly involved during walking or running (p. 617).



Adduction. Adductores longus, brevis et magnus, assisted by pectineus and gracilis. Adduction is limited by contact with the opposite limb, but a wider range of movement can be obtained when the thigh is flexed. Adduction of the flexed thigh is limited by the tension of the abductor muscles, the lateral band of the iliofemoral ligament and the ligament of the head of the femur.

Medial rotation. Tensor fasciae latae and anterior fibres of the glutei minimus and medius. The movement is relatively weak and is limited by the tension of the lateral rotator muscles, the ischiofemoral ligament and the posterior part of the fibrous capsule. Electromyographical data suggest that the adductors also assist in medial (rather than lateral) rotation, but this is dependent upon the primary position.



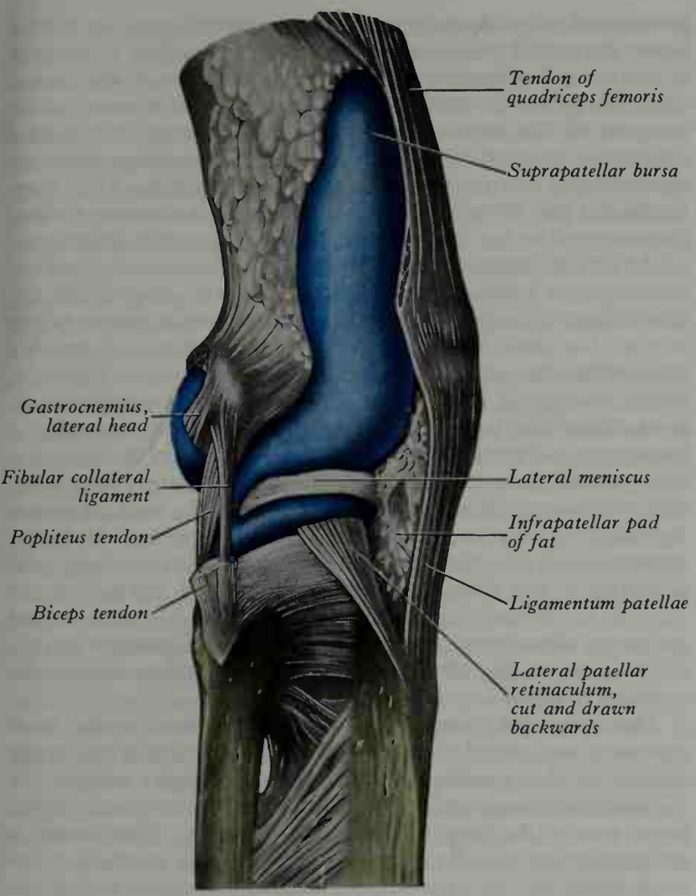
Lateral rotation. The obturator muscles, gemelli and quadratus femoris, assisted by piriformis, gluteus maximus and sartorius. The movement is powerful and is limited by the tension of the medial rotator muscles and by the lateral band of the iliofemoral ligament.

Applied Anatomy. The iliofemoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these uncommon dislocations. It is made to act as the fulcrum to a lever, of which the long arm is the body of the femur, and the short arm the neck of the bone.

Congenital dislocation is met with more commonly in the hip joint than in any other articulation. The displacement usually

4.66 The left hip joint, opened by the removal of the floor of the acetabulum from within the pelvis.

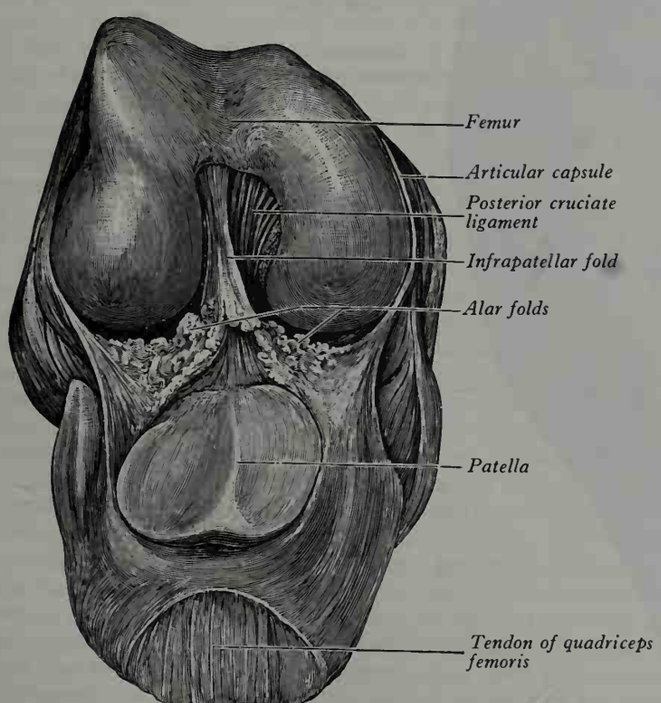
4.67 A dissection to display the structures surrounding the right hip joint. The head of the femur has been disarticulated and removed.



takes place on to the gluteal surface of the ilium, the upper part of the rim of the acetabulum being deficient.

When manipulating the sacro-iliac joint the surgeon takes advantage of the fact that the iliofemoral and ischiofemoral ligaments are taut in extension of the hip joint. So strong are these ligaments that forcible attempts to produce hyperextension of the hip joint accompanied by forward pressure on the iliac crest result in movement at the sacro-iliac joint.

The Knee (Genual) Joint

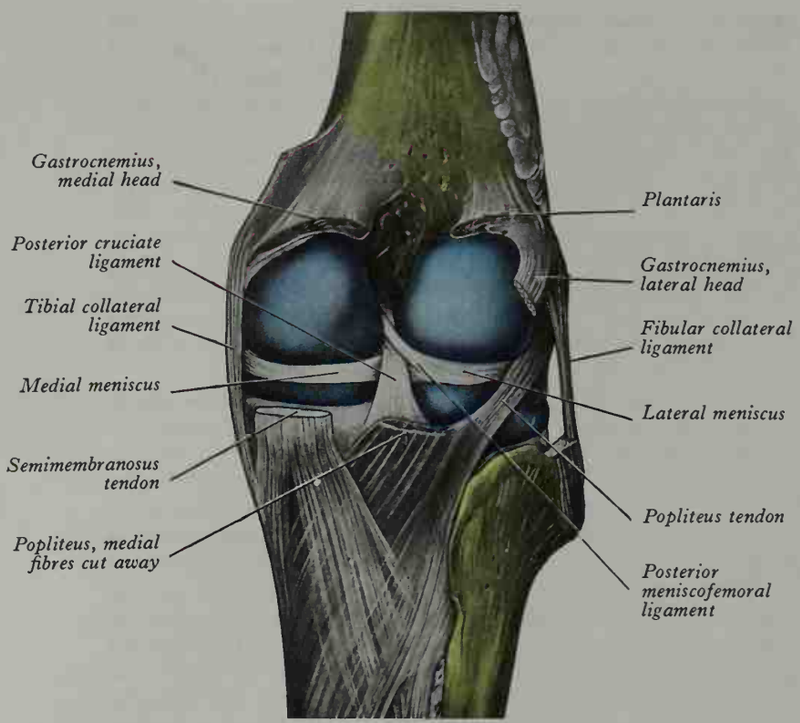


The knee joint (**4**.4), the largest in the body, is of the compound variety (**4**.77, 78). It has been held that the compound mammalian knee joint is derived from a primitive double condylar articulation, but contrary evidence has been adduced (Haines 1942). Nevertheless, and despite its single joint cavity in man, it is convenient to describe it as consisting of two condylar joints between the corresponding condyles of the femur and tibia and a sellar joint between the patella and the patellar surface of the femur. The condylar joints are partially subdivided by two menisci between the corresponding articular surfaces. The level of the joint corresponds to the upper margins of the tibial condyles (**4**.77).

The articular surfaces (pp. 394, 397, 399) are obviously not congruent. The femoral condyles are convex from side to side and from before backwards; in profile they are both spiral in shape with the curvature greatly accentuated posteriorly (**3**.187), but the lateral condyle flattens from back to front more rapidly than the medial one. The tibial articular surfaces are the cartilage-covered areas of the condyles which are separated by the intercondylar area and each surface is gently hollowed out centrally and flattened peripherally where it is covered by the corresponding meniscus. The articular surface on the lateral tibial condyle is almost circular, and smaller than that on the medial condyle, which is oval, with its long axis lying anteroposteriorly. Both tibial articular surfaces are somewhat raised where they border the intercondylar area and pass on to the intercondylar eminences. Posteriorly the lateral tibial surface is prolonged over the back of the condyle in relation to the popliteus tendon, whilst anteriorly, the surface adjacent to the anterior horn of the lateral meniscus passes for a short distance on to the anterior sloping surface of the condyle (*vide infra*). The opposing femorotibial surfaces are adapted to one another more closely by the menisci, which are so shaped that they increase the concavity of the tibial surfaces, but the combined tibiomeniscal upper surface of the lateral condyle has a deeper concavity than the medial one. The articular surface of the lateral femoral condyle is marked in front

4.68 A dissection of the right knee joint. Lateral aspect. The joint cavity has been injected and the synovial membrane is coloured blue.

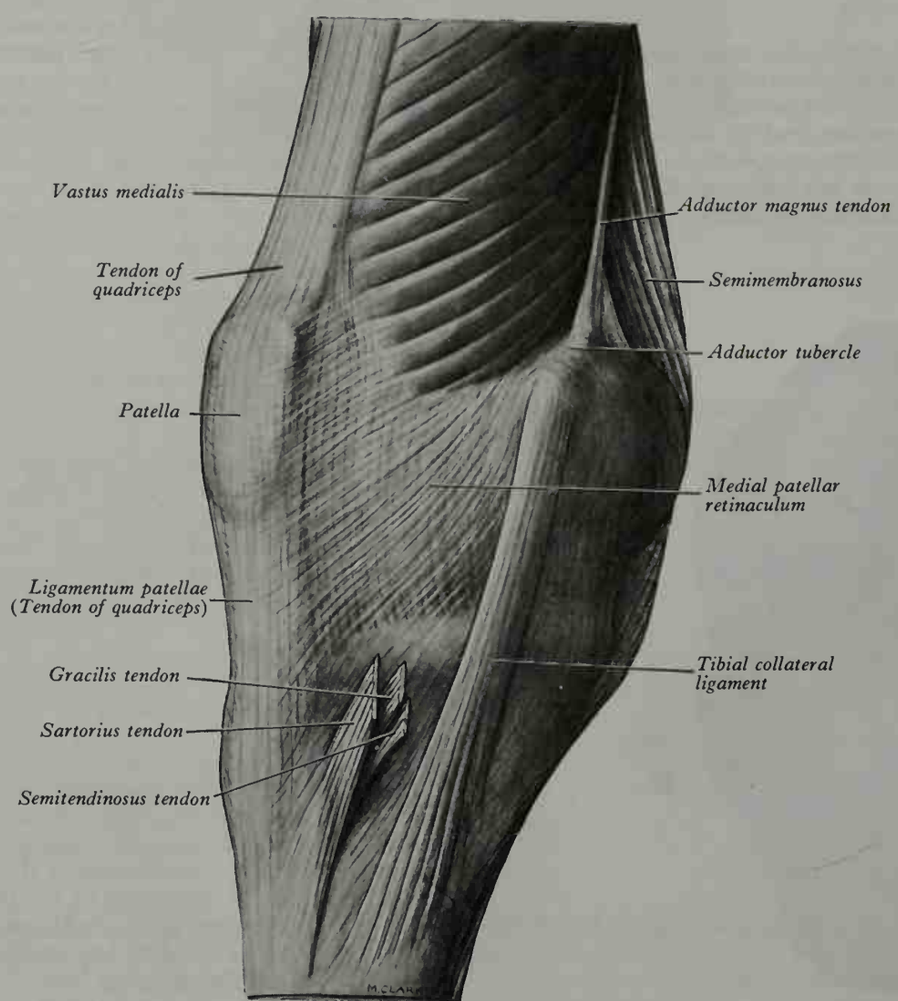
by a faint groove (**3**.186) which rests on the peripheral border of the lateral meniscus in full extension of the joint. A similar groove marks the articular surface of the medial condyle, but it does not reach the lateral border of the condyle, where a narrow strip is marked off which comes into contact with the medial part of the patellar articular surface in full flexion of the knee. Thus the grooves just described demarcate the patellar surface of the femur from its condylar surfaces which articulate exclusively with the tibial surfaces and menisci. When seen from below the *outline* of the femoral (**4**.69) surfaces conform in a general way to the shape of the tibial articular surfaces. That on the lateral femoral condyle is almost circular in outline whereas the medial, larger, surface is somewhat oval, elongated anteroposteriorly, and curved with its concavity facing laterally. These differences in shape, of course, correlate well with the movements of the joint (*vide infra*). The joint surfaces approach full congruence in full extension, the position of close-packing. This has been confirmed by casting techniques, and by radiological studies of excised human knee-joints. (*Vide infra* for a more detailed discussion of close-packing in the knee joint. Consult Kettlekamp *et al.* 1972 for a relevant bibliography.)



4.69 The right knee joint. Anterior exposure.

The articular surface of the patella is adapted in a general way to the patellar surface of the femur (p. 397). The latter covers the anterior surfaces of both condyles and its outline is like an inverted U. An oblique groove, which passes downwards and a little laterally, divides the patellar surface of the femur into a more extensive lateral and a smaller medial area. The lateral part is wider, passes more steeply on to the prominent anterior boss of the lateral condyle, and ascends higher on its anterior surface. Since the whole patellar surface of the femur is concave transversely and convex in a parasagittal plane it can be regarded as an asymmetric saddle-shaped or sellar surface (p. 432). The rounded obliquely vertical ridge which divides the articular surface of the *patella* into a larger, lateral part and a smaller, medial part fits into the corresponding groove on the femur, but the lateral and medial parts are only imperfectly congruent with the corresponding parts of the femur. The articular surface of the patella may be divided still further by two faint, horizontal ridges which, with the vertical ridge, map out three pairs of facets. In many patellae only one horizontal ridge can be made out. It is better marked on the lateral area, and the upper and lateral facet differs from the others in being more deeply hollowed out. On the medial side a second vertical ridge cuts off a narrow, elongated, semilunar strip from the medial border of the surface. This strip comes into contact with the lateral part of the anterior end of the medial femoral condyle in full flexion, and in that position of the joint the uppermost lateral facet on the patella is in contact with the anterior part of the lateral condyle. As the knee is extended the middle facets of the patella make contact with the lower half of the femoral patellar surface, and in full extension only the lowest patellar facets are in contact with the femur (**4**.79). Seedham and Tsubuku (1977) have elaborated a special technique for investigation of contact areas between visco-elastic bodies which they have applied specifically to the patella-femoral joint. They emphasize the temporal factor in such compressive contacts.

The ligaments of the joints are the fibrous capsule, ligamentum (tendo) patellae, tibial and fibular collateral, oblique and arcuate popliteal, anterior and posterior cruciate, and transverse ligaments.



The fibrous capsule is a very complicated structure, for in part it is deficient and in part it is augmented by strong expansions from the tendons of the muscles which surround the joint. Posteriorly, it consists of vertically running fibres which are attached above to the margins of the femoral condyles and the posterior margin of the intercondylar fossa, and below to the posterior margins of the tibial condyles and the posterior border of the intercondylar area. This part of the capsule is blended above on each side with the origin of the corresponding head of the gastrocnemius, and centrally it is strengthened by the oblique popliteal ligament. On the medial side the fibres are attached to the medial surfaces of the femoral and tibial condyles beyond the articular margins. In this situation the fibrous capsule blends with the posterior part of the tibial collateral ligament of the joint. Between the medial epicondyle and the convex border of the medial meniscus is a thickening of the capsule which can be regarded as a deep component of the tibial collateral ligament (Last 1948). On the lateral side the fibres are attached to the femur above the origin of popliteus; they descend over the tendon to the lateral condyle of the tibia and head of the fibula. The fibular collateral ligament of the joint stands clear of the capsule and is separated from it by a little fat and the inferior lateral genicular

4.70 A posterior dissection of the right knee joint. The fibrous capsule has been removed, exposing the unopened synovial membrane, which is coloured blue. The cavity of the joint had been partially distended by injection.

vessels and nerve. Anteriorly, the fibrous capsule does not extend above the patella nor, of course, over the patellar area. Elsewhere it blends indistinguishably with expansions from the vastus medialis and vastus lateralis. The expansions are attached to the margins of the patella and ligamentum patellae and extend backwards on each side as far as the corresponding collateral ligament and downwards to the condyles of the tibia. They form the *medial* and *lateral patellar retinacula*, and the latter is further strengthened by the iliotibial tract. Above the patella the absence of the fibrous capsule allows the suprapatellar bursa (p. 598) to communicate freely with the cavity of the joint. Posteriorly, the attachment of the fibrous capsule to the posterior surface of the lateral tibial condyle is interrupted where the popliteus emerges from within the capsule (**4**.72). The oblique popliteal ligament, which is derived from the tendon of the semimembranosus, strengthens the posterior aspect of the capsule. Laterally, a prolongation from the iliotibial tract fills the interval between the oblique popliteal and the fibular collateral ligaments of the joint, and partly covers the latter; expansions from the tract also reach the lateral patellar retinaculum and patellar ligament. Medially, expansions from the sartorius and semimembranosus pass upwards to the tibial collateral ligament and strengthen the capsule. On its deep surface the fibrous capsule is attached to the periphery of each meniscus and connects it to the adjacent margin of the head of the tibia. This connexion is often termed the *coronary ligament*.

The synovial membrane of the knee joint is the most extensive and complex in the body. Commencing at the upper border of the patella, it forms a large pouch, termed the *suprapatellar bursa*, under cover of the quadriceps femoris on the lower part of the front of the femur (**4**.68, 75). This 'bursa' is preferably regarded, for practical purposes, as an extension of the joint cavity of the knee. The pouch is sustained during the movements of the knee, by a small muscle, the articularis genus,

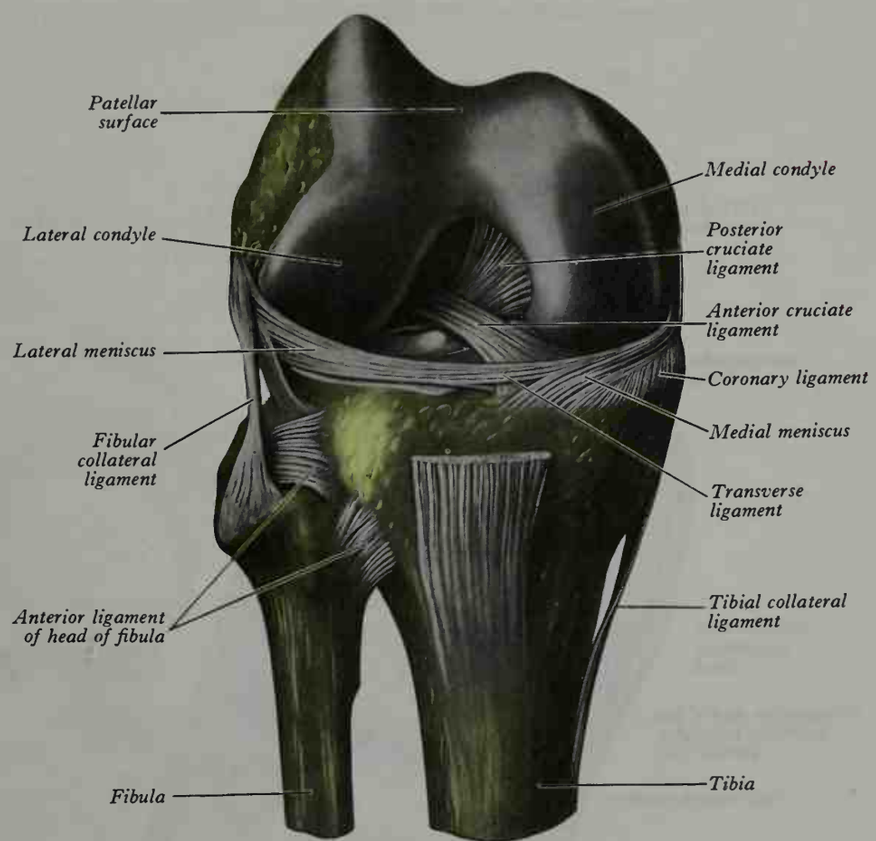
 4.71 The right knee joint. Anteromedial aspect.

which is inserted into it. On each side of the patella, the synovial membrane extends beneath the aponeuroses of the vasti, more extensively beneath that of the vastus medialis. Below the patella it is separated from the ligamentum patellae by the *infrapatellar pad of fat*. Opposite the medial and lateral borders of the lower part of the articular surface of the patella, the synovial membrane covering the infrapatellar pad is projected into the interior of the joint in the form of two fringe-like *alar folds*; behind, these folds converge and are continued as a single band, the *infrapatellar fold* (or *ligamentum mucosum*), to the front of the intercondylar fossa of the femur (4.69). This fold is often regarded as a vestige of the inferior boundary of an originally separate femoropatellar joint (p. 482).

At the sides of the joint the synovial membrane passes downwards from the femur, lining the fibrous capsule as far as its attachment to the menisci, the free surfaces of which possess no covering of synovial membrane. At the back of the lateral meniscus the synovial membrane forms a cul-de-sac, the *subpopliteal recess*, between the groove on the surface of the meniscus and the tendon of the popliteus (4.70). This may communicate with the superior tibiofibular joint (p. 490). The relation of the synovial membrane to the cruciate ligaments is described on p. 486.

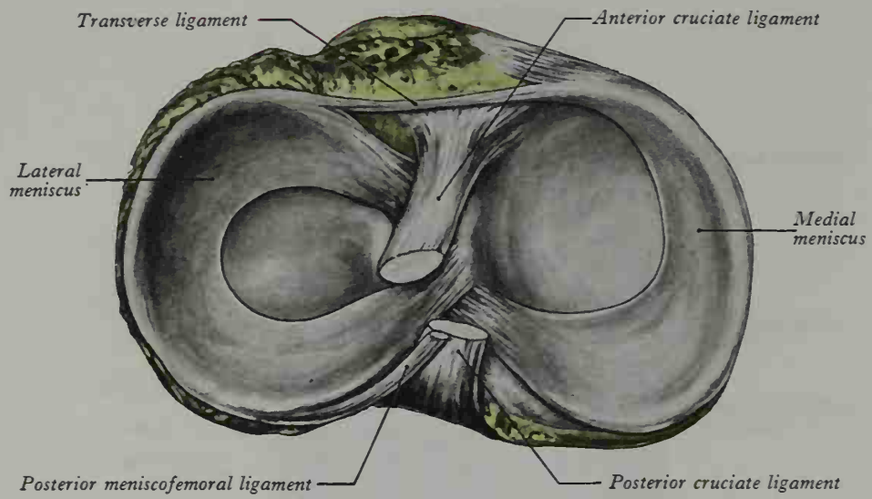
The ligamentum patellae (4.71) is, despite its name, the central portion of the common tendon of the quadriceps femoris, which is continued from the patella to the tuberosity of the tibia. It is a strong, flat band, about 8 cm in length, attached, above, to the apex, adjoining margins and the rough depression on the lowest part of the posterior surface of the patella; and below, to the upper part of the tuberosity of the tibia. Its superficial fibres are continous over the front of the patella with those of the tendon of the quadriceps femoris. The medial and lateral portions of the tendon of the quadriceps pass down, on each side of the patella, to be inserted into the upper extremity of the tibia, on the sides of the tuberosity; they merge into the fibrous capsule, as stated above, forming the *medial* and *lateral patellar retinacula*. The posterior surface of the ligamentum patellae is separated from the synovial membrane by a large infrapatellar pad of fat, and from the tibia by a bursa (4.75).

The oblique popliteal ligament (4.75) is an expansion from the tendon of the semimembranosus close to its insertion into the tibia. It partially blends with the fibrous capsule passing upwards and laterally to be attached above to the lateral part of the intercondylar line and to the lateral condyle of the femur. It consists of fasciculi separated from one another by apertures for the passage of vessels and nerves; it forms part of the floor of the popliteal fossa and the popliteal artery is in contact with it.



The arcuate popliteal ligament (4.72) consists of a Y-shaped system of capsular fibres, the stem of which is attached to the head of the fibula. The posterior limb arches medially over the emerging tendon of popliteus to be attached to the posterior border of the intercondylar area of the tibia. The anterior limb, sometimes absent, extends to the lateral epicondyle of the femur, where it is connected with the lateral head of the gastrocnemius. This limb is often termed the *short lateral ligament*.

The tibial collateral ligament (4.71, 76), a broad, flat band, nearer to the back than the front of the joint, is attached, above, to the medial epicondyle of the femur immediately below the adductor tubercle and, below, to the medial condyle and medial surface of the shaft of the tibia. Its anterior part is a flattened band, about 10 cm long, easily distinguishable from the fibrous capsule deep to it. One or more bursae may separate it from the fibrous capsule and medial meniscus (Brantigan and Voshell 1943). It inclines forwards as it descends to the medial margin and the posterior part of the medial surface of the shaft of the tibia (3.195). It is crossed, below, by the tendons of sartorius, gracilis and semitendinosus, a bursa being interposed. Its deep surface covers the medial inferior genicular vessels and nerve, and the anterior part of the tendon of semimembranosus, to which it is connected to a slight extent. The posterior part of the ligament is fan-shaped and blends with the capsule posteriorly; it is short and inclines backwards and downwards to the medial condyle of the tibia above the groove for semimembranosus.



The fibular collateral ligament (4.73) is a strong, rounded cord, attached above to the lateral epicondyle of the femur, immediately above the groove for the tendon of the popliteus and, below, to the head of the fibula, in front of its apex. It is largely hidden by the tendon of biceps femoris, which embraces and is partly attached to the ligament. Deep to the ligament are the tendon of popliteus and the inferior lateral genicular vessels and nerve. The ligament is *not* attached to the lateral meniscus.

4.72 The right knee joint. Posterior aspect.

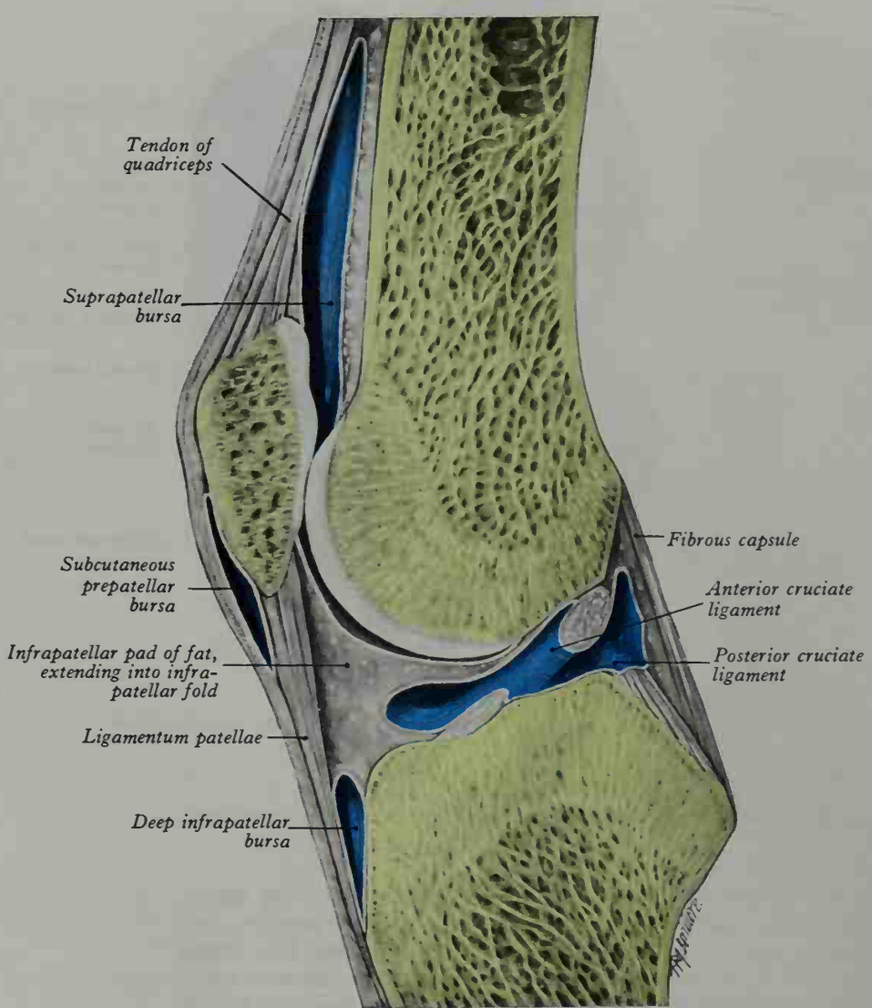
4.73 The right knee joint in full flexion. Dissection from anterior aspect.

4.74 The superior aspect of the left tibia, showing the menisci and the tibial attachments of the cruciate ligaments. See also 3.194A.

The cruciate ligaments are of considerable strength, and are situated a little posterior to the centre of the joint. They are called *cruciate* because they cross each other, and *anterior* and *posterior* from the position of their attachments to the tibia. Their position within the joint suggests their identification as collateral ligaments of originally separate medial and lateral femorotibial joints (p. 482, 485).

The anterior cruciate ligament (4.74) is attached to the medial part of the anterior intercondylar area of the tibia, being partly blended with the anterior end of the lateral meniscus; it passes upwards, backwards and laterally, twisting on itself, and fans out to be attached to the posterior part of the medial surface of the lateral condyle of the femur (Last 1951). It lies anterolateral to the posterior cruciate ligament.

The posterior cruciate ligament (4.73, 74) is stronger, but shorter and less oblique in its direction than the anterior. It is attached to the posterior intercondylar area of the tibia, and to the posterior extremity of the lateral meniscus; it passes upwards, forwards and medially, broadening out to be attached to the lateral surface of the medial condyle of the femur.



In a recent study of the cruciate ligaments (Girgis *et al.* 1975) observations on 24 fresh knee joints suggested that each ligament has two parts—a main posterolateral band and a smaller anteromedial band, which behave differently in joint movements (*vide infra*). In each ligament some spiralization is apparent and becomes more pronounced in certain positions. Average dimensions were given: anterior cruciate length 38 mm, width 11 mm; posterior cruciate length 38 mm, width 13 mm.

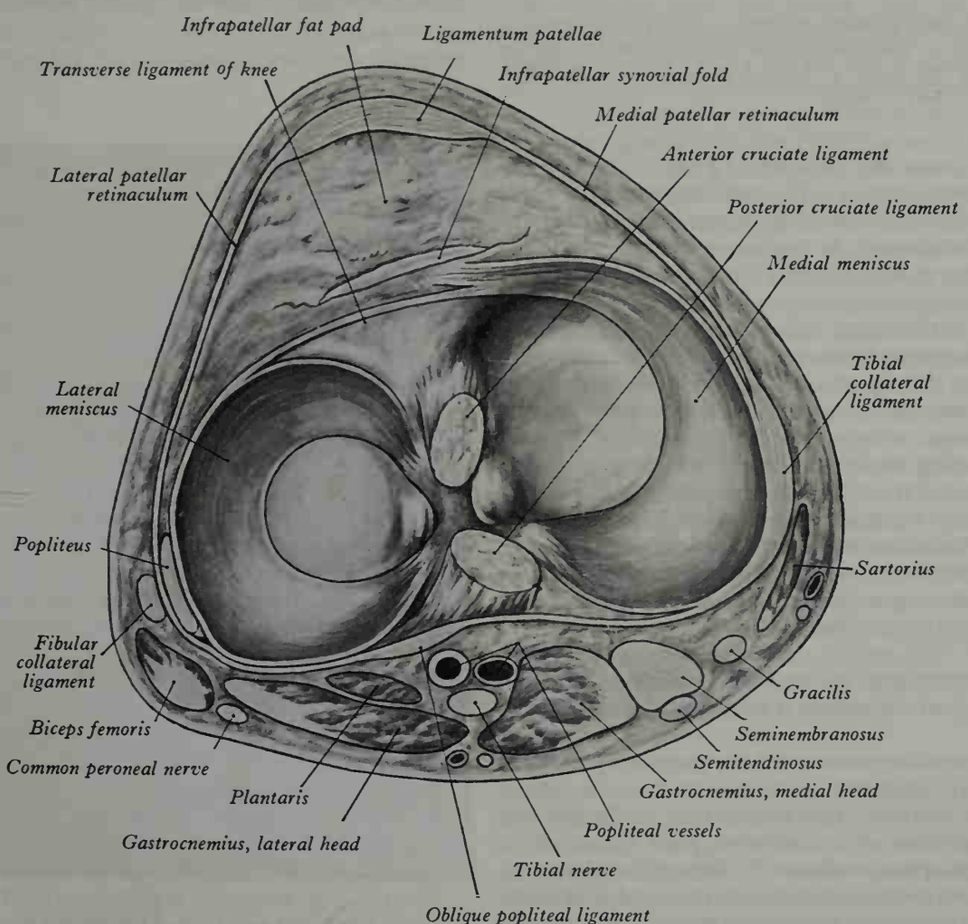
Synovial membrane covers the cruciate ligaments anteriorly and on each side but posteriorly it is reflected from the sides of the posterior cruciate ligament on to the adjoining parts of the fibrous capsule. Thus the middle, or intercondylar, part of the posterior portion of the fibrous capsule is devoid of any synovial covering on its anterior surface. A bursal recess passes in between the two ligaments from their lateral aspect (4.75) and may reach the medial wall of the intercondylar fossa of the femur.

The menisci (semilunar cartilages) (4.74) are two crescentic lamellae which deepen the surfaces of the upper end of the tibia in articulation with the femoral condyles. The peripheral attached border of each meniscus is thick and convex; the free border is thin and concave. The thick peripheral zone is vascularized by capillary loops from the fibrous capsule and synovial membrane, while the inner region is avascular (Davies and Edwards 1948). The upper surfaces of the menisci are smooth and concave, and in contact with the condyles of the femur; their lower surfaces are smooth and flat, and rest upon the tibia. Each covers approximately the peripheral two-thirds of the corresponding articular surface of the tibia.

The medial meniscus is nearly semicircular in form, but is broader behind than in front (4. 74); its anterior end is attached to the anterior intercondylar area of the tibia, in front of the anterior cruciate ligament, its posterior fibres being continuous with the transverse ligament. This end or cornu of the meniscus lies in the floor of the depression on the medial side of the upper part of the ligamentum patellae. The posterior end of the meniscus is fixed to the posterior intercondylar area of the tibia, between the attachments of the lateral meniscus and the posterior cruciate ligament. Its peripheral border is attached to the fibrous capsule and is firmly adherent to the deep surface of the tibial collateral ligament (4.78).

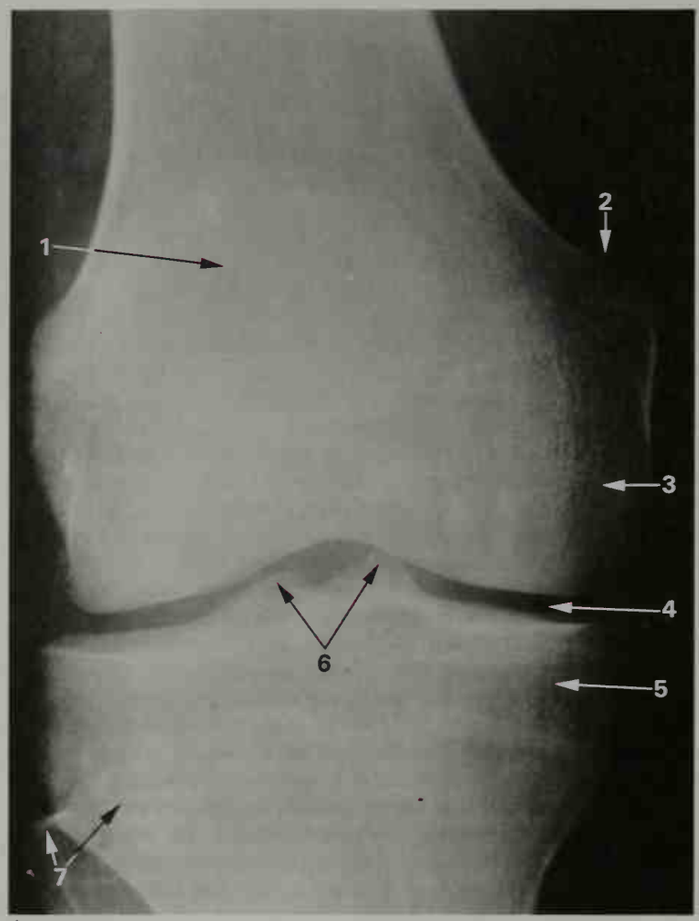
The lateral meniscus forms about four-fifths of a complete ring (4.74) covering a larger area of articular surface than the medial. It is of the same breadth throughout its extent, and is grooved posterolaterally by the tendon of popliteus, which separates it from the fibular collateral ligament. Its anterior end is attached in front of the intercondylar eminence of the tibia, behind and lateral to the anterior cruciate ligament, with which it partly blends; the posterior end is attached behind the intercondylar eminence of the tibia, in front of the posterior end of the medial meniscus. The anterior attachment of the lateral meniscus is twisted so that its free margin looks backwards and upwards, its anterior end resting on a sloping shelf of bone on the front of the lateral intercondylar tubercle. Close to its posterior attachment it commonly sends off a strong fasciculus, the *posterior meniscofemoral ligament* (4.74), which passes upwards and medially behind the posterior cruciate ligament to the medial condyle of the femur. Another oblique band, the *anterior meniscofemoral ligament*, may connect the posterior part of the meniscus and pass to the medial condyle of the femur in front of the posterior cruciate ligament. The meniscofemoral ligaments are often the sole attachments of the posterior horn of the lateral meniscus (Hiller and Langman 1964). It is important to note that the tendon of the popliteus intervenes between the lateral meniscus and the fibular collateral ligament. The more medial

4.75 A sagittal section through the left knee joint. Lateral aspect. The synovial membrane is shown in colour.



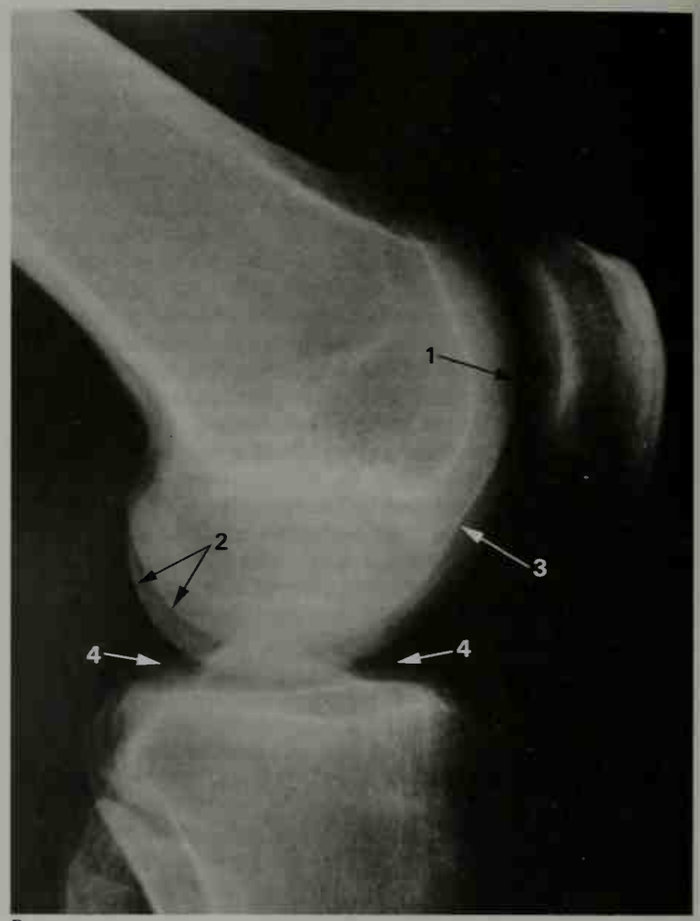
part of the tendon is inserted into the lateral meniscus and thus the mobility of the posterior horn of the lateral meniscus may be controlled by meniscofemoral ligaments and popliteus (Last 1948). A distinct *meniscofibular ligament* has been described as present in about 80 per cent of knee joints (Živanović 1973).

That the menisci meet a functional need is demonstrated by the fact that they are re-formed following excision, provided that their whole breadth is removed, since regeneration can only occur from the vascular fibro-areolar tissue around their periphery. After complete excision of a meniscus and prior to re-formation, the knee joint can be used actively without any sign of instability; but if it is subjected to continued active and violent exercise, the subsequent clinical history indicates that the articular cartilage suffers permanent damage, and this has been attributed to inefficient lubrication during the period of regeneration.



The transverse ligament (4.74) connects the anterior convex margin of the lateral to the anterior end of the medial meniscus; its thickness varies considerably in different subjects, and it is sometimes absent. According to Živanović (1974) this anteriorly situated *menisco-meniscal* ligament varies much in development and is even absent in about 40 per cent of joints. A posterior menisco-meniscal ligament was observed in 20 per cent of 300 knee joints. The same authority described other rare ligamentous arrangements in this articulation.

Bursae associated with the knee joint are numerous. **Anteriorly** there are four; (1) a large *subcutaneous prepatellar bursa* is interposed between the lower part of the patella and the skin; (2) a small *deep infrapatellar bursa* between the upper part of the tibia and the ligamentum patellae; (3) a *subcutaneous infrapatellar bursa* between the lower part of the tuberosity of the tibia and the skin; and (4) one of large size, the *suprapatellar bursa* lies between the anterior surface of the lower part of the femur and the deep surface of quadriceps femoris (4.75). They develop as separate bursae in the fetus and later communicate with the joint, and better regarded as an extension of it. **Laterally** there are four bursae: (1) one (which sometimes communicates with the joint) *between* the *lateral head of gastrocnemius* and the capsule; (2) one *between* the *fibular collateral ligament* and the *tendon of biceps femoris*; (3) one *between the* same *ligament* and the *tendon of popliteus* (this is sometimes only an expansion from the next bursa); (4) one *between* the *tendon of popliteus* and the *lateral condyle* of the femur, usually an extension from the synovial membrane of the joint. **Medially**, bursae may be found in the following positions: (1) *between* the *medial head of gastrocnemius* and the capsule: this sends a prolongation between the tendon of the medial head of gastrocnemius and the tendon of semimembranosus and often communicates with the joint; (2) *superficial* to the *tibial collateral ligament*, between it and the *tendons of sartorius, gracilis and semitendinosus*; (3) *deep* to the *tibial collateral ligament* intervening in variable numbers and positions between this and the femur, capsule of the knee joint, medial meniscus, tibia or the tendon of semimembranosus; (4) *between* the *tendon of semimembranosus* and the *medial condyle* of the tibia and the medial head of gastrocnemius: this is termed the semimembranosus bursa and may communicate with (1) above; (5) occasionally between the tendons of semimembranosus and semitendinosus. **Posteriorly**, bursal extensions are variable.



Structures around the joint. *Anteriorly*, the quadriceps femoris covers the joint, and tendinous expansions from the vastus medialis and vastus lateralis extend backwards from its margins over the *anteromedial* and *anterolateral* aspects of the capsule respectively, forming the patellar retinacula. On the *posteromedial* side the sartorius, with the gracilis tendon lying along its posterior border, descends across the joint; on the *posterolateral* side the biceps tendon, with the common peroneal nerve on its medial side, is in contact with the fibrous capsule,

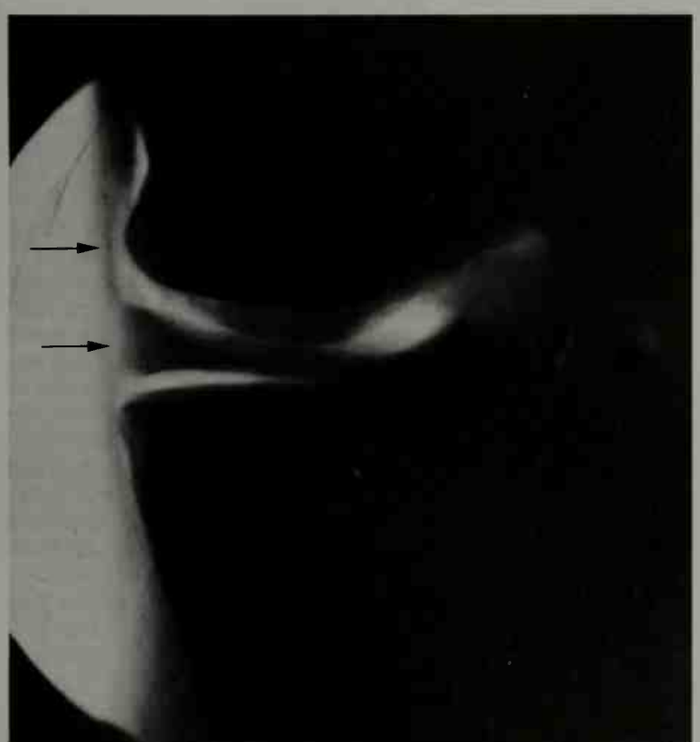
which separates it from the popliteus (**4.76**). The *posterior* relations are the most numerous. The popliteal artery, with its associated lymph nodes, lies on the oblique popliteal ligament; the popliteal vein is posteromedial, or medial, to the artery; and the tibial nerve is posterior to both vessels. The nerve and vessels are overlapped by the adjoining edges of the two heads of gastrocnemius and, on the lateral side, by plantaris. On each side of the vessels the corresponding head of gastrocnemius comes into intimate relation with the capsule, and on the medial side of the medial head semimembranosus intervenes between the capsule and the semitendinosus.

The *arteries* supplying the joint are the descending genicular, the genicular branches of the popliteal, the recurrent branches of the anterior tibial, and the descending branch from the lateral circumflex femoral branch of the arteria profunda femoris. For details consult Scapinelli (1968) and Wladmirow (1968); these studies indicate a more penetrative ligamentous supply than usually described, even parts of the cruciate ligaments receiving a few small vessels.

The *nerves* are derived from the obturator, femoral, tibial and common peroneal nerves (Gardner 1948; Freeman and Wyke 1967).



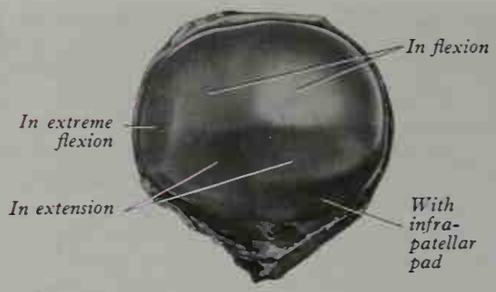
Movements. The active movements carried out at the knee joint are customarily described as flexion, extension, medial rotation and lateral rotation. The movements of flexion and extension differ from those of a true hinge joint in two ways. Firstly, because of the spiral profiles of the femoral condyles, the axis around which the movement occurs is not fixed, but shifts upwards and forwards during extension of the leg on the thigh and backwards and downwards during flexion. Secondly, with the foot fixed on the ground, the last 30° of extension is associated with conjunct medial rotation of the femur, and the first few degrees of flexion with a corresponding degree of lateral rotation; being conjunct rotations they are a consequence of the geometry of the articular surfaces and the disposition of the ligamentous structures. Conversely, with the foot off the ground extension is associated with lateral rotation of the tibia and flexion with medial rotation of this bone. In full flexion the posterior parts of the tibial articular surfaces are in contact with the posterior parts of the articular surfaces of the femoral condyles. During extension the tibia and its menisci glide forwards on the femoral condyles, and the area of contact between the two bones increases and moves forwards also, carrying the menisci with it. As the movement progresses the flatter curve of the femoral condyles makes contact with the tibia, and the menisci are opened out, the net result being that their anterior ends move forwards, while their posterior ends suffer little change in position. In flexion the reverse movement occurs, so that the menisci, moving with the tibia, adapt their outline to the curve of the parts of the femoral condyles which are making contact with that bone.

The movements of rotation at the knee joint have a much smaller range than the movements of flexion and extension, and during their execution the menisci move with the femoral condyles on the upper articular surfaces of the tibia. These rotations occur in two ways — either as *conjunct rotations* integral with the movements of flexion and extension, or as *adjunct rotations* which can occur quite independently and are best demonstrated with the knee joint in the semiflexed position.

The range of extension is about 5–10° beyond a vertical axis through the femur and tibia. Flexion can be carried to about 120° with the hip joint extended, to some 140° when the latter is flexed, and to 160° when a passive element, such as sitting on the heels, is

introduced. *Passive* rotation is about 60–70° in range; in contrast *conjunct* rotation between femur and tibia is limited to about 20°.

The movement of conjunct medial rotation of the femur on the tibia associated with the later stages of extension of the knee is a constituent part of a 'locking' mechanism, which is an asset when the knee, fully extended and under load, is subjected to strain. The position of full extension of the joint is of course a condition of close-packing, with maximum congruence, compression and contact area of the articular surfaces, and with maximum spiralization and tautening of the ligaments. The precise role of the various factors—geometry of articular surfaces, activity of musculature, disposition of ligaments—in the generation of the conjunct rotations has been the subject of considerable dispute (consult, for example, Barnett 1952; Kapandji 1974; Girgis *et al.* 1975), but the following points should be borne in mind. As we have seen, the lateral, upper, combined meniscotibial 'receiving surface' is smaller, more circular and more deeply concave than its medial counterpart. Additionally, the tibial surface of the lateral femoral condyle is also smaller, rounder and flattens more rapidly in an anterior direction, than the medial condyle. Consequently, the lateral femoral condyle approaches a fully congruent relationship with its apposed tibiomeniscal surface some 30° before full extension has been reached (and of course long before the medial condyle is in a similar state). A continuation of simple extension is therefore impossible, but medial rotation of the femur about a vertical axis (through its head and lateral condyle) is possible. As this occurs, the medial femoral condyle moves backwards in an arc, whilst the rotation of the lateral femoral condyle and meniscus causes the anterior horn of the meniscus to pass progressively on to the sloping anterior surface of the lateral tibial condyle. In this manner, full congruence of the lateral condyle is delayed (by deformation of its 'receiving surface') and continuing extension is possible. Of course in practice, these elements of rotation and extension continue simultaneously and smoothly until final close-packing of both condyles occurs together. At the beginning of flexion from the fully extended position (with the foot on the ground) lateral rotation of the femur occurs—often called 'unlocking' of the joint. While the conformation of the joint surfaces and disposition of ligaments are again inevitably involved in this movement, electromyographic evidence indicates the importance of contraction of the popliteus muscle, which pulls downwards and backwards on the area of attachment of its tendon to the lateral condyle of the femur, which is of course lateral to the axis of femoral rotation. Furthermore, through its attachment to the lateral meniscus, its contraction displaces the posterior horn backwards during lateral rotation and continuing flexion of the knee joint, thereby reducing the risk of traumatic compression of the fibrocartilage (Last 1950).



4.78 Radiograph taken after injection of air into the knee joint, showing the shadow thrown by the medial meniscus. The upper arrow points to the medial ligament and the lower to the medial meniscus. (Aerogram by Wing-Commander A. A. Butler, R.A.F.)

It has been seen that during extension of the knee joint the first discernible rotation of the femur occurs some 30° before full extension; it progresses only slowly at first, but increases more rapidly in the last 5°. Over this terminal phase there is a progressive increase in the passive mechanisms which resist further extension, i.e. not only the spiralizing and tautening ligaments and increasing congruence and compression of articular surfaces, but gradually increasing tension in all the extra-articular tissues which cross the posterior aspect of the joint (Smith 1956). Accordingly, the actual position of extension assumed by the joint is the result of a balance between the forces (torque) acting to extend the joint and these passive mechanisms which resist this movement. A range of positions just short of the fully close-packed position is functionally of great importance. In the erect symmetrical standing posture, the line of body weight passes in front of the transverse axes of the knee joints but the passive mechanisms discussed above are sufficient to preserve the posture with a minimal expenditure of muscular energy (Joseph 1960). Active contraction of the joint extensors and the assumption of a fully extended, close-packed position of the knee joints only occurs in asymmetrical postures, or during forward swaying, heavy loading of the trunk, or when a powerful thrust is to be exerted.

Thus, in extension parts of both cruciate ligaments, the tibial and fibular collateral ligaments, the posterior aspect of the capsule and oblique posterior ligament, and the skin and fasciae are all taut, and there is passive and sometimes active tension in the hamstring and gastrocnemius muscles; the anterior parts of the menisci are compressed between the femoral condyles and the tibia. (Kaplan 1958 and Evans 1977, have pointed out the importance of the iliotibial tract as a strong tibial collateral ligament. *See* p. 596.) In the act of extending the knee the ligamentum patellae is tightened by the quadriceps femoris but in the erect attitude it is relaxed. When the knee is flexed the fibular collateral ligament and the posterior part of the tibial collateral ligament are relaxed, but the cruciate ligaments and anterior part of the tibial collateral ligament remain taut; the posterior parts of the menisci are compressed between the femoral condyles and the tibia. Flexion is normally checked by the tension of the quadriceps extensor and its tendon, and tension in the anterior parts of the capsule, posterior cruciate ligament, and compression of soft tissues behind the knee joint. In extreme *passive* flexion, contact with the flexor aspect of the thigh may become a limiting factor. Parts of both cruciate ligaments become tense in this extreme movement. In addition to the movements of conjunct rotation associated with the termination of extension or the commencement of flexion, because of the relaxation of the collateral ligaments, medial and lateral rotation of the leg can be effected independently (adjunct rotation) when the joint is flexed. One at least of the cruciate ligaments is taut in all positions and they act as a direct bond between the tibia and femur and to prevent the former bone being carried too far backwards or forwards. In extension they are assisted in this function by the collateral ligaments. Forward gliding of the tibia on the femur is prevented by the anterior cruciate ligament and backward gliding of the tibia on the femur is prevented by the posterior cruciate ligament (Voshell 1956).

During extension of the femur on a relatively fixed tibia, the movements of the femoral articular surfaces involve simultaneous forward rolling, backward sliding and a medial spin. However, the extension of a freely moving tibia upon a relatively fixed femur involves a simultaneous forward roll and slide, and a lateral spin of the tibial articular surfaces. This analysis of the arthrokinematics of the knee joint is illustrated in **4**.16A, B. For a method of geometrical analysis of the knee joint, allowing for individual variation, consult Low and Lewis (1977).

4.79 The posterior surface of the right patella, showing areas of contact with the femur and infrapatellar fat pad in different positions of the knee joint as indicated.

The menisci probably assist lubrication, facilitate combinations of sliding, rolling and spinning of the surfaces, and may also act as cushions at the extremes of flexion and extension (p. 424). Seedham and his collaborators (1974, 1979) have adduced considerable evidence of the role of menisci in accepting part of compression forces in the knee joint.

Accessory movements. A wider range of rotation can be obtained by passive movements than can be performed actively when the joint is semiflexed, and in this position the tibia can also be made to glide backwards and forwards on the femur. Abduction and adduction are prevented in the fully extended position by the taut collateral and cruciate ligaments. When the knee is slightly flexed a limited amount of adduction and abduction can be obtained, and it may be noted that these movements can be performed actively, provided that the foot is on the ground. A slight amount of separation of the femur and tibia can be obtained on strong traction.

Muscles producing the movements.

Flexion. biceps femoris, semitendinosus and semimembranosus, assisted by gracilis, sartorius and popliteus. When the foot is on the ground, gastrocnemius and plantaris are capable of participating in the movement.

Extension. Quadriceps femoris with some assistance from tensor fasciae latae.

Medial rotation of the flexed leg. Popliteus, semimembranosus and semitendinosus, assisted by sartorius and gracilis.

Lateral rotation of the flexed leg. Biceps femoris alone.

Applied Anatomy. It would appear that the knee is one of the least secure joints in the body. It is formed between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is considerable; the articular surfaces are but ill-adapted to each other, and the range of motion which it enjoys is great. Nevertheless, on account of the powerful ligaments which bind the bones together and the strength of the muscles concerned, the joint is one of the strongest in the body, and traumatic dislocation is a rare accident. Many of these muscles have a direct attachment to the fibrous capsule of the joint.

Injuries to one or other meniscus are of common occurrence and result from twisting strains applied to the knee when it is slightly flexed or when it is in full flexion. The damage may be a tear *in* the cartilage, or occasionally its periphery may be detached from the capsule over a variable extent. The torn or detached portion may become displaced towards the centre of the joint and jammed between the articular surfaces of the femur and tibia, arresting all movement. It should be noted that the menisci are largely avascular and that a tear cannot be expected to heal unless it has occurred close to the capsule (p. 487). The medial meniscus is much more commonly affected than the lateral, probably because it is more securely attached to neighbouring structures and is therefore less able to adapt itself to sudden changes of position. Further, during rotation of the flexed or partially flexed joint it moves through a greater interval than the lateral meniscus. On the other hand, it has been suggested that the medial fibres of the popliteus may draw the posterior part of the lateral meniscus backwards on to the groove on the back of the lateral tibial condyle and so prevent its being trapped between the articular surfaces.

Injuries to the cruciate ligaments are also common and range from simple sprain to complete rupture. The anterior ligament is more commonly affected. Sprain or rupture of the tibial collateral ligament is a less common injury, since excessive strain is likely to fall upon it only when the knee is in full extension.

Osteoligamentous preparations have aided the understanding of the excessive movements resulting from ligamentous injuries. These movements occur particularly in the flexed knee, the fibular collateral ligament and the posterior part of the tibial collateral ligament being relaxed in this position. If the anterior or posterior cruciate ligament is cut, gliding of the tibia forwards or backwards is increased. Similarly rotation is increased if either of the cruciate ligaments or the tibial collateral ligament is cut. Division of both collateral ligaments leads to excessive lateral rotation with untwisting of the cruciate ligaments, but medial rotation is unaffected. Abduction and adduction occur to an excessive degree if both cruciate ligaments are cut (Voshell 1956).

Acute synovitis, the result of injury, is of frequent occurrence in the knee joint. When the cavity is distended with fluid, the swelling shows itself above and at the sides of the patella, reaching 5 cm or more above the patellar surface of the femur, and extending a little higher under the vastus medialis than under the vastus lateralis. The lower level of the synovial membrane is just below the upper end of the tibia.

The bursae about the knee joint are sometimes distended. The subcutaneous prepatellar or infrapatellar bursae are frequently affected in those who are in the habit of kneeling. The bursa beneath the semimembranosus tendon also occasionally becomes enlarged, and forms a fluctuating swelling at the back of the knee. During extension the swelling is firm and tense; but during flexion it may become soft, since the bursa often communicates with the synovial cavity of the joint. The fluid it contains can then be made to disappear by pressure when the knee is flexed and hence loosely packed.

The Tibiofibular Articulations

The tibia and fibula are connected at both extremities, by a synovial articulation above and a fibrous joint below. In addition, the shafts of the bones are connected by the crural interosseous membrane.

THE SUPERIOR TIBIOFIBULAR JOINT

This articulation (4.80) is approximately a plane joint between the lateral condyle of the tibia and the head of the fibula. The *articular surfaces* of the bones are variable in size, form and inclination. The facet on the head of the fibula is generally elliptical or circular in shape and almost flat or slightly grooved. These facets are covered with cartilage, and by the anterior and posterior ligaments.

The fibrous capsule is attached to the margins of the articular facets on the tibia and fibula; it is much thicker in front than behind. In about 10 per cent of persons the synovial membrane of the joint is continuous with that of the knee joint through the subpopliteal recess (p. 485). **The anterior ligament** consists of two or three flat bands, which pass obliquely upwards from the front of the head of the fibula to the front of the lateral condyle of the tibia. **The posterior ligament** is a thick band, which passes obliquely upwards from the back of the head of the fibula to the back of the lateral condyle of the tibia. It is covered by the tendon of the popliteus. These ligaments are not entirely separable from the fibrous capsule.

The *arteries* to the joint are derived from the anterior and posterior tibial recurrent branches of the anterior tibial artery.

The *nerves* are derived from the common peroneal nerve and from the nerve to popliteus.

THE CRURAL INTEROSSEOUS MEMBRANE

The crural interosseous membrane (4.80) connects the interosseous borders of the tibia and fibula, and intervenes between the muscles on the front and those on the back of the leg, some of

4.80 The crural interosseous membrane. Posterior aspect.

which are attached to it. The anterior tibial artery passes to the front of the leg through a large oval opening in the uppermost part of the membrane, and the perforating branch of the peroneal artery pierces it below. Its fibres, largely oblique, descend laterally for the most part, but a few descend medially, including a bundle which forms the upper border of the opening for the anterior tibial artery. The membrane is continuous below with the interosseous ligament of the inferior tibiofibular joint. It is related, in front, with tibialis anterior, extensor digitorum longus, extensor hallucis longus, peroneus tertius, and the anterior tibial vessels and deep peroneal nerve, behind, the tibialis posterior and flexor hallucis longus.

THE INFERIOR TIBIOFIBULAR JOINT

This joint is between the rough, *convex* surface on the medial side of the lower end of the fibula and the rough, *concave* surface of the fibular notch of the tibia. Below, these surfaces are separated for a distance of about 4 mm by an upward prolongation of the synovial membrane of the talocrural joint, and may be covered with articular cartilage in the lowest millimetre. Apart from this, the part of the joint which is of the fibrous type is usually described as a syndesmosis (p. 421).

The anterior tibiofibular ligament (4.86) is a flattened band which extends obliquely downwards and laterally between the adjacent margins of the tibia and fibula, on the front of the syndesmosis.

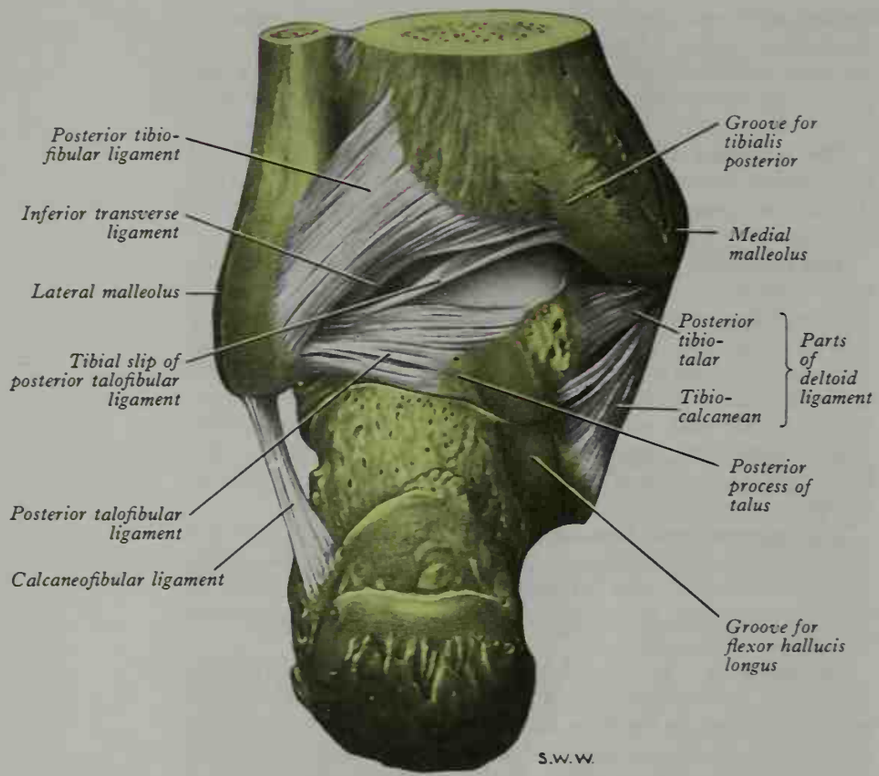
The posterior tibiofibular ligament (4.81), stronger than the preceding, is disposed in a similar manner on the posterior surface of the syndesmosis. Its lower and deep portion forms the *inferior transverse ligament*—a strong, thick band of yellowish fibres which passes transversely from the upper part of the lateral malleolar fossa of the fibula to the posterior border of the articular surface of the tibia, almost as far as the medial malleolus. The inferior transverse ligament projects below the margins of the bones, and forms part of the articulating surface for the talus. It contains a proportion of yellow elastic fibres.

The interosseous ligament is continuous, above, with the crural interosseous membrane and consists of numerous, short, strong bands which pass between the adjacent rough surfaces of the tibia and fibula, and constitute the largest bonds between the lower ends of the bones.

Movements. The joints between the tibia and fibula permit very slight movements. Owing to the varying inclination of the articular surface on the talus for the lateral malleolus, the fibula undergoes a small amount of lateral rotation during dorsiflexion of the ankle (Barnett and Napier 1952). The bones are also forced apart to a small extent in full dorsiflexion. Although it is possible that slight bending or torsion of the fibular shaft could permit the movements of the inferior tibiofibular joint (caused by activities of the talocrural joint) the existence of a proximal synovial tibiofibular articulation doubtless improves efficiency. (See also movements of talocrural articulation.)

The *arteries* to the joint are derived from the perforating branch of the peroneal artery and the medial malleolar branches of the anterior and posterior tibial arteries.

The *nerves* are derived from the deep peroneal, tibial and saphenous nerves.



The Talocrural Joint

The talocrural or ankle joint is of uni-axial type. The lower end of the tibia and its malleolus, the malleolus of the fibula, and the inferior transverse tibiofibular ligament together form a deep recess in which the body of the talus is embraced. The line of the joint can be gauged from the anterior margin of the lower end of the tibia, which can be felt through the skin in the living when the overlying tendons are relaxed. Although anatomically this joint appears to be a simple hinge, and is usually styled 'uniaxial', it must be emphasized that the axis of rotation is dynamic, taking up a series of different positions during dorsiflexion-plantar flexion changes. (*See* Sammarco 1977, for an analysis.)

The articular surfaces are covered with hyaline cartilage. The trochlear surface of the talus, which is convex from before backwards and gently concave from side to side, is wider in front than behind, and the inferior articular surface of the tibia is reciprocally shaped. The articular surface for the medial malleolus is restricted to the upper part of the medial surface of the talus. It is fairly flat and comma-shaped, being deeper in front than behind. The articular surface on the lateral side of the talus is triangular in outline and concave from above downwards; that on the lateral malleolus is reciprocally curved. Posteriorly, the edge between the trochlear and fibular articular surfaces of the talus is bevelled to form a flattened triangular area which articulates with the inferior transverse tibiofibular ligament (4.84, 85). It is to be emphasized that all these talar surfaces are continuous; separate description is a mere convenience.

The bones are connected by a fibrous capsule, and by deltoid, anterior and posterior talofibular, and calcaneofibular ligaments.

The fibrous capsule surrounds the joint; it is thin in front and behind and attached above to the borders of the articular surfaces

4.81 Left talocrural joint. Posterior aspect. (From a specimen in the Museum of the Royal College of Surgeons of England, by permission of the Council.)

of the tibia and malleoli, and below, to the talus close to the margins of the trochlear surface except in front where it is attached to the dorsum of the neck of the talus at some distance in front of its superior articular surface. It is supported on each side by strong collateral ligaments. The posterior part of the capsule consists principally of transverse fibres. It blends with the inferior transverse ligament and is somewhat thickened laterally where it reaches as far as the malleolar fossa of the fibula.

A synovial membrane lines the fibrous capsule, and the joint cavity ascends for a short distance between the tibia and fibula (4.87).

The medial ligament, or deltoid collateral ligament (4.82, 87) is a strong, triangular band, attached above to the apex and anterior and posterior borders of the medial malleolus. It consists of superficial and deep fibres. Of the superficial fibres the anterior (*tibionavicular*) pass forwards to the tuberosity of the navicular bone, and immediately behind this they blend with the medial margin of the plantar calcaneonavicular ligament; the middle fibres (*tibiocalcanean*) descend almost perpendicularly to the whole length of the sustentaculum tali of the calcaneus; the posterior fibres (*posterior tibiotalar*) pass backwards and laterally to the medial side of the talus, and to its medial tubercle. The deep fibres (*anterior tibiotalar*) are well developed and are fixed above to the tip of the medial malleolus and below to the non-articular part of the medial surface of the talus. The deltoid ligament is crossed by the tendons of tibialis posterior and flexor digitorum longus.

The anterior talofibular ligament (4.86) passes from the anterior margin of the fibular malleolus, forwards and medially, to the talus, where it is attached in front of the lateral articular facet and to the lateral aspect of the neck. **The posterior talofibular ligament** (4.81), strong and deeply seated, runs almost horizontally from the lower part of the lateral malleolar fossa to the lateral tubercle of the posterior process of the talus. A bundle of fibres (the 'tibial slip') leaves it to be attached to the medial malleolus. **The calcaneofibular ligament** (4.86) is a long rounded cord, running from the depression in front of the apex of the fibular malleolus downwards and backwards to a tubercle on the lateral surface of the calcaneus. It is crossed by the tendons of peroneus longus and brevis. The foregoing three ligaments together constitute the **lateral ligament** of the talocrural joint.

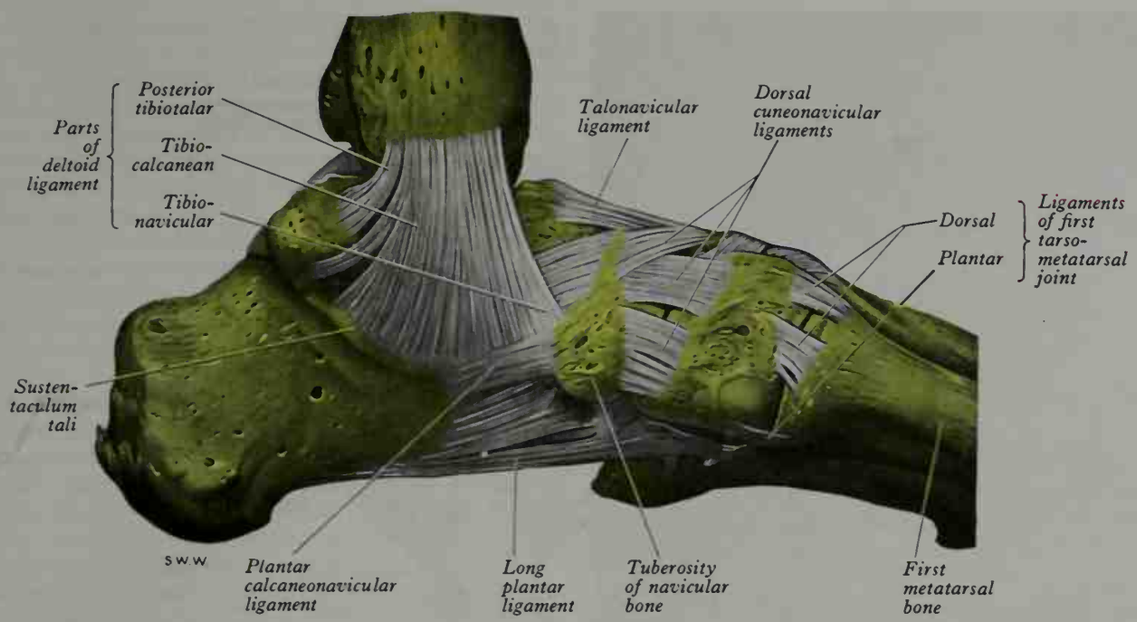
Relations. The tendons, vessels and nerves in relation with the joint are: in front, from the medial side, the tibialis anterior, extensor hallucis longus, anterior tibial vessels, deep peroneal nerve, extensor digitorum longus and peroneus tertius; behind, from the medial side, the tibialis posterior, flexor digitorum longus, posterior tibial vessels, tibial nerve, flexor hallucis longus; in the groove behind the fibular malleolus, the tendons of the peroneus longus and brevis (4.83).

The *arteries* supplying the joint are derived from the malleolar branches of the anterior tibial and from the peroneal arteries.

The *nerves* are derived from the deep peroneal and tibial nerves.

Movements. When the body is in the erect position the foot is at right angles to the leg. The *active movements* of the talocrural joint are those of dorsiflexion (*c.* 10°) and plantar flexion (*c.* 20°); in dorsiflexion the angle between the front of the leg and the dorsum of the foot is diminished; in plantar flexion the angle is increased, the heel being raised and the toes pointed downwards. Dorsiflexion is the position of 'close-pack' with maximal congruence of the joint surfaces and ligamentous tension. This is the initial position from which all major thrusting movements are developed, whether in walking, jumping or running. The malleoli embrace the talus in the position of rest, and no appreciable degree of side-to-side movement can occur without stretching the ligaments of the tibiofibular syndesmosis, and slight bending of the fibula. The superior articular surface of the talus is broader in front than behind. In dorsiflexion, therefore, greater space is required between the two malleoli. This is obtained by a slight lateral rotation of the lower end of the fibula and is consequent on slight movement at the tibiofibular syndesmosis; this is facilitated by a minor degree of gliding at the superior tibiofibular joint. The deltoid ligament is exceedingly strong—so much so, that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the calcaneofibular ligament, binds the bones of the leg firmly to the foot, and resists displacement in every direction. The posterior talofibular ligament assists the calcaneofibular in resisting displacement of the foot backwards, and deepens the cavity for the reception of the talus. The anterior talofibular ligament is a security against displacement of the foot forwards. Plantar flexion of the foot is limited by the tension of the opposing muscles, by the anterior fibres of the deltoid ligament and by the anterior talofibular ligament. Dorsiflexion of the foot is limited by the tension of the calcareal tendon, by the posterior fibres of the deltoid ligament and by the calcaneofibular ligament (4.86). Dorsiflexion and plantar flexion are commonly increased in range by movement at the intertarsal articulations, which can add about 10° to the former and 20° to the latter.

Accessory movements. Slight amounts of side-to-side gliding movement, rotation, abduction and adduction are permitted, when the foot is in plantar flexion.



Muscles producing the movements (see also pp. 604–611, 617–619).

Dorsiflexion. Tibialis anterior, assisted by extensor digitorum longus, extensor hallucis longus and peroneus tertius.

Plantar flexion. Gastrocnemius and soleus, assisted to a lesser degree by plantaris, tibialis posterior, flexor hallucis longus and flexor digitorum longus.

In the symmetrical erect posture, the line of the body weight falls in front of the ankle joint which is not in, or even near, its close-packed position. Stabilization of this posture requires persistent activity of the soleus muscles (and often intermittent activity of the gastrocnemius muscles). However, the force of contraction of these muscles undoubtedly fluctuates—increasing with forward sway and decreasing with backward sway. If backward sway is sufficient to carry the line of weight behind the transverse axis of the talocrural joint there is immediate relaxation of the plantar flexors and contraction of the dorsiflexors.

Applied Anatomy. Owing to the depth of the tibiofibular embrasure into which the talus projects, the talocrural joint is rarely dislocated unless one of the malleoli is fractured. So-called sprains of the talocrural joint are almost always abduction sprains of the subtalar joints, although some of the fibres of the deltoid ligament also are torn. True sprains of the talocrural joint are

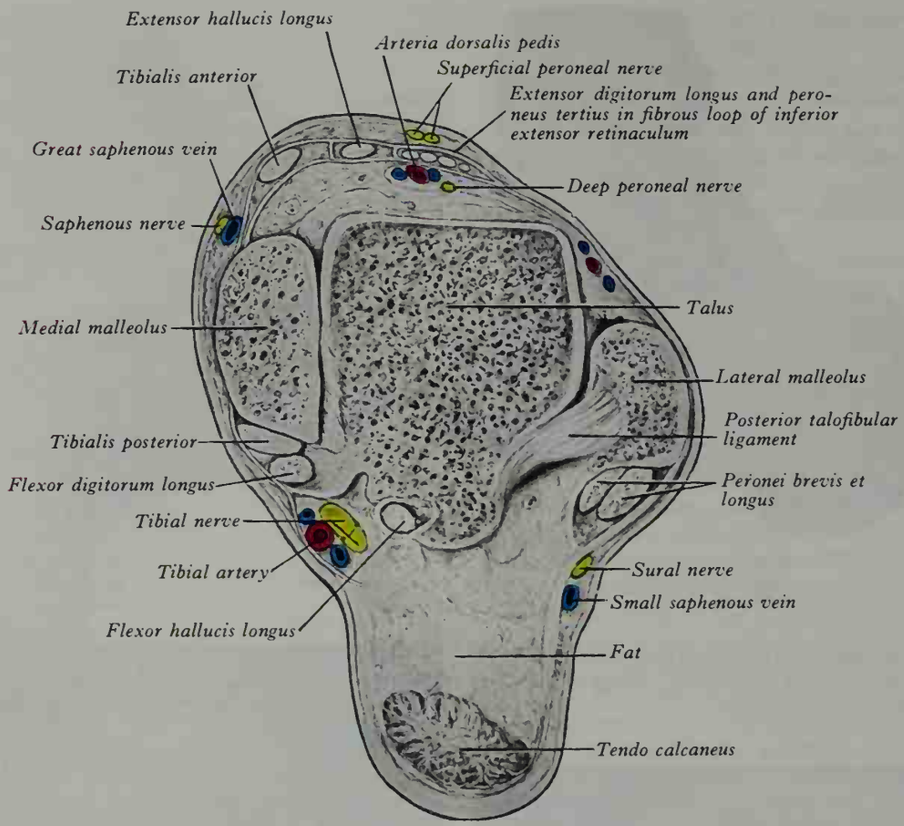
4.82A and B The articular surfaces of a human cadaveric talocrural joint. A displays the tibiofibular mortice, which includes the principal talar surface of the tibia with its medial malleolar facet, the interosseous tibiofibular ligament, and the articular surface of the fibular (lateral) malleolus. B shows the characteristically sellar articular surface of the talus; note the obliquity of its principal axes relative to the sagittal axis of the foot. (Preparation by Dr. M. C. E. Hutchinson and photography by Mr. Kevin Fitzpatrick, Guy's Hospital Medical School, London.)

usually caused by forced plantar flexion and they result in tearing of the capsular ligament on the front of the joint and bruising by impaction of the structures at the back of the joint.

When disease or injury of the talocrural joint is likely to lead to ankylosis, the optimal position to encourage is slight plantar flexion.

The Intertarsal Joints



THE SUBTALAR (TALOCALCANEAN) JOINT

There are two articulations between the calcaneus and talus, anterior and posterior. These form a single functional unit which is often termed the 'subtalar joint', but this term is used here for the posterior joint only, the anterior being described as part of the talocalcaneonavicular joint (*vide infra*).

The subtalar joint, as defined above, involves the concave posterior calcanean facet on the inferior surface of the talus and the convex posterior facet on the upper surface of the calcaneus. The joint is of modified multi-axial type, the more usually stationary surface (talus) being concave or 'female' (*see* p. 429). The two bones are connected by a fibrous capsule and by lateral, medial, interosseous talocalcanean and cervical ligaments.

The fibrous capsule (4.88) envelops the joint, and consists for the most part of short fibres; it is split into slips, and between these there is only a weak fibrous investment. It is lined with synovial membrane, and the joint cavity does not communicate with any other tarsal joint.

The lateral talocalcanean ligament is a short, flattened

4.83 Transverse section through the lower part of the right talocrural joint. Superior aspect.

4.84 Lateral radiograph of ankle and foot, in full plantigrade contact with the ground, during symmetrical standing, of a man aged 44 years: (1) navicular, (2) talonavicular joint, (3) head of talus, (4) subtalar joint, (5) os trigonum, (6) calcaneus—note trabecular pattern, (7) sinus tarsi, (8) calcaneocuboid joint, (9) sesamoid in tendon of peroneus longus, (10) cuboid, (11) tuberosity on base of fifth metatarsal, (12) head of first metatarsal.

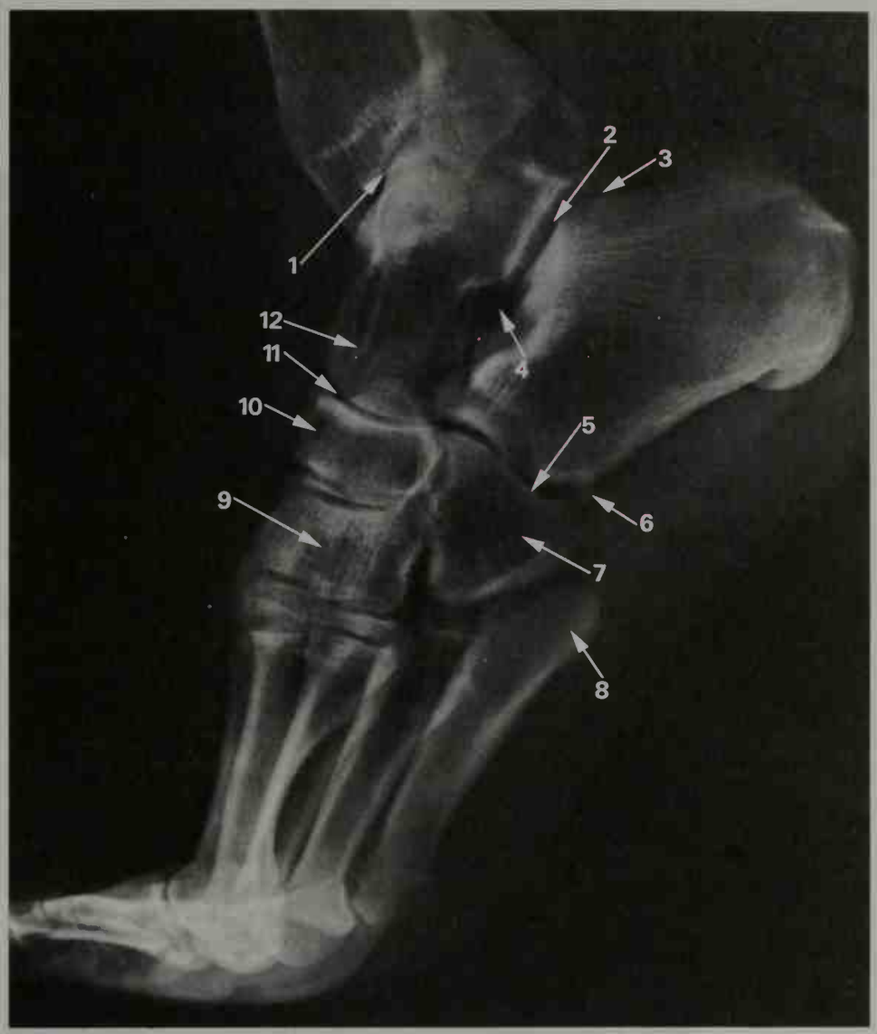
fasciculus, which passes downwards and backwards from the lateral process of the talus to be attached to the lateral surface of the calcaneus, above and in front of the calcaneofibular ligament.

The medial talocalcanean ligament connects the medial tubercle of the talus with the back of the sustentaculum tali and the medial surface of the calcaneus immediately behind the latter. Its fibres blend with those of the deltoid ligament; the most posterior fibres line the groove for the flexor hallucis longus between the talus and the calcaneus.

The interosseous talocalcanean ligament (**4**.87, 88) is a broad, flattened band lying somewhat transversely in the sinus tarsi. It passes obliquely downwards and laterally from the sulcus tali to the sulcus calcanei. Its medial fibres are rendered taut in eversion.

The cervical ligament is placed just lateral to the sinus tarsi and is attached to the upper surface of the calcaneus, medial to the origin of extensor digitorum brevis. From here it passes upwards and medially to a tubercle on the inferior and lateral aspect of the neck of the talus (Barclay Smith 1896, Smith 1958). It is regarded as being taut when the foot is inverted and prevents the occurrence of too great a degree of this movement.

Movements. The movements permitted between the talus and calcaneus are closely associated with the movements at the talocalcaneonavicular joint and will be described with them.



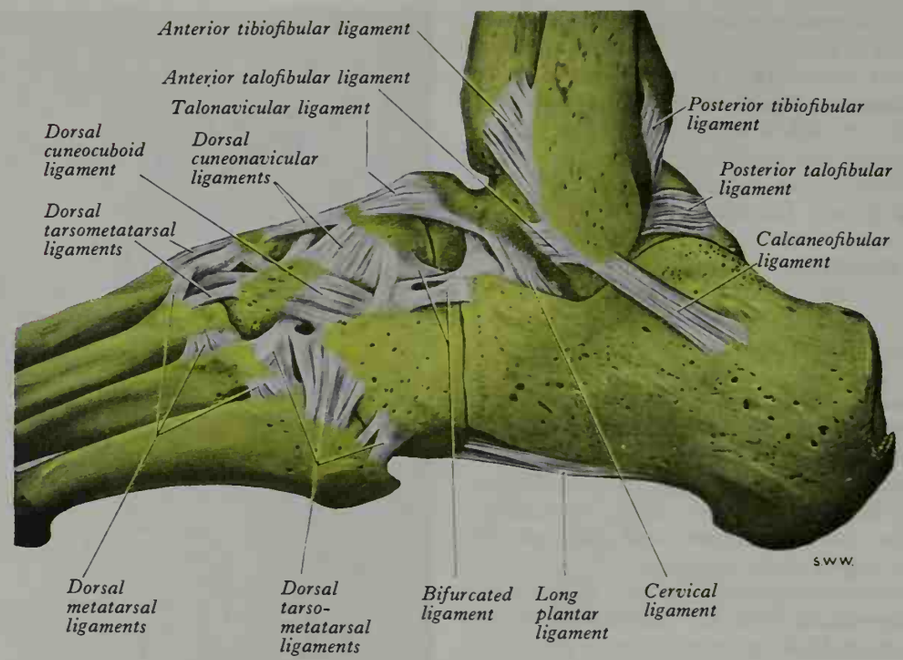
THE TALOCALCANEONAVICULAR JOINT

This articulation is multi-axial; the compounded ovoid head of the talus fits the complex concavity formed by the posterior surface of the navicular, the middle and anterior facets for the talus on the calcaneus, and the upper surface of the plantar calcaneonavicular ligament. In contrast to the subtalar joint, the proximal and less mobile surface is convex or 'male' (*see* p. 429). The position of the joint can be gauged from the head of the talus, which can be both seen and felt 3 cm in front of the lower end of the tibia, when the foot is passively inverted. The bones forming the joint are connected by a fibrous capsule, and by the talonavicular, the plantar calcaneonavicular and bifurcated (calcaneonavicular part) ligaments.

The fibrous capsule is imperfectly developed except posteriorly, where it is considerably thickened and forms the anterior part of the interosseous ligament which fills the sinus tarsi.

The talonavicular ligament (**4**.82, 86) is a broad, thin band, connecting the neck of the talus to the dorsal surface of the navicular bone; above it are the extensor tendons. The *plantar calcaneonavicular ligament* (p. 496) is the plantar and the *calcaneonavicular part of the bifurcated ligament* (**4**.86) the lateral ligament for this joint.

Movements. A considerable range of gliding and rotation occurs at both the talocalcanean and the talocalcaneonavicular joints by which the calcaneus and the navicular, carrying the foot with them, can rotate medially on the talus. This results in elevation of the medial border and corresponding depression of the lateral border of the foot, so that the plantar aspect of the foot faces medially. This is the position of *inversion*. The greater part of the movement occurs at the subtalar joint and at the articulation between the head of the talus and the sustentaculum tali, front of the calcaneus, plantar calcaneonavicular ligament and the posterior surface of the navicular. The surfaces of these two joints are curved in opposite directions and the movements occurring at them have sometimes been likened to the movements between the radius and ulna at the superior and inferior radio-ulnar joints (but in the foot the terms supination and pronation are used in a different context—*vide infra*). The axis of the movements may be considered as a line joining the approximate centres of curvature of the two joints, and runs forwards, upwards and medially, from the back of the calcaneus through the sinus tarsi to emerge at the superior and medial aspect of the neck of the talus (Shepard 1951). The obliquity of this axis accounts in part for the adduction and slight plantar flexion of the forefoot which occur in inversion. The movement of the calcaneus around the talus is, however, accompanied by movement at the *transverse tarsal articulation* which comprises the talonavicular and the calcaneocuboid



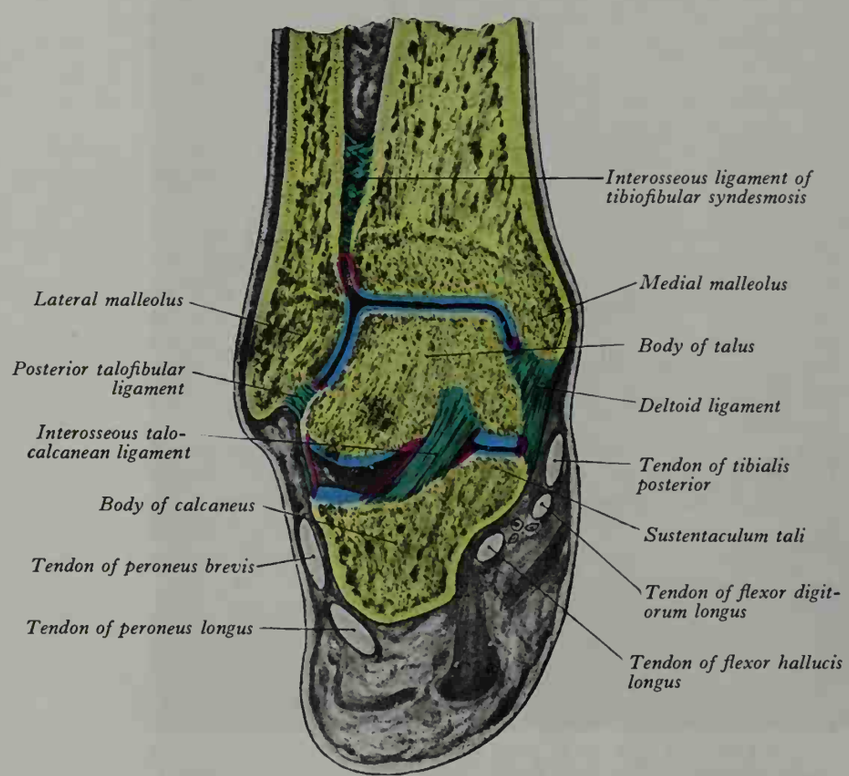
4.85 The same foot as in **4**.84 with heel raised from the ground, as near the end of the 'stance phase' in walking. Note forward angulation of leg bones, plantar flexion at the talocrural joint, and the position of the metatarsals and phalanges. (1) talocrural joint, (2) subtalar joint, (3) os trigonum, (4) sinus tarsi, (5) calcaneocuboid joint, (6) sesamoid in peroneus longus tendon, (7) cuboid, (8) tuberosity on base of fifth metatarsal, (9) cuneiforms, (10) navicular, (11) talonavicular joint, (12) head of talus.

articulations and the range of movement is thereby increased. These lie almost in the same transverse plane and during inversion the navicular rotates on the head of the talus whilst the cuboid glides downwards and rotates on the front of the calcaneus at the sellar (or saddle-shaped) calcaneocuboid joint. The range of the movement of inversion is also further increased in plantar flexion of the foot, for in this position the narrow part of the trochlear surface of the talus occupies the tibiofibular mortice and a slight amount of movement of the talus in the mortice gives an increased range of adduction with inversion. The opposite movement, which is much more limited in range, is termed *eversion*.

The chief factor in the limitation of inversion is the tension of the peronei and the strong lateral part of the interosseous talocalcanean ligament (*vide supra*). The other tarsal interosseous ligaments and the calcaneofibular ligament are less powerful factors. Eversion is arrested by the tension of the tibialis anterior and tibialis posterior and the deltoid ligament.

The complex movements of inversion and eversion as described above refer to changes in position and form of the whole foot (with only minor movements of the talus), *when the foot is off the ground*. When the foot is fully inverted it is also plantar flexed, and conversely, eversion is associated with dorsiflexion.

When the foot is on the ground, transmitting weight and thrust, these movements are modified to maintain plantigrade contact. The distal part of the tarsus and metatarsus are *pronated* or *supinated*, relative to the calcaneus and talus, the former



4.86 The ligaments of the left talocrural and tarsal joints. Lateral aspect. (Drawn from a specimen in the Museum of the Royal College of Surgeons of England, by kind permission of the Council.)

movement involving (by analogy with the hand) a downward rotation of the medial border and hallux towards the ground, supination being the reverse of this, to bring the lateral border into more direct plantigrade contact. Unfortunately, the terms inversion and eversion are sometimes equated with or confused with pronation and supination, whereas the latter are really components of the former, just as are the slight movements of adduction and abduction which may accompany inversion and eversion. Moreover, supination and pronation can be dissociated from inversion and eversion in adaptation of the forefoot to surfaces in plantigrade standing or progression (pp. 501–503, 617–619).

The terminology of movements of the foot is a matter of some confusion amongst orthopaedists, theoreticians and others. The above account represents widely accepted usage. (Consult also MacConaill 1950; Kapandji 1977; MacConaill and Basmajian 1977; Keller 1977). According to Kapandji (1965, 1977) inversion is a combination of adduction and supination whereas eversion involves simultaneous abduction and pronation.

Muscles producing the movements.

Eversion. Peroneus longus and brevis.

4.87 A coronal section through the left talocrural and talocalcanean joints.

THE CALCANEOCUBOID JOINT

The articular surfaces of the calcaneocuboid joint, which lies 2 cm behind the tubercle on the base of the fifth metatarsal bone, are saddle-shaped. The ligaments of the joint are: the fibrous capsule, the calcaneocuboid portion of the bifurcated ligament, the long plantar and the plantar calcaneocuboid ligaments.

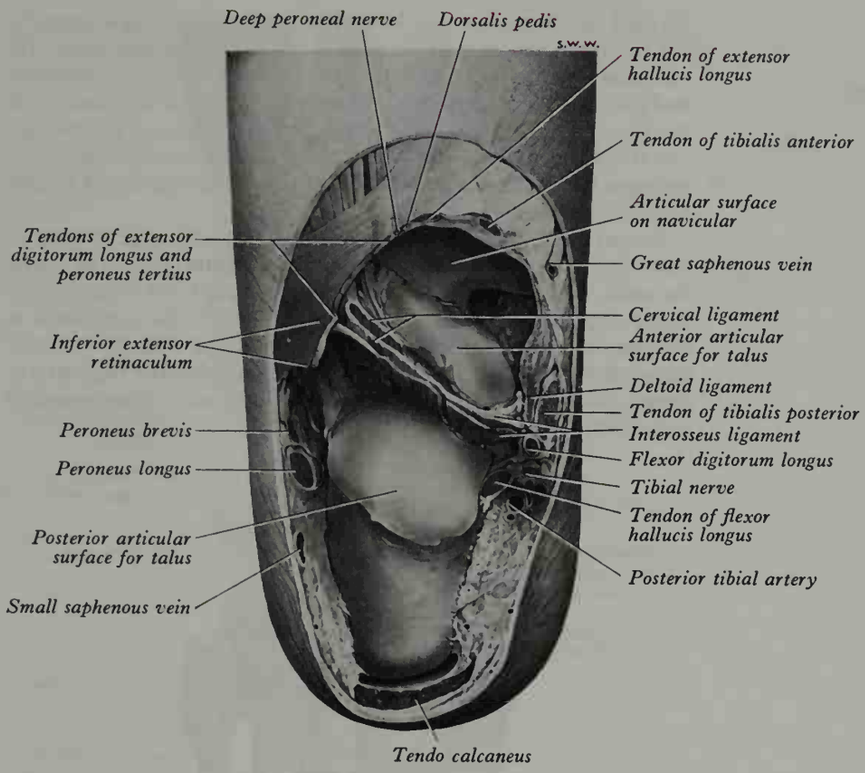
The fibrous capsule is slightly thickened over the dorsal surface of the joint, as the *dorsal calcaneocuboid ligament*. The synovial membrane is distinct from that of the other tarsal articulations (**4**.91).

The bifurcated ligament (**4**.86) is a strong band attached behind to the anterior part of the upper surface of the calcaneus and dividing in front into calcaneocuboid and calcaneonavicular parts. The *calcaneocuboid ligament* is fixed to the dorsal part of the medial side of the cuboid bone and forms one of the principal bonds between the first and second rows of the tarsal bones. The *calcaneonavicular ligament* is attached to the dorsolateral aspect of the navicular bone.

The long plantar ligament (**4**.89), the longest of the tarsal ligaments, is attached posteriorly to the plantar surface of the calcaneus in front of the medial and lateral processes of the tuberosity, and to the anterior tubercle, and anteriorly to the ridge and tuberosity on the plantar surface of the cuboid bone, to which the deep fibres are attached, the more superficial fibres being continued forwards to the bases of the second, third, fourth and, sometimes, the fifth metatarsal bones. This ligament converts the groove on the plantar surface of the cuboid bone into a tunnel for the tendon of the peroneus longus. It possesses great strength and is an important factor in limiting flattening of the lateral longitudinal arch of the foot (p. 501).

The plantar calcaneocuboid ligament (*short plantar ligament*) lies nearer to the bones than the preceding ligament, from which it is separated by a little areolar tissue. It is a short but wide band of great strength, and stretches from the anterior tubercle of the calcaneus and the depression in front of it, to the adjoining part of the plantar surface of the cuboid bone. Like the

preceding ligament, it limits flattening of the lateral longitudinal arch of the foot.



Movements. The movements permitted between the calcaneus and the cuboid bone are limited to gliding with conjunct rotation of the bones upon each other during the complex movements of inversion and eversion of the free foot and during the pronative or supinative changes of relationship of the forefoot to the hindfoot (pp. 501–503).

THE LIGAMENTS CONNECTING THE CALCANEUS AND NAVICULAR BONE

Though the calcaneus and the navicular bone do not articulate directly, they are connected by two ligaments, the calcaneonavicular and the plantar calcaneonavicular.

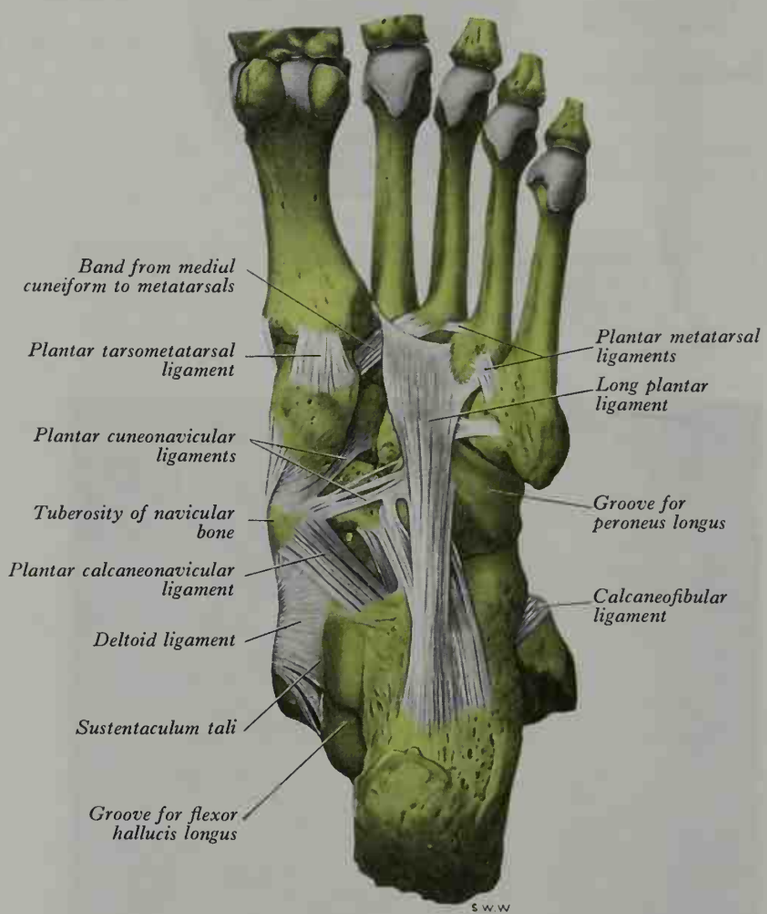
The calcaneonavicular ligament has been described above; it forms the medial band of the bifurcated ligament.

The plantar calcaneonavicular (spring) ligament (**4**.82, 88, 90) is a broad, thick band connecting the anterior margin of the sustentaculum tali of the calcaneaus to the plantar surface of the navicular bone. This ligament ties the calcaneus to the navicular bone, and lies below the head of the talus, forming part of the articular cavity for its head; it limits flattening of the medial longitudinal arch of the foot (p. 501). The *dorsal surface* of the ligament presents a triangular fibrocartilaginous facet upon which a portion of the head of the talus rests (**4**.88). Its *plantar surface* is supported by the tendon of the tibialis posterior medially, and by the tendons of the flexor hallucis longus and the flexor digitorum longus, laterally; its *medial border* is blended with the anterior fibres of the superficial part of the deltoid ligament of the talocrural joint. (Despite its vernacular name there is no real evidence that the 'spring' ligament is peculiarly resilient.)

4.88A The left talocalcanean and talocalcaneonavicular joints. Exposed from above by removal of the talus.

THE CUNEONAVICULAR JOINT

The navicular articulates in front with the three cuneiform bones. The joint is often described as of the plane variety, but in fact the distal surface of the navicular is convex from side to side and



4.88B and C A dissection in which the talus has been removed from the subjacent osseous and ligamentous tarsal elements. Compare the reciprocal articular curvatures of the inferior surface of the talus (B) and those of the superior aspects of their conarticular tarsal elements (C). Note the ovoid surfaces of the (posterior) talocalcaneal articulation (the *subtalar* joint of some authorities). Anteriorly, the complex convexity of the talar head is received into the '*acetabulum pedis*', which is formed by the calcaneus, navicular, the plantar calcaneonavicular ligament, and part of the deltoid ligament. The detailed ligamentous architecture between these articulations is described in the text, and illustrated diagramatically (A).

(Preparation by Dr. M. C. E. Hutchinson and photography by Mr. Kevin Fitzpatrick, Guy's Hospital Medical School, London.)

divided into three facets by low ridges, each of which is adapted to the proximal, slightly curved surface of a cuneiform bone. Its articular capsule is continuous with those of the intercuneiform and the cuneocuboid joints. Its *synovial cavity* is continuous with the synovial cavities of these joints and with those of the second and third cuneometatarsal joints and of the intermetatarsal joints between the bases of the second and third, and third and fourth metatarsal bones (p. 499).

Dorsal and plantar ligaments connect the navicular to each of the cuneiform bones. **The dorsal ligaments** are three small fasciculi, one attached to each of the cuneiform bones. The fasciculus connecting the navicular with the medial cuneiform is continuous round the medial side of the joint with the plantar ligament which unites these two bones. **The plantar ligaments** have a similar arrangement to the dorsal, and are strengthened by slips from the tendon of the tibialis posterior.

4.89 The ligaments of the plantar surface of the left foot. Some of the fibres of the long plantar ligament which arise in front of the medial tubercle of the calcaneus have been removed. (Drawn from a specimen in the Museum of the Royal College of Surgeons of England, by kind permission of the Council.)

THE CUBOIDEONAVICULAR JOINT

The cuboideonavicular joint is usually a fibrous joint, the two bones being connected by dorsal, plantar and interosseous ligaments. **The dorsal ligament** extends obliquely forwards and laterally, while the **plantar** passes nearly transversely from the cuboid to the navicular bone. **The interosseous ligament** consists of strong transverse fibres, and connects the rough nonarticular parts of the adjacent surfaces of the two bones (4.91).

Not infrequently the syndesmosis is replaced by a synovial joint. In that event the joint is of an almost plane variety and its articular capsule and synovial cavity are continuous with those of the cuneonavicular joint.

THE INTERCUNEIFORM AND CUNEOCUBOID JOINTS

The intercuneiform joints and the joint between the lateral cuneiform bone and the cuboid are all synovial in character and approximately plane or with only minor degrees of curvature. Their articular capsules and synovial cavities are continuous with those of the cuneonavicular joint.

The bones are connected together by dorsal, plantar and interosseous ligaments.

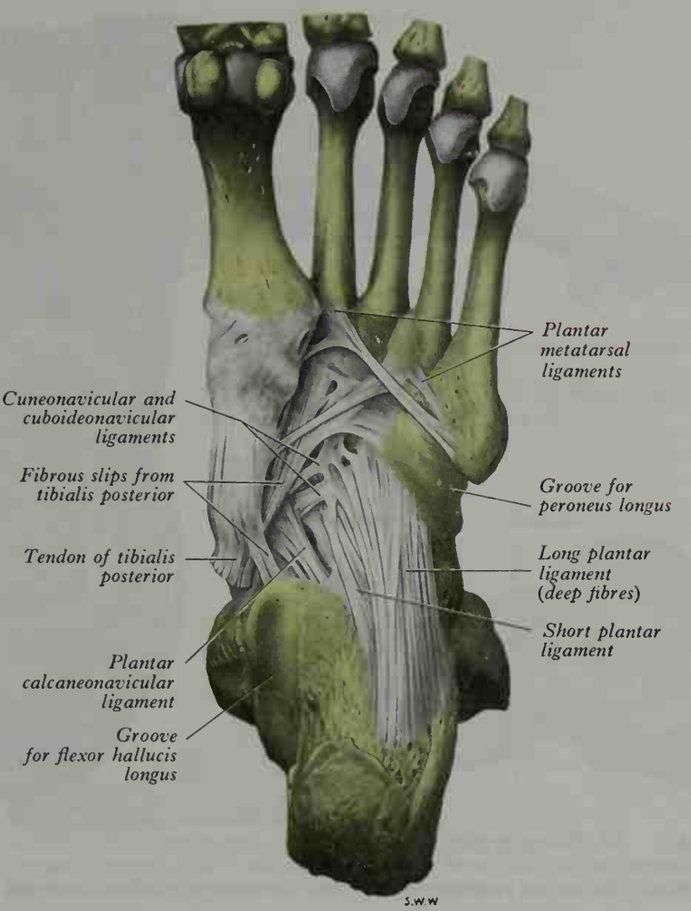
The dorsal and plantar ligaments each consist of three transverse bands: one connects the medial and intermediate cuneiform bones, another the intermediate and lateral cuneiform bones, and another the lateral cuneiform and cuboid bones. The plantar ligaments are strengthened by slips from the tendon of the tibialis posterior. **The interosseous ligaments** connect the rough nonarticular portions of the adjacent surfaces of the bones and possess considerable strength; they are a factor in the transverse arch of the foot (p. 502).

Movements. The movements permitted at the cuneonavicular, cuboideonavicular, intercuneiform and cuneocuboid joints are limited to a slight amount of gliding and rotation of the bones concerned on each other. These movements occur during pronation or supination of the foot (p. 499), i.e. during positional alterations of the loaded foot when in contact with the ground. For example, they greatly increase the suppleness of the foot when its forepart is stressed, as in the initial thrust of running and jumping.

The Tarsometatarsal Articulations

These are synovial joints of approximately plane variety. The first metatarsal articulates with the medial cuneiform; the second is recessed between the medial and lateral cuneiforms, articulating between them with the intermediate cuneiform; the third articulates with the lateral cuneiform; the fourth joints with the lateral cuneiform and cuboid, and the fifth, with the cuboid alone. These joints lie on a line joining the tubercle of the fifth metatarsal bone to the tarsometatarsal joint of the great toe, with the exception of the joint between the second metatarsal and the intermediate cuneiform bone, which lies 2 mm to 3 mm proximal to the line of the others (4.91). The first joint possesses an independent articular capsule and synovial cavity. The articular capsules and synovial cavities of the second and third joints are continuous with those of the intercuneiform and cuneonavicular joints, but are shut off from those of the fourth and fifth joints by an interosseous ligament which passes between the lateral cuneiform and the base of the fourth metatarsal bone. The bones are connected by dorsal and plantar tarsometatarsal and interosseous cuneometatarsal ligaments.

The dorsal ligaments are strong, flat bands. The first metatarsal is joined to the medial cuneiform bone by an articular capsule; the articular capsules of the remaining tarsometatarsal joints are largely blended with their dorsal and plantar ligaments. the second metatarsal receives three bands, one from each cuneiform; the third, one from the lateral cuneiform; the fourth one from the lateral cuneiform, and another from the cuboid and The fifth, one from the cuboid bone.



The plantar ligaments consist of longitudinal and oblique bands, disposed with less regularity than the dorsal ligaments. Those for the first and second metatarsal bones are the strongest; the second and third metatarsal bones are joined by oblique bands to the medial cuneiform; the fourth and fifth metatarsal bones are connected by a few fibres to the cuboid.

The interosseous cuneometatarsal ligaments are three in number. The first is the strongest; it passes from the lateral surface of the medial cuneiform to the adjacent angle of the second metatarsal bone and is constant (4.91). The second connects the lateral cuneiform with the adjacent angle of the second metatarsal bone; it does not completely divide the joint between the second metatarsal and the lateral cuneiform and is inconstant. The third connects the lateral angle of the lateral cuneiform with the adjacent side of the base of the fourth metatarsal bone.

Movements. The movements permitted between the tarsal and metatarsal bones are limited to gliding of the bones upon each other. This movement is very limited in range except in the case of the joint between the medial cuneiform and the first metatarsal bone, where an appreciable amount both of flexion and extension and rotation of the metatarsal bone can be obtained passively when the muscles concerned are relaxed. These movements are carried out actively in standing and walking and form part of the mechanism by which the foot is kept in adequate ground contact. Because of the mortice-like recession of the proximal end of the second metatarsal between the medial and lateral cuneiform bones, it is the least mobile of the metatarsals. The shape of the proximal articular surfaces of the latter is such that they become more closely pressed together in plantar flexion (the close-packed position of the tarsometatarsal joints), and they splay out in dorsiflexion.

It is the movements of **pronation** and **supination** which make it possible to keep the feet in plantigrade apposition to flat surfaces in a wide range of positions, from straddling to actual crossing of the feet. This is usually ascribed to inversion or eversion, but these affect the whole foot below the talus, and even the talus if the slight additional movements of adduction and abduction possible at the plantar-flexed ankle joint are added.

When the feet are planted far apart, the whole foot inverts, but there is a change between the relative positions of the forefoot and the hindfoot, to maintain full plantigrade contact. This is necessary because the talus is tilted medially with the tibiofibular mortice, and is followed by the calcaneus as soon as the limited degree of movement between them is exhausted. Were the rest of the foot to follow the same medial tilting (inversion) weight would be largely taken from the lateral border and concentrated on the medial. To correct this, and bring about a more even distribution of weight in full plantigrade contact with the ground, the forefoot rotates in the opposite sense. That is, it *supinates* or *untwists*. Much of this movement occurs at the transverse tarsal joint, but other tarsal and tarsometatarsal joints also contribute and in particular the joint between the medial cuneiform and first metatarsal. Conversely, when the feet are close together or even crossed, full ground contact can only be maintained if the forefoot is maximally *twisted* or *pronated* relative to the calcaneus and talus. (See also pp. 501–503.)

4.90 The ligaments on the plantar surface of the left foot. The long plantar ligament has been removed. (Drawn from a specimen in the Museum of the Royal College of Surgeons of England, by kind permission of the Council.)

THE INTERMETATARSAL JOINTS

The *base* of the first metatarsal bone is not connected with that of the second by any ligaments; in this respect the great toe resembles the thumb. (It differs, of course, in being so connected at its distal end.) A small bursa often occurs between the lateral side of the base of the first metatarsal bone and the medial side of the shaft of the second (**4**.91).

The bases of the second, third, fourth and fifth metatarsal bones are connected by dorsal, plantar and interosseous ligaments.

The heads of all the metatarsal bones are connected indirectly by the deep transverse metatarsal ligaments (p. 500).

The dorsal and plantar ligaments pass transversely between the bases of the adjacent bones.

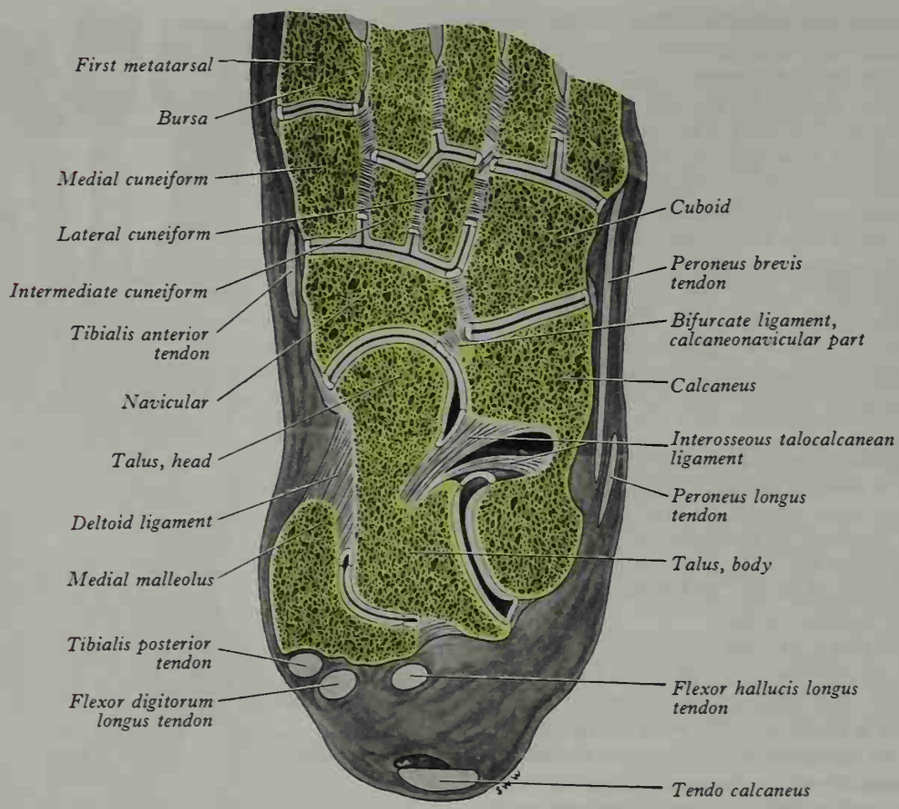
The interosseous ligaments consist of strong transverse fibres which connect the rough nonarticular portions of the adjacent surfaces (**4**.91).

Movements. The movements between the tarsal ends of the metatarsal bones are limited to a slight gliding of the articular surfaces one upon another when the anterior part of the foot is working under load (cf. movements of the intercuneiform joints, etc., p. 498).

THE SYNOVIAL ARRANGEMENT OF THE TARSUS AND METATARSUS

The synovial cavities (**4**.91) in the tarsus and metatarsus are six in number, one for the subtalar, a second for the talocalcaneonavicular, a third for the calcaneocuboid, a fourth for the cuneonavicular, intercuneiform, and cuneocuboid articulations, the articulations of the intermediate and lateral cuneiform bones with the bases of the second and third metatarsal bone, and the adjacent surfaces of the bases of the second, third and fourth metatarsal bones; there is a fifth for the medial cuneiform with the metatarsal bone of the great toe, and a sixth for the articulation of the cuboid with the fourth and fifth metatarsal bones. A small synovial cavity is sometimes found between the contiguous surfaces of the navicular and cuboid bones; it usually communicates with that between the cuboid and lateral cuneiform bones.

The Metatarsophalangeal Articulations



The metatarsophalangeal joints are ovoid or ellipsoid; they are formed by the reception of the rounded heads of the metatarsal bones in shallow cavities on the bases of the proximal phalanges. These are all ovoid surfaces. They lie 2·5 cm proximal to the webs of the toes.

The *articular surfaces* cover the distal and plantar surfaces of the heads of the metatarsal bones but do not extend on to their dorsal surfaces. The plantar part of the head of the first metatarsal presents two longitudinal grooves separated by an intervening ridge. Each groove articulates with a sesamoid bone embedded in the plantar part of the capsule of the joint, formed by the tendons of the intrinsic muscles of the hallux. The articular surface of the base of the proximal phalanx is concave in all diameters.

The ligaments of the joints are capsular, plantar, deep transverse metatarsal and collateral.

The fibrous capsules surround the joints and are attached to the margins of the articular surfaces. Dorsally, they are thin and may be separated from the tendons of the long extensors by small bursae: they are inseparable from the deep surfaces of the plantar and collateral ligaments.

The plantar ligaments are thick, dense, fibrous structures.

4.91 An oblique section through the right foot, showing the synovial cavities of the intertarsal and tarsometatarsal joints. Superior aspect. *Note.* The section passed below the joint between the medial cuneiform and the base of the second metatarsal bone; no synovial joint was present between the navicular and cuboid bones.

They are placed on the plantar surfaces of the joints in the intervals between the collateral ligaments, to which they are connected; they are loosely united to the metatarsal bones, but are firmly fixed to the bases of the proximal phalanges. Their margins are continuous with the deep transverse metatarsal ligaments, and their plantar surfaces are grooved for the flexor tendons, the fibrous sheaths of which are connected to the sides of the grooves; the deep surfaces of the ligaments form parts of the articular facets for the heads of the metatarsal bones.

The deep transverse metatarsal ligaments consist of four short, wide, flattened bands which connect the plantar ligaments of adjoining metatarsophalangeal joints to one another. Their dorsal surfaces are related to the interossei and their plantar aspects to the lumbricals and the digital vessels and nerves. They closely resemble the deep transverse metacarpal ligaments (p. 472), but, in contrast, they are connected to the plantar ligament of the first metatarsophalangeal joint.

The collateral ligaments are two strong, rounded cords, on each side of each joints; each is attached by one end to the dorsal tubercle on the side of the head of the metatarsal bone, and runs obliquely forwards and downwards to reach the corresponding side of the base of the phalanx.

Movements. The active movements possible at the metatarsophalangeal joints are very similar to those permitted at the corresponding joints in the hand but differ in their range. In marked contrast to the condition in the hand, the range of active extension (50–60°) is greater than the range of flexion (30–40°), and this is associated with the requirements of walking. This is especially the case in the metatarsophalangeal joint of the great toe, where flexion is limited to a few degrees but extension may be possible up to 90°. In this connexion it should be remembered that when the foot is on the ground the metatarsophalangeal joints are already extended to rather more than 25° owing to the participation of the metatarsal bones in the longitudinal arches of the foot (4.92A, B). The *passive* range of extension–flexion of these joints is increased to 90° (extension) and 45° (flexion), according to Kapandji (1974). Adduction is associated with flexion and abduction with extension, except that abduction of the little toe is always associated with a slight degree of flexion. As in the hand, the *accessory movements* comprise gliding movements and rotation of the phalanges around their long axes.

Muscles producing the movements.

Flexion. Flexor digitorum brevis, lumbricals and interossei, assisted by flexor digitorum longus and accessorius. In the little toe the flexor digiti minimi brevis assists and in the great toe the flexores hallucis longus et brevis are the only muscles concerned.

Extension. Extensores digitorum longus et brevis and extensor hallucis longus.

Adduction. Of the great toe, adductor hallucis; of the third, fourth and fifth toes, the first, second and third plantar interossei respectively.

Abduction. Of the great toe, abductor hallucis; of the second toe, to the medial and lateral sides, the first and second dorsal interossei respectively; of the third and fourth toes, the corresponding dorsal interossei; of the little toe, abductor digiti minimi.

Note. The line of reference in adduction and abduction passes through the *second toe*, whose metatarsal is the least mobile.

THE INTERPHALANGEAL ARTICULATIONS

The interphalangeal joints are hinge joints in which the trochlear surface on the head of a phalanx articulates with a reciprocally curved surface on the base of the neighbouring phalanx. Each has an articular capsule and two collateral ligaments. The arrangement of these ligaments is similar to that in the metatarsophalangeal joints (p. 499). The plantar surface of the articular capsule is strengthened to form a fibrous plate, similar to the plantar metatarsophalangeal ligament. This is often termed the *plantar ligament*.

Movements. The only active movements possible in the joints of the digits are flexion and extension; these movements are of greater amplitude between the proximal and middle phalanges than between the middle and distal. The amount of flexion is very considerable, but extension is limited by the tension of the flexor muscles and by the plantar ligaments.

The *accessory movements* comprise abduction, adduction and rotation.

Muscles producing the movements.

Flexion. Flexores digitorum longus, brevis et accessorius, flexor hallucis longus.

Extension. Extensor hallucis longus, extensores digitorum, longus et brevis.

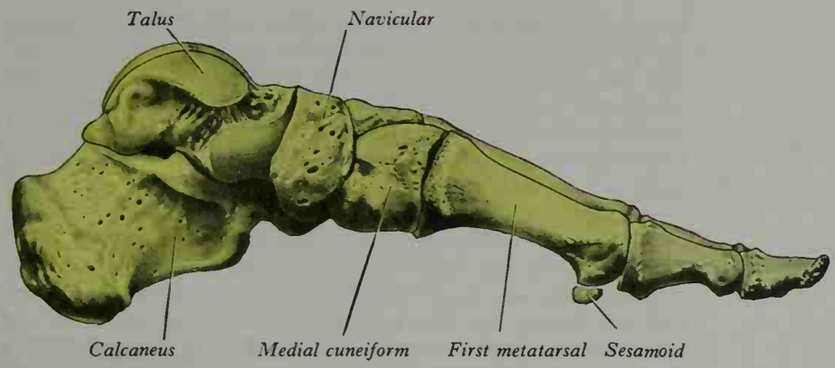
Movements of the Foot

Movements of the foot take place both when it is off the ground and free to move on the leg, and when it is on the ground and bearing weight or taking thrust. In the latter case the movements are more limited in range and are, to some extent, imposed on the foot by body weight acting through the femur, tibia and talus; but they are also the resultant of muscular contraction. (See also pp. 617–619.)

Active movements occur at the talocrural, talocalcaneonavicular and subtalar joints. At the talocrural joint the movements are almost restricted to dorsi- and plantar-flexion, though a small degree of rotation may occur in plantar-flexion (abduction and adduction). At the talocalcaneonavicular and subtalar joints the range of movement is greater, and it is here that the inversion and eversion largely occur.

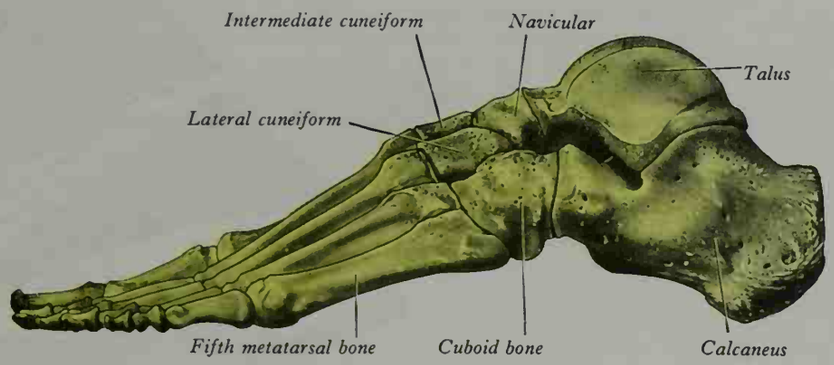
When the foot is on the ground in the resting position, the body weight brings about some degree of supination with flattening of the longitudinal arches. About one-third of the weight borne by the fore part of the foot is carried through the head of the first metatarsal. When this position of rest, as in standing, is changed to the active position on commencing to walk, the foot becomes pronated by muscular effort; the head of the first metatarsal (and to a lesser extent the second) is depressed and the longitudinal arch is accentuated to its maximum height (Hicks 1953).

Similar movements can be imposed on the weight-bearing foot by active rotation of the femur, lateral rotation of which is transmitted through the tibia to the talus. This entails passive inversion of the foot at the subtalar joints. Medial rotation of the femur has the opposite effect.



It is important to note at this point that, when the foot is relatively immobilized in contact with the ground, muscles which move it when freely suspended may exert their effects upon the leg itself. For example, the dorsiflexors of the foot can pull the leg forwards at the ankle joint when the foot is prevented from moving by contact with the ground.

The foot has two equally important functions to carry out—to support the weight of the body in standing or progression, and to act as a lever to propel the body forwards in walking, running or jumping.

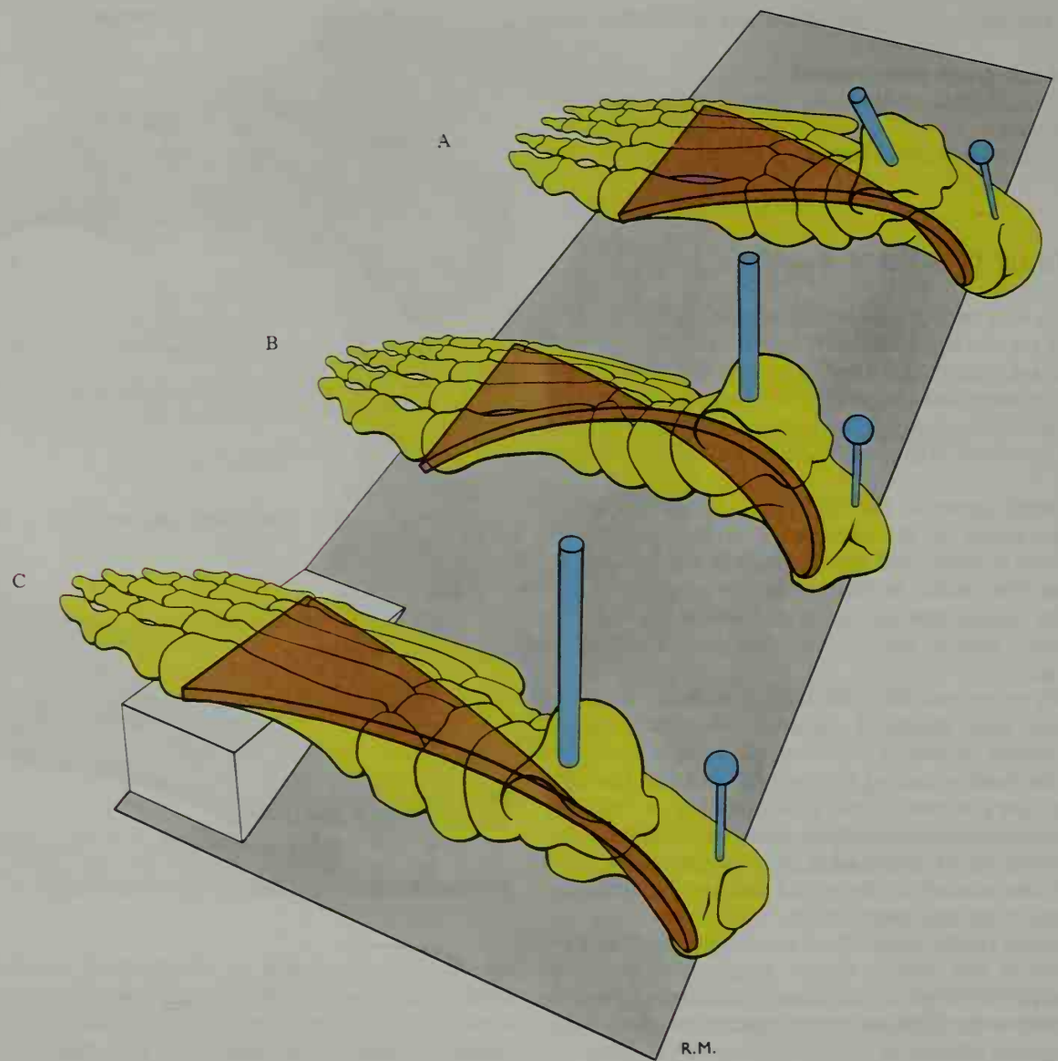


To fulfil the first function the foot must be an adequate platform on which to spread the stresses of standing and moving; it must also be pliable enough to do so on uneven and sloping surfaces. To fulfil the second function the foot must be capable of transformation into a strong and adjustable lever which will not collapse under body weight or powerful muscular thrust. A segmented lever such as the foot can best meet such stresses if it is built upon an arched form.

In the child, due to the fatty connective tissue in the sole, the foot may appear flattened; and soft tissues also modify external appearances to a variable extent at all ages. Nevertheless, the human foot, unlike that of other primates, normally presents an arched or curved form in its skeletal basis, and this is usually associated with a visible concavity in the sole.

It is worthy of note at this point that the word 'arch', as applied to the human foot, has perhaps been customarily interpreted in too architectural a sense, and this has led to some rigidity in classical descriptions of the curved form of the foot, and to differences of opinion based sometimes more upon linguistics than fact. In common usage the word has several meanings, and doubtless the expression, 'arches of the foot', has different implications. As a starting point, it is perhaps wisest to accept the simplest meaning, which in this case implies little more than a curved form, concave on the plantar aspect. Such an arch need not be confused with a piece of static masonry, with two extremities

4.92A The skeleton of the left foot. Medial aspect. Note the height of the medial part of the longitudinal arch and compare with 4.92B.



4.92B The skeleton of the left foot. Lateral aspect.

set on terra firma and an intermediate structure of keystone pattern. The pedal arch is a dynamic arrangement, from which muscles and ligaments are functionally inseparable; it is, moreover, much of the time off the ground at its calcanean end. In the account which follows, therefore, the term 'arch' is used to denote no more than a curved form, just as the back is merely curved when it is 'arched'.

The curved or bowed form of the foot is customarily analysed into subsidiary components—longitudinal and transverse arches—and this has some value as an initial analysis. These arches, especially the longitudinal and particularly its medial part, vary in height in different individuals; even more importantly, being dynamic, they vary thus in the same individual in different phases of activity. The arched form is often said to be largely dependent on bony configurations and the effects of ligamentous ties, the muscles associated with the arches playing a secondary role (Jones 1941; Hicks 1955). On the other hand, clinical experience points to muscular insufficiency as the commonest cause of flat foot, in which ligaments elongate and bones ultimately alter their configuration. It is therefore unwise, perhaps, to pick one or other factor for particular emphasis, especially since all work together in the functioning of the living foot. Nevertheless, loading experiments on the knee, both in amputated legs and by electromyography in the living, strongly suggest that in *standing* ligaments play the major role. Immediately movement upon the foot occurs, however, the muscular factor comes into play.

The longitudinal curvature of the foot is usually accounted as consisting of medial and lateral arches or components, and this is to some degree justified by the arrangement of bones in the foot and by functional differences in its medial and lateral parts.

The medial arch comprises the calcaneus, talus, navicular, the cuneiforms and the medial three metatarsal bones. Its summit is the superior articular surface of the talus, taking the full thrust of the tibia; from this, stresses are passed backwards to the calcaneus, and forwards through the navicular, cuneiforms, to the medial three metatarsals. When the foot is on the ground, forces are transmitted to the ground through the heads of the three metatarsals and the plantar aspect of the calcaneus (more

4.93 The concept of the pedal skeleton as a twisted plate which may be untwisted (supination) or further twisted (pronation) during the maintenance of a plantigrade stance in various positions of the foot. (Based upon MacConaill 1945, 1950.) A The pedal skeleton in supination, as in standing with the feet widely separated. Note the marked medial tilting of the talus and, to a lesser degree, of the calcaneus, and the depression of the medial longitudinal arch. B Relative pronation of the foot, as in standing with the feet close together. C Supination of the foot when standing on an inclined surface; if the position of the wedge had been reversed, the pedal skeleton would, of course, approach maximal pronation.

especially its tuberosity). This arch is considerably higher, more mobile and resilient than the lateral. Flattening of the medial arch progressively tightens up the plantar ligaments of all the joints involved, including the plantar calcaneonavicular (p. 497), and the plantar fascia. The tibialis posterior, flexor digitorum longus, flexor hallucis longus and intrinsic mucles in the foot all aid in controlling the medial arch, with the advantage of being almost infinitely adjustable, unlike the ligaments. Nevertheless, they are often considered to play a secondary part, and it is claimed that they are not usually active in standing, but come into marked activity in any movement which involves elevation of the arch. This view, as regards static posture, does not accord with clinical views on the aetiology of flat foot.

The lateral arch is composed of the calcaneus, cuboid and lateral two metatarsal bones. Its summit is considered to be the subtalar articulation, and it is hence skeletally much lower than the medial arch. Its chief joint is the calcaneocuboid part of the 'transverse tarsal joint' (p. 495), with a markedly limited range of movement. The lateral arch is characteristically low, of limited mobility, and built to transmit weight and thrust to the ground, rather than to provide a mechanism for the absorption of such forces. As it flattens under stress, the long plantar and plantar calcaneocuboid ligaments are tightened; muscles of particular significance in the activities of the arch are the peroneus longus and the short muscles of the fifth toe. The lateral arch makes more extensive contact with the ground than the medial, under the stress of weight and thrust. With the foot flat on the ground its anterior and posterior extremities (heads of lateral two metatarsals and calcanean tuberosity) of course transmit these forces; but as the arch flattens, an increasing fraction of the load is transmitted through the soft tissues inferior to the whole of the arch. In fact, in the living part, the whole of the lateral border usually contacts the ground, whereas the medial border does not, exhibiting a concavity in most subjects, even when standing. This accounts for the usual outline of the human footprint, though this varies according to the positioning of the feet, whether apart or together (**4**.93) and according to the development of soft tissues within the arch. As soon as the heel is raised, preparatory to walking or standing on tip-toe, the toes become extended and the muscular structures (including the plantar aponeurosis) tighten up in the sole with a consequent accentuation of the longitudinal arches. It is deduced that in this phase of activity tension diminishes in the deeper plantar ligaments (Hicks 1955).

Since the sole is to some extent transversely concave, both in skeletal configuration and in external form, it is usual to describe a series of transverse arches, most developed inferior to the metatarsus and adjoining distal part of the tarsus. Apart from the region of the metatarsal heads, and to some degree along the lateral border of the foot, the transverse arch mechanism is not capable of transmitting forces to the ground though the subjacent soft tissues of the sole; on the medial side only the heads of the metatarsals can do so. For this reason the foot has been likened to a half-dome, with a concavity directed downwards and medially, which becomes a complete dome when the feet are placed together. The peroneus longus has a particular function in maintaining the transverse curvature.

The foregoing, largely structural analysis, is chiefly useful as a prelude to considerations of the integrated activities of the living foot, direct observation of which coupled with the findings of electromyography, kinesiology and clinical data are all necessary to a complete comprehension of the dynamic events in the foot during natural use. Unfortunately, disagreements persist, with the usual indication of uncertainties. The following remarks are hence not to be taken as dogmatic.

In standing, with body weight only to support, there is a tendency to relax the intrinsic and extrinsic muscles of the foot, and to rely upon the tension in plantar ligaments to tie the bones into their arched form. This they can do only if the longitudinal arches are allowed to sink by muscular relaxation. If the feet are close together, the medial arch is more elevated than when they are set well apart. That is to say, a degree of inversion with supination becomes increasingly apparent as the feet are separated. This sag of the medial arches can, of course, be taken up by voluntary contraction of muscles such as the anterior tibial.

Pronation and supination of the foot ensure that, in standing, whatever the position of the feet, a maximal weight-bearing area, from the metatarsal heads along the lateral border to the calcaneus, is close to the ground. The twist imparted to the foot by pronation, and to some extent undone in supination, prompted MacConaill (1945, 1950) to liken the foot to a twisted plate (**4**.93), able to untwist in a resilient manner. This mechanism not only ensures adequate ground contact whatever the state of angulation between the foot and leg, but also imparts an adaptable resilience to the foot in standing and progression. It is likely, too, that such a form adds strength to the foot in leverage, perhaps by spiral tautening of ligaments.

In walking, the suspended foot, with arches accentuated by muscular action, is swung forward until the heel meets the ground. As it plantar-flexes, the lateral border, or arch, and then the metatarsal heads roll into contact with the ground, the foot being supinated to bring about maximum contact. As the foot is now raised, heel first, pronation (with elevation of the medial arch) occurs, and thrust is largely transferred to the ball of the hallux. At this point, the ankle (in dorsiflexion) and the metatarsus (well elevated) are admirably adapted to meet the stresses of maximum thrust. As in the repetitive activities at the hip and knee joints, there is a cycle of events from a position of near close-pack, coupled with maximal effort, through a return to the mobile range of the joints which is merely a preparation for a re-entry into the phase of thrust. For a wide and detailed analysis of foot movements consult Kapandji (1970).

5

MYOLOGY

Introduction

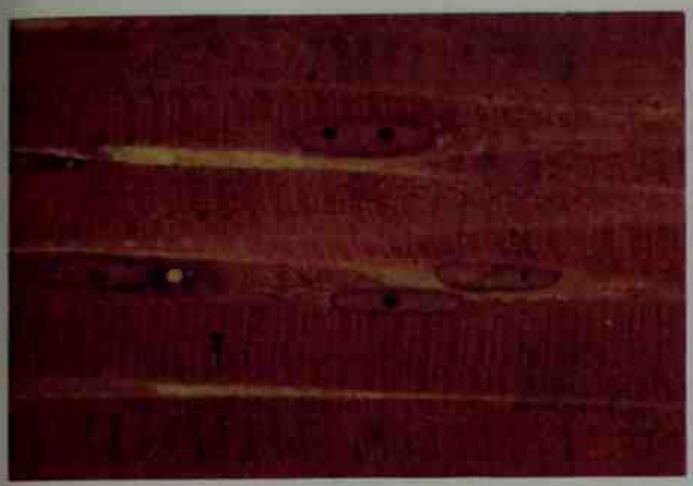
One of the characteristics of living organisms is their ability to react to changes in their environment by an appropriate response, which may be chemical, electrical, photic or mechanical. All such responses involve the utilization of metabolic energy by some sort of effector system. Several types of mechanical effector system exist. One, common to probably all nucleated cells, is that which produces cytoplasmic streaming, exemplified particularly well in unicellular organisms such as *Amoeba* and in the motile cells of vertebrates typified by macrophages and leucocytes. Intracellular streaming also forms an important transport mechanism which facilitates diffusion; the axoplasmic flow in neurons is a well-studied example of this.

Other examples of mechanical effectors include the cilia and flagella of motile cells and of the respiratory and genital tracts, the mitotic apparatus of all dividing cells, and the relatively unspecialized contractile systems of endothelial and myoepithelial cells. It is interesting that in all these examples the proteins *actin* and *myosin*, or proteins similar to them, have been demonstrated in the region of the mechanical responses (*see* p. 36). Muscles, also, contain high proportions of these proteins in their total mass, and can be viewed as cells which are specialized for the synthesis of the contractile apparatus, which is present in a rudimentary form in most cells; muscle cells also possess specially excitable plasma membranes capable of initiating cellular contractions. The organization of such cells into distinct groups, their association with surrounding tissues such as those of the skeleton, and their coordination by the nervous system, transform them into an effector system capable of a wide range of highly complex actions.

Muscle cells are mainly derived from mesenchymal cells at various sites throughout the body of the embryo, and may differentiate along one of three pathways to produce physiologically and anatomically distinct muscle types. Two of these categories are similar in that they possess a highly organized structure capable of relatively fast contractions, and constitute the types of **striated muscle**. The latter include firstly those muscles usually associated with the bony skeleton, composed of a tissue termed here **skeletal muscle**. It is also, less appropriately, sometimes known as voluntary muscle because it is, in some sites, under direct voluntary control. The second type is peculiar to the myocardium of the heart and is termed **cardiac muscle**. Both skeletal and cardiac muscle, when viewed microscopically, exhibit regularly spaced transverse bands and are therefore often loosely grouped as either **striated muscle**, or **striped muscle**. It should be added that the terminology chosen is not wholly satisfactory since not all 'skeletal' muscle is attached directly to the hard skeleton but may transmit forces to connective tissue sheets instead. It must also be pointed out that the terms 'striated' or 'striped' muscle are often used exclusively for skeletal muscle.

The third type of muscle has a relatively poorly organized contractile apparatus; it is able to make prolonged tonic contractions of considerable extent. This type is termed here **non-striated muscle**, but it is also known as smooth, plain or, alternatively, involuntary muscle, since it is rarely under direct volitional control. It is found in many regions of the body such as the walls of the alimentary tract, blood vessels, the urinary and genital tracts, and also as the arrector pili muscles of the skin, where slow but maintained responses are required. Its particular type of contraction makes it especially suitable for the regulation of the internal environment, and disturbances in its function often result in impaired homeostasis.

The various muscle types originate from distinct regions of the embryo (*see* p. 154). Skeletal muscles are largely derived from the myotomes of the paraxial mesodermal somites; others, however, appear to differentiate *in situ*, e.g. the extrinsic ocular muscles in condensations of premandibular and maxillo-mandibular mesenchyme near the developing optic cup (p. 154), the tongue muscles in pharyngeal floor mesenchyme (often considered a derivative of occipital myotomes—p. 197), the limb musculature in condensed limb-bud mesenchyme of somatopleuric origin (p. 153), and the various striated 'special visceral' muscles which develop in condensations of the unsplit lateral plate mesenchyme (of mixed origin) in the branchial arches and post-branchial region (p. 150). Cardiac muscle stems from splanchnopleuric mesenchyme of the primitive pericardium, whilst the non-striated muscle of the viscera also arises in splanchnopleuric cells elsewhere, or those derived from intermediate mesoderm. Vascular non-striated muscle may, however, develop at any point from unspecialized mesenchymal cells. The non-striated muscle of the iris is widely held to be derived from cells (of ectodermal origin) near the margin of the optic cup; similarly the various myoepitheliocytes (p. 39) are considered to have an ectodermal origin, whereas the non-striated ciliaris oculi and arrectores pili stem from local mesenchymal sources. In a number of situations fasciculi of non-striated muscle develop in close association with, or even intermingle with, skeletal or striated 'special visceral' muscle. Such sites include the anal and vesical sphincters, in relation to the tarsi of the upper and lower eyelids and the orbitalis muscle, the suspensory muscle of the duodenum (but *see* p. 1344), the intermediate zones of the oesophagus, and the many fasciculi which are admixed with the fasciae and ligaments on the pelvic aspect of the pelvic diaphragm (which some authors have called the *smooth muscle diaphragm*).

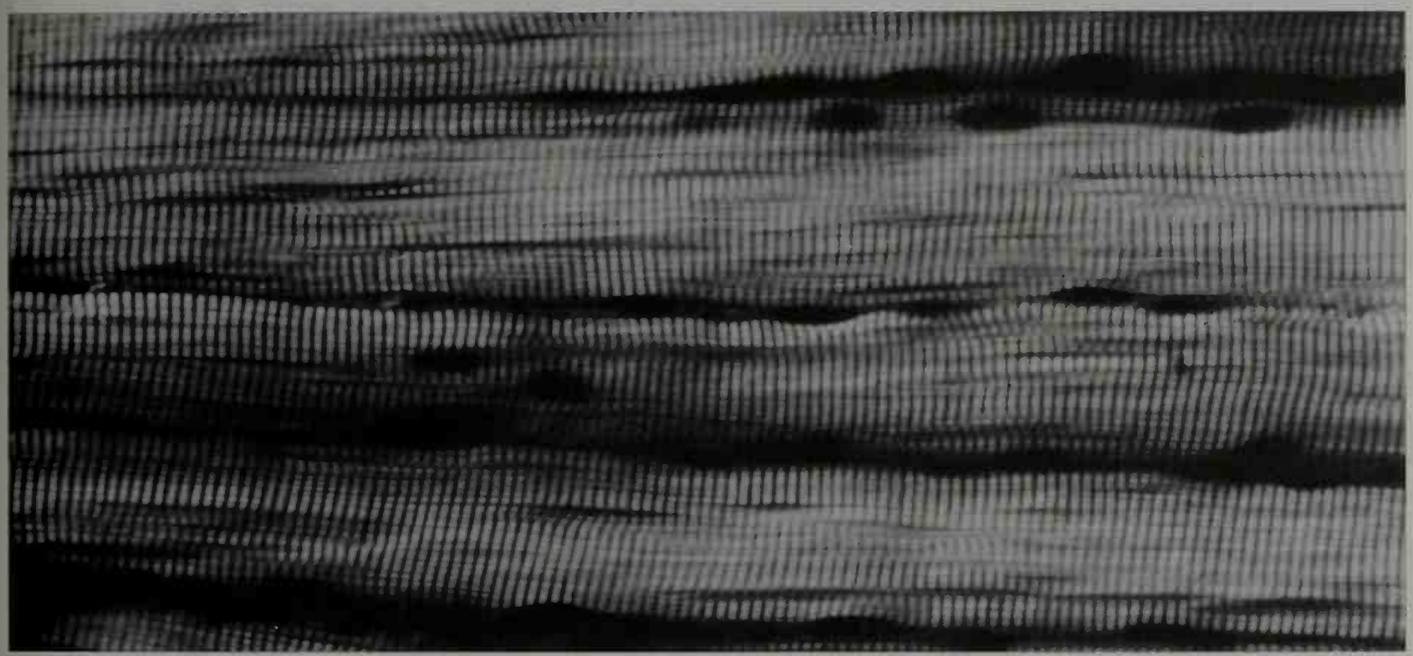


Skeletal Muscle

The units of skeletal muscle are the *muscle fibres*, each of which some regard as a 'single cell' provided with many hundreds of nuclei (i.e. each fibre is a *syncytial striated myocyte*). The fibres are arranged in bundles (*fasciculi* or *myonemes*) of various sizes and patterns within each muscle. Connective tissue fills the spaces between muscle fibres within a fasciculus, where it is known as the *endomysium*; each fasciculus is also surrounded by a stronger connective tissue sheath or *perimysium*; surrounding the whole muscle lies the more substantial *epimysium*, which is continuous on the one hand with the outer perimysial septa and externally with the connective tissues of surrounding structures.

With the light microscope skeletal muscle fibres appear as closely packed cylinders in teased preparations, as parallel ribbons in longitudinal section, and with either circular, elliptical, or polygonal profiles in cross-section, of 10–100μm in diameter in adult muscles (**5**.1, 2). Each fibre is elongated, and may stretch from one end of a muscle to the other, even achieving a length of over 30 cm in long muscles. Elsewhere they may traverse only part of the length of a muscle, ending in tendinous or other connective tissue intersections which penetrate the body of the muscle.

The flattened nuclei of muscle fibres lie peripherally in the zone immediately within the cell membrane or *sarcolemma*, whilst their cytoplasm, or *sarcoplasm*, is divided into longitudinal threads or *myofibrils* each about 1 μm in diameter (Gould 1973). In transverse sections prepared by older techniques myofibrils frequently appear aggregated in small groups, the *fields of Cohnheim*, but this is now widely regarded as artefactual and better methods of preservation show them to be evenly distributed.



In longitudinal section, or surface view, the myofibrils are seen to be traversed by striations apparently continuous right across the fibre (**5**.1), which vary in their staining reactions and optical properties. Some stain lightly with basic dyes such as haematoxylin, and only rotate the plane of polarization of light slightly, being termed therefore the *isotropic* or *I bands* (also sometimes called J bands). Others, alternating with the former, have the converse properties of staining deeply with haematoxylin and strongly rotating the plane of polarization of light (**5**.3) in a manner which indicates a highly ordered longitudinal structure—these are the *anisotropic* or *A bands* (also sometimes called Q bands). The I bands are bisected transversely by a thin line also stained by basic dyes, the *zwischenscheibe* or *Z band* (Krause's membrane). The A band is also bisected by a paler (Hensen's) line—the *H band*. This description applies to relaxed or minimally contracted muscle; with continued unopposed contraction the I and H bands narrow to extinction, but the A bands remain unaltered, and *contraction bands* appear on each side of the Z band.

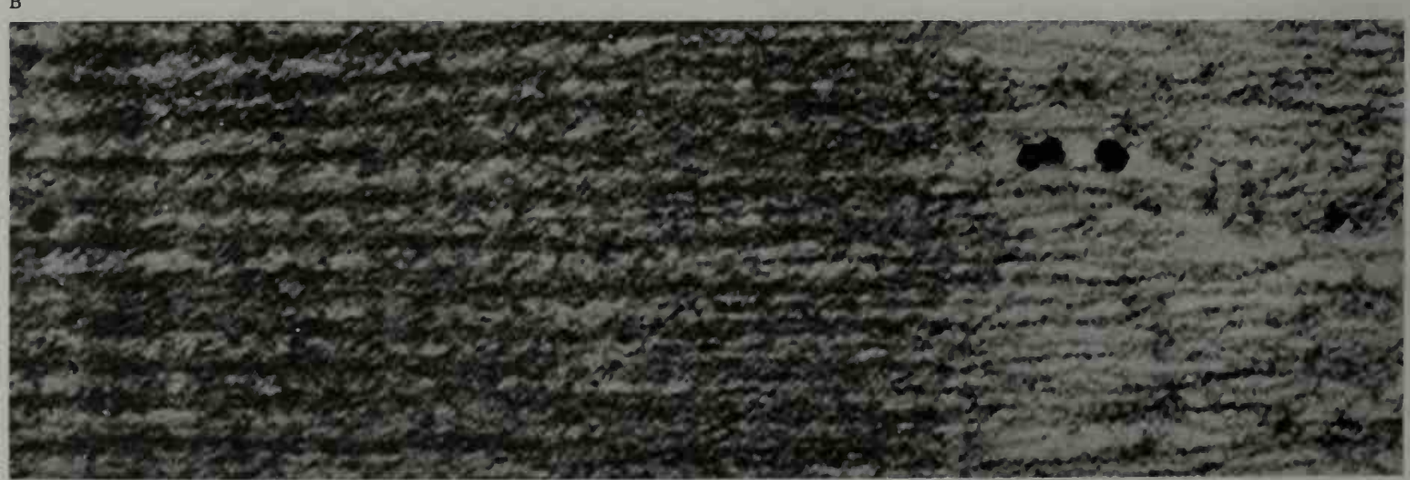
Note also the dark muscle cell nuclei, and longitudinal striations corresponding to the myofibrils. (Photography by Mr. Kevin Fitzpatrick, Department of Anatomy, Guy's Hospital Medical School, London.) Magnification × 500.

The significance of these various bands and their behaviour during contraction were discovered independently by two groups of workers (A. F. Huxley and Neidegerke 1954; H. E. Huxley and Hanson 1954); to appreciate these concepts the ultrastructural appearance of skeletal muscle must first be described.

The Ultrastructure of Skeletal Muscle



Electron microscopy shows each myofibril to be composed of longitudinally disposed fine *myofilaments* (**5**.4–8). These are divided transversely by the Z bands into serially repeating regions termed *sarcomeres*, each about 2·5 μm long in resting muscle. Two types of myofilament are distinguishable in each sarcomere, fine ones about 5 nm in diameter and thicker ones about 12 nm across; these have been characterized chemically as actin and myosin respectively. The actin filaments are each attached at one end to a Z band and are free at the other to interdigitate with the myosin filaments. The latter are co-extensive with the A band of light microscopy. The I bands represent those regions of the actin filaments which do not overlap with the myosin. The H bands are the middle region of the A bands into which the actin filaments have not penetrated. Another line, the M band, lies transversely across the middle of the H band and close examination shows this to consist of fine strands interconnecting adjacent myosin filaments (*see* Page 1965, and **5**.7). In contracted muscle the actin filaments have slid in relation to the myosin towards the centre of the sarcomere, so bringing the attached Z bands closer together, with shortening of the whole contractile unit. X-ray diffraction studies of unfixed muscle support this interpretation (Huxley and Brown 1969). The manner in which this sliding is brought about has been the subject of much study. The myosin filaments show lateral projections which extend towards the adjacent actin filaments (Huxley 1969, 1972), and the latter are arranged around the myosin filaments in a hexagonal pattern (**5**.5, 6, 7). It has been shown that, when relaxed, the lateral projections of the myosin lie close to their parent filament, whereas in contraction they project to contact the adjacent actin strands (**5**.8A and B). This and many other observations, indicate that muscle contraction may be caused by the successive making and breaking of cross-connexions between the thick myosin and thin actin filaments in a cyclical fashion, so pulling the thin ones between the thick ones towards the sarcomere centre. If contraction is continued to give a sarcomere length of less than 2 μm the actin filaments from each

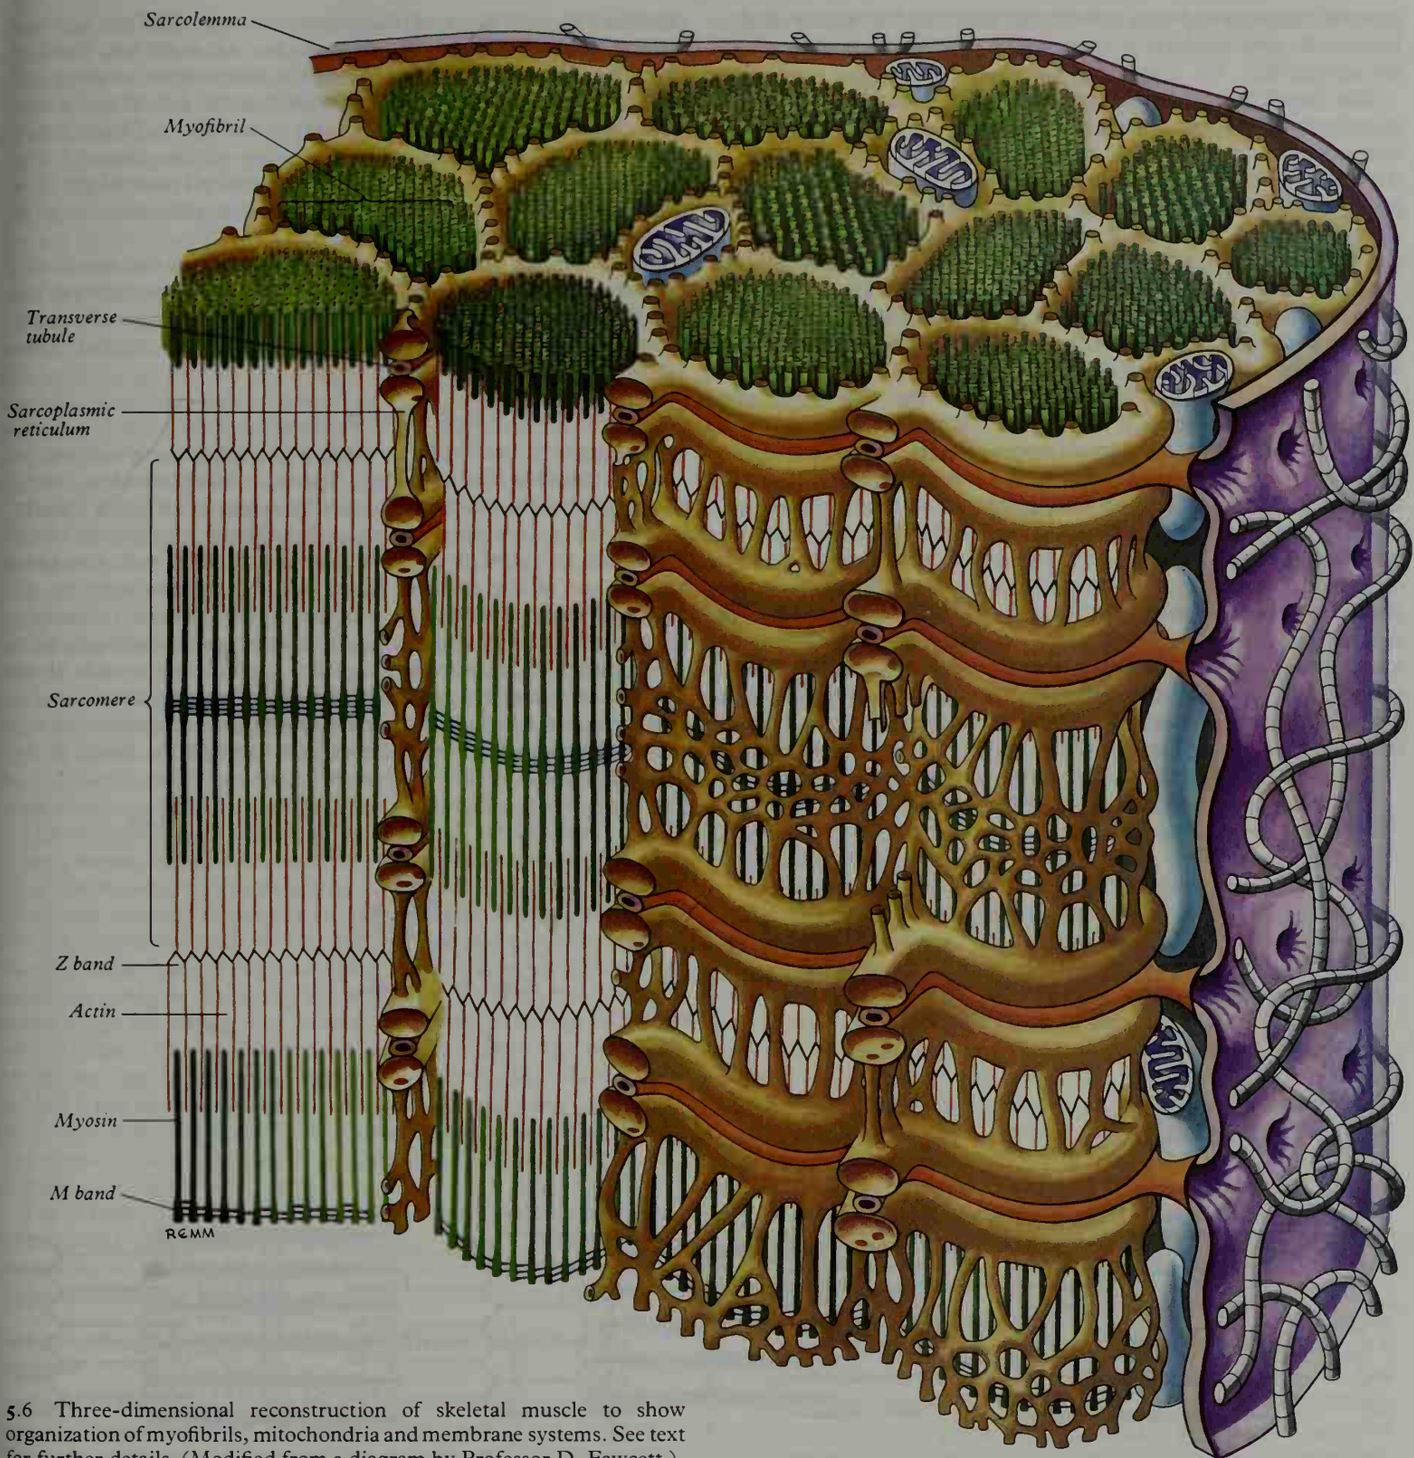
end of the sarcomere come to overlap in the middle of the A band and their hexagonal arrangement is disrupted. On further contraction the Z bands meet the ends of the myosin filaments and distort them, forming the 'contraction band' of light microscopy.

As the length of a sarcomere changes, the amount of overlap between its actin and myosin filaments also changes proportionately; since the numbers of possible cross-links between the two depend upon the overlap between them, it might be expected that a muscle would generate different tensions if it were made to contract at different lengths without being allowed to shorten (isometric contraction). Measurements confirm this expectation: if a muscle is held experimentally in clamps so that its sarcomeres are in excess of 3·5 μm long, when little or no overlap of actin and myosin exists, practically no tension is generated. At shorter lengths of sarcomere, the observed tension rises to a maximum value at a sarcomere length of about 2·0 μm, when there is maximum overlap of filaments without distortion of their arrangement. At sarcomere lengths shorter than this the tension drops rapidly to zero at 1·9 μm which is coincident with the meeting of the myosin filaments with the Z bands.

5.5D Longitudinal section through a group of myofibrils, showing the sarcoplasmic reticulum and associated transverse tubules (arrow). Note the darkly granular terminal cisternae of the sarcoplasmic reticulum where it lies adjacent to the transverse tubules. Magnification × 40,000.

It is useful when correlating the fine structure of muscles with their behaviour *in vivo* to consider briefly three ways in which they may contract. First, a muscle may shorten under constant load thus performing positive external work, a type of contraction termed *isotonic*; second, it may contract at a fixed length, performing no external work but creating tension in its attached structures—*isometric contraction*; third, a muscle may generate tension whilst it is being actively stretched, for example when decelerating a limb segment at the termination of a movement (p. 525). In the first type of contraction, actin-myosin cross bridges are active in causing mutual sliding of filaments. In the second, cross bridges are made and broken repetitively to maintain length under conditions of external loading. In the third case the precise behaviour of the filaments has not been established, but it is probable that cross bridges interact in the same manner whilst the filaments are sliding apart.



In practice there are, of course, many combinations of the foregoing three 'types' of contraction, with variations in the conditions of external loading, initial length, etc. It should be appreciated, however, that in the body muscles are so arranged that their habitual contractions involve only limited length changes compared with the overall length of the muscle. Further, maximum overlap of the myosin and actin filaments occurs at a sarcomere length which is close to that of resting muscle, and it is probable that they normally operate at near maximum force per contracting unit, i.e. in the energetically most efficient range.

Detailed Structure of the Myofilaments (5.7, 8)

Each myosin filament can be separated by appropriate chemical treatment into its constituent myosin molecules of which there are about 180 members per filament. Each has a molecular weight of 500,000 daltons and consists of a long 'tail' and a 'head'; the latter, on close examination, is seen to be a double structure. On further treatment the molecule can be broken into two moieties, *light meromyosin* comprising most of the tail, and *heavy meromyosin* representing the head with part of the tail. The heavy meromyosin can be further cleaved enzymatically to release the head. These cleavage points are probably regions where the molecule can flex during muscle contraction (Huxley 1972; Offer 1974). The myofilament is formed by the tails of the molecules, which lie parallel in a bundle, with their free ends directed towards the midpoint of the long axis. The heads project laterally from the filament in pairs or triplets, at 14·3 nm intervals. Each pair is rotated 120° with respect to its neighbours to form a spiral pattern along the filament. The precision of this arrangement probably has much to do with the rapidity with which contraction occurs in skeletal muscle. It has been demonstrated biochemically that each myosin head bears two sites for splitting adenosine triphosphate with the release of chemical energy. This enzymic action is stimulated by the presence of calcium ions, which are liberated during contraction from adjacent cytomembranes. The manner in which this energy is converted into a mechanical movement is still not clear, but may involve a change in the structure of the myosin molecule such that the head projects laterally at a different angle, and can also make a temporary bond with an adjacent actin filament.

The actin filaments (*f-actin*) are composed of globular sub-units of *g-actin*, each about 5·5 nm in diameter with a molecular weight of 42,000 daltons; these sub-units are attached end to end in two longitudinal filaments wound round each other in an extended helix with 13 sub-units to each complete turn. Another protein, *tropomyosin B* is associated with the actin filaments, and lies in the groove between the two strands of the helix; at 40 nm intervals yet another protein, *troponin*, is present, bound to the tropomyosin B. Tropomyosin B and troponin exert a regulatory effect on muscle contraction; in resting muscle, tropomyosin B prevents the myosin heads from attaching to actin, but when calcium ions are released before contraction, the ions cause troponin to push tropomyosin B away from the actin, allowing the myosin to bind. It has been proposed that the shearing movement of actin and myosin filaments may be caused by a change in the angulation of the myosin head (**5**.8B) after it has been bound, thus exerting a pull via the attached myosin tail to the whole filament (Huxley 1972). It is interesting that the actin filament helices on each side of a Z band spiral in opposite directions, and this polarity may underlie the directional sliding of the actin on the myosin during contraction.

At the Z band the actin filaments enter into a square lattice with a complex substructure (Landon 1970; Kelly and Cahill 1972). Many other proteins are also known to be associated with the contractile apparatus. Some of them are probably so soluble that they are beyond the reach of available structural methods, but recently, various proteins have been located in the neighbourhood of the myosin filaments to which they are bound at regularly spaced intervals. They include the so-called *'C' proteins* (Offer 1973) which may have enzymic activities, and also creatine phosphokinase (Turner *et al.* 1973).

5.6 Three-dimensional reconstruction of skeletal muscle to show organization of myofibrils, mitochondria and membrane systems. See text for further details. (Modified from a diagram by Professor D. Fawcett.)

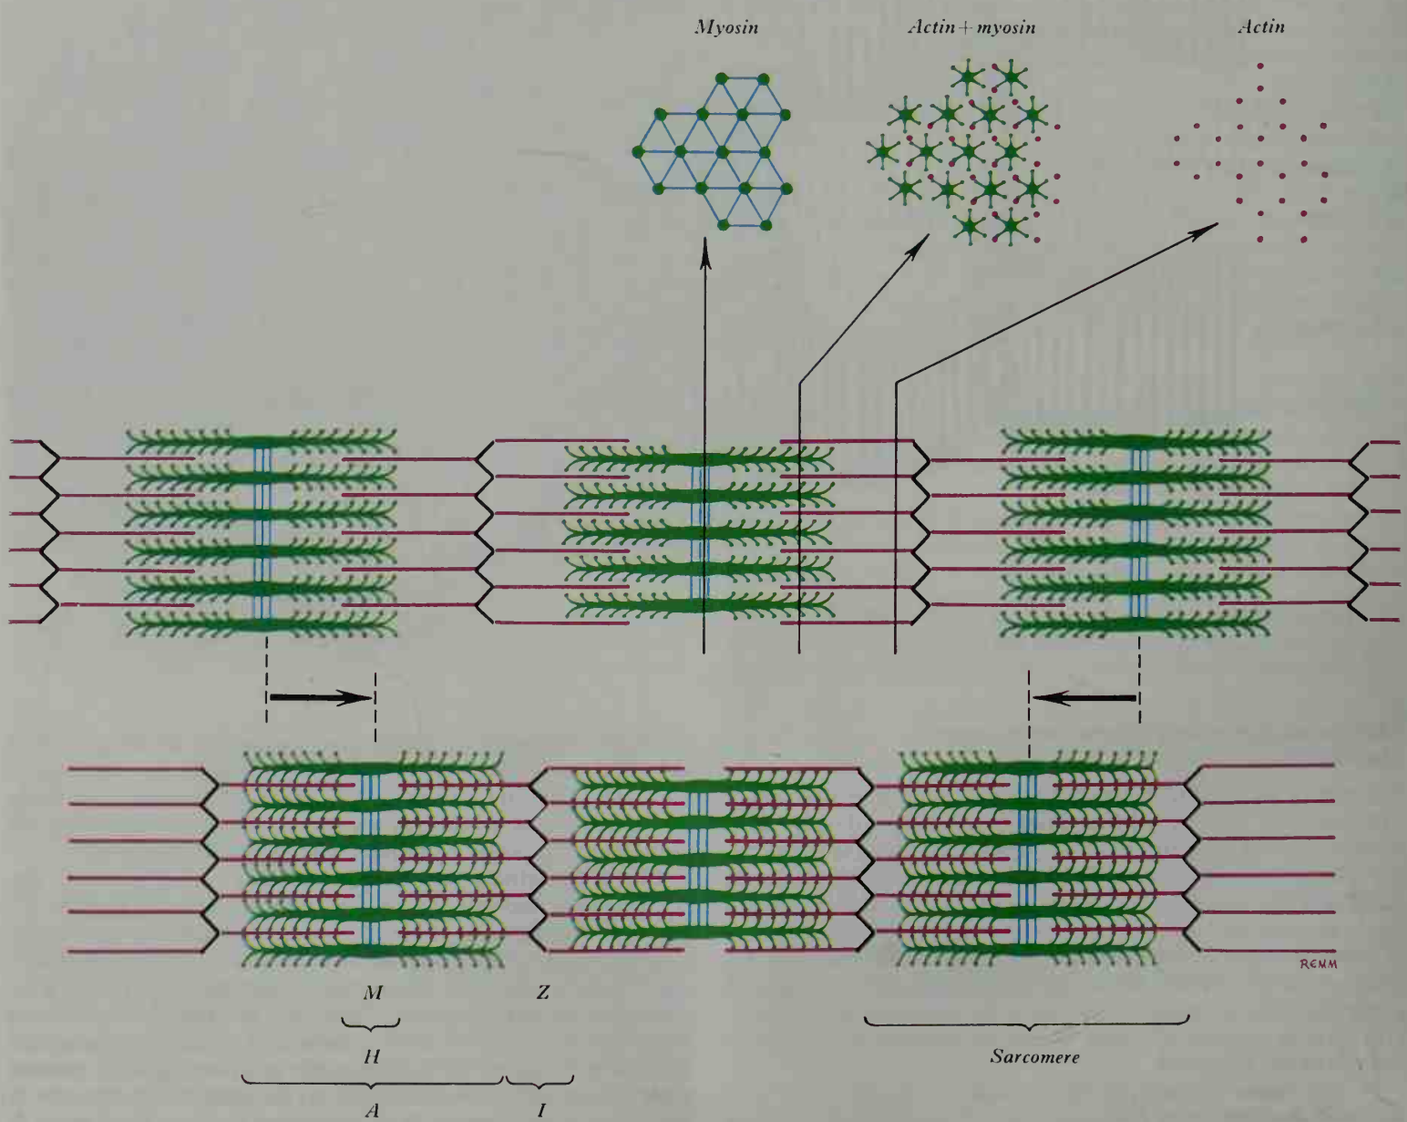
The Sarcoplasm and Cytomembranes of Muscle Fibres

Ribosomes are present in the perinuclear cytoplasm and also in that scattered between the myofibrils. The maintenance of a protein-synthesizing machinery is obviously important for the manufacture of enzymes and other cell components which have a rapid rate of turnover. Perinuclear Golgi bodies, lysosomes and lipid vascuoles also occur, while glycogen is distributed as clusters of small granules between the myofibrils and amongst the actin filaments of the I bands. Muscle glycogen plays an important role in the economy of energy within the body; its immediate function is to serve as a source of energy which can be mobilized rapidly at the site of its utilization.

It has been found, by physiological, biochemical and anatomical studies, that the membranes of striated muscle play a vital role in the initiation of contraction (Taylor 1972).

The outer membrane of muscle fibres (*sarcolemma*) has the fine structural appearance of typical plasma membranes elsewhere. It is coated externally by a basement membrane to which adhere reticulin and collagen fibres of the endomysium. Crushed fibres viewed by light microscopy *in vivo* show a thin coherent sheath, often interpreted as sarcolemma but in reality a complex of cell membrane, basement membrane and extracellular fibres.

The sarcolemma also sends tubular invaginations, the *centrotubules*, into the cell interior (forming the transverse or *T-system* of membranes). These penetrate amongst the myofibrils, running transversely at the level of the junctions between the A and I bands, and they branch and anastomose in these planes (Franzini-Armstrong 1973). There are, accordingly, two planes of tubular structures in each sarcomere (**5**.6) and this characterizes the musculature of reptiles, birds and mammals; in contrast other vertebrates (fish and amphibia) show centrotubules only at the levels of the Z bands. The connexion between the lumina of the centrotubules and the extracellular space was for some time in dispute but has been convincingly demonstrated by infusion of colloidal suspensions of heavy metals into the endomysium: such



materials penetrate deeply into the fibres within the centrotubules but do not communicate with the other membranous channels of the sarcoplasm.

The latter constitute the true intracellular membranes of the cytoplasm, or *sarcoplasmic reticulum*. This consists of a plexiform series of branching and anastomosing channels which fill much of the space between the myofibrils (*see* **5**.6). A typical feature is the presence of transverse channels, the *terminal cisternae* at the level of the A–I band junctions where they lie on both sides of, and in close apposition to, a transverse centrotubule, the complex of the three membranous channels being termed a *muscle triad*. The two membranous components show dense fibrous interconnexions, and are probably in close functional relationship. However, they are thought to play quite distinct roles in the coupling of the electrical excitation of the cell membrane and the contractile events consequent upon it. Electrical recordings show that the sarcolemma is depolarized when appropriately stimulated at the motor end plate, and that it propagates a wave of depolarization to all parts of the muscle fibre. Electrical stimulation of restricted areas of cell membrane with fine microelectrodes indicates that electrical changes are carried along the membranes of the centrotubular system, and so reach the depths of the fibre. It has also been shown biochemically that the sarcoplasmic reticulum is capable of binding calcium ions strongly to its constituent membranes and of releasing them under appropriate ionic stimuli. It is thought that when electrical disturbances occur in the T-system these cause the release of calcium and magnesium from the sarcoplasmic reticulum into the adjacent myofibrils, so causing the activation of the myosin-bound ATPase and the consequent contraction of the muscle. As electrical stability returns to the sarcolemma at the end of contraction, calcium and magnesium are re-bound to the endoplasmic reticulum (a step requiring the expenditure of energy), and the ATPase action ceases, with the consequent relaxation of the muscle. The significance of the T-system seems to be that all parts of the fibre can be stimulated to contract more or less simultaneously, to produce the characteristic 'twitch'.

Mitochondria (*sarcosomes*) are found between the myofibrils; they are usually highly elongate structures with densely packed cristae, and their number varies according to the type of muscle, being more plentiful in slow than in fast twitch muscles (Hess 1970).

Slow and Fast Muscle Fibres

It has long been known that two types of contraction are shown by skeletal muscles (Buller 1969), that is, a relatively slow 'tonic' twitch lasting (in mammals) about 75 msec. and a faster 'phasic' twitch with a duration of 25 msec. It has been possible in several mammals to correlate the speed of contraction with the gross appearance of the muscle. 'Slow twitch' muscles such as the soleus of the cat are red because of the large amounts of the protein myoglobin (a pigment similar in properties to haemoglobin), while 'fast twitch' muscles are paler in colour, although in the extrinsic ocular muscles of mammals (Salpeter *et al.* 1974), and in the general musculature of some of the lower vertebrates this correlation does not always hold. In mammals, the fibres of the

5.7 Diagram showing the organization of sarcomeres in skeletal and cardiac muscle and the changes occurring during shortening. Transverse sections are shown at various levels and indicate the packing of actin and myosin filaments. Compare with **5**.4 and see text for a detailed description.

slow muscles and those of fast muscles are different in their structure and histochemical properties. Most muscles show a mixture of two types of fibre, which are known as type I (slow) and type II (fast) fibres (Dubowitz 1969; Gauthier 1974). Slow fibres in mammals are narrower than fast fibres; they have poorly defined myofibrils, irregular in size, with thick Z bands (Rowe 1973; Eisenberg *et al.* 1974), and are rich in mitochondria and oxidative enzymes but poor in phosphorylases (Beckett and Bourne 1974). Fast fibres, in contrast, have fewer mitochondria, more extensive sarcoplasmic reticulum, thin Z bands, and are poor in oxidative enzymes but rich in phosphorylases; they also possess more glycogen. The significance of these differences lies partly in their respiratory metabolism; fast fibres obtain energy primarily by glycolytic respiration but are quite easily fatigued, whereas slow fibres also have a well-developed aerobic metabolism and are highly resistant to fatigue. Predominantly 'red' muscles also possess a richer circulation than 'white', relating to their respective oxygen demands (Carrow *et al.* 1967).

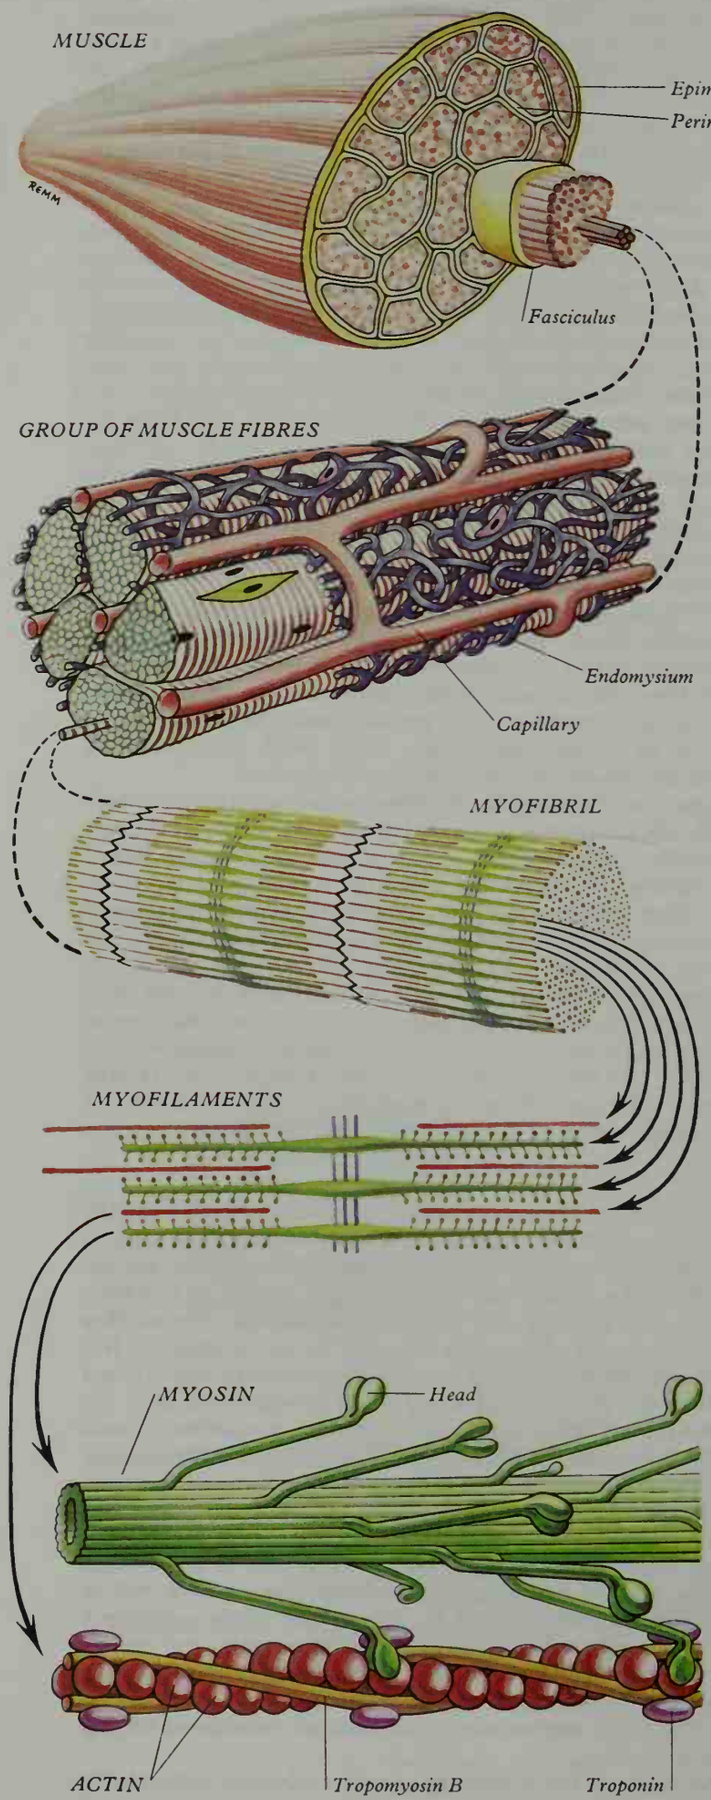
Type I fibres seem well suited to a relatively slow but repetitive type of contraction which generates the sustained 'tonic' forces characteristic of postural muscles. Type II fibres in contrast are adapted to produce more rapid phasic forces which operate in large-scale movements of body segments. Recent studies combining electrophysiological and histochemical approaches (Burke *et al.* 1973) have shown that type II ('fast') muscle fibres can be subdivided into those which fatigue easily, and those which are relatively resistant to fatigue, but not to the same extent as the type I fibres. Other histochemical investigations have also demonstrated two subdivisions of the type I fibres, although their functional significance is not yet clear (Askanas and Engel 1975).

The variations in enzyme content of muscle fibres appear to be, in part, dependent upon the activity of the fibres; this is shown in experiments where the nerves supplying 'fast' and 'slow' muscles have been crossed, thereby inducing a partial change in enzyme patterns corresponding to the type of nerve now serving the muscle (Buller 1970; Close 1972). It was first suggested that this alteration could be caused by the secretion of a chemical 'trophic factor' from the nerve, but subsequent work indicated that the type of muscle fibre is determined primarily by the frequency of neural activity in the axon serving it (Riley and Allin 1973). Indeed it has been suggested that three chief categories of muscle fibre type exist (types I, II, and intermediate), and that these correspond to the different types of motor unit commonly found in mammals (Burke *et al.* 1974).

The distribution of the various muscle fibre types has not been investigated extensively in man, but, where known, their proportions reflect the habitual activities of the muscle (Schmalbruch and Kamieniecka 1974; Thorstensson 1977).

Development, Growth and Regeneration of Skeletal Muscle

The precursors of muscle fibres are the embryonic mesenchyme cells of the myotomes or other regions of the body (p. 78, 114, 154). The various stages of differentiation and maturation of these cells to form mature muscle fibres have been the subject of some controversy, from which a number of different schemes of nomenclature have emerged (Boyd 1960; Fischman 1972; Murray 1972). However, it is generally agreed that specific mesenchyme cells (*promyoblasts*), grow into large fusiform elements, up to some 400 μm long (*myoblasts*), which cease dividing, and then fuse end to end, thus forming long multinucleate cylinders or *myotubes*, so named because, initially, the nuclei form a centrally placed row with a surrounding 'tube' of cytoplasm. The myotubes grow in length as further myoblasts fuse to form the fetal muscle fibres. Almost immediately after fusion the assembly of myofilaments begins, and these form myofibrils with highly organized sarcomeres. The myofibrils first appear near the centre of the cell, and further myofilaments are added to the outside of the existing ones, and in this manner the nuclei become displaced to the periphery of the fibre. Somewhat later, sarcoplasmic reticulum begins to form, followed by the ingrowth of the transverse tubule system.



Myotubes have been classed in three grades of increasing maturity, and it has been shown that for a period areas of the surface of early myotubes are enveloped by a characteristic multinucleate syncytium presenting numerous pseudopodial projections which invaginate the surface of the myotube especially opposite the myotube nuclei (Kelly and Zacks 1969; Landon 1970). This surface syncytium has been variously interpreted as a stage in fusion with the myotube, or as a close conjunction which may have a morphogenetic significance, but does not lead to fusion, the surface syncytium eventually disappearing. The final number of fibres within a muscle is reached some time before birth (Jaubert 1955). Subsequent longitudinal growth of the muscle is brought about by an increase in the number of sarcomeres which are added primarily at the ends of the muscle fibres where fusion of myoblasts with the muscle fibres is continuing. A further elongation is also achieved by a slight increase in the resting lengths of the sarcomeres themselves. Growth in diameter is by addition of myofilaments around the periphery of myofibrils which, after they have reached a critical size, appear to each split longitudinally into two myofibrils. These processes continue well into postnatal life, with myoblasts probably fusing with established muscle fibres to increase the number of nuclei in each fibre. Some of these myoblasts are thought to persist into adult life as *satellite cells* which lie close to muscle fibres beneath their basement membrane (Schmalbruch and Hellhammer 1976). The fibre diameter is subsequently much affected by use, reacting to exercise by hypertrophy and to disuse by atrophy (Rowe and Goldspink 1969). The postnatal growth of skeletal muscle is greatly affected by hormone levels, particularly the anabolic steroids such as testosterone, which is responsible for the greater development of muscle fibre size in males. When denervated the fibres become progressively reduced in diameter and finally degenerate, being replaced by connective tissue, which with time becomes increasingly fibrous and may undergo contracture.

Skeletal muscle is capable of limited regeneration in man; fibres on each side of a damaged zone break up into nucleated cylinders of cytoplasm, macrophages enter the necrotic area and engulf dead materials but leave the basement membrane intact. The muscle fibre cylinders now fuse and grow back inside the original basement membrane to form a myotube until eventually the two growing undamaged ends fuse and fill the gap completely (Carlson 1973). Varying degrees of maturation of this zone then follow. Satellite cells (*myosatellitocytes*) are thought to take part in this process, fusing at the ends of the existing cytoplasm to form part of the new fibre (Bischoff 1975; Hall-Craggs 1974). If large regions are damaged, however, regeneration may not occur and the missing muscle is replaced with connective tissue.

The Innervation of Skeletal Muscle

Each skeletal muscle receives one or more nerves of supply. In the limbs, face and neck, the supply is usually single, but where a muscle more obviously retains its segmental arrangement (e.g. the muscles of the abdominal wall), its nerve supply is multiple. Usually, after dividing into several small branches, the nerve of supply enters the deep surface nearer to its customarily less mobile attachment (origin) and, together with the principal blood vessels of the muscle, enters at a small elongate oval area, the *neurovascular hilum*, which is fairly constant in position for each muscle (Coërs and Woolf 1959; Brash 1955). Each nerve contains both motor and sensory fibres; the motor fibres comprise the large myelinated efferents of ventral grey column motor neurons (*alpha-efferents*) which supply extrafusal muscle fibres, the smaller myelinated *gamma-efferents* which run to the muscle spindles, and the fine nonmyelinated *autonomic efferents* which supply vascular smooth muscle. The sensory fibres comprise a range of myelinated fibre diameters distributed to the muscle spindles, neurotendinous sensory endings and terminals in the fasciae, and non-myelinated pain afferents of uncertain origin. Details of these various nerve terminals are considered further elsewhere (p. 847).

Once the nerve has entered the muscle it breaks up into a plexus which runs in the epi- and peri-mysial septa before passing into the endomysial spaces around the muscle fibres. The alpha-efferents then branch and finally lose their myelin sheaths as they terminate on a variable number of individual muscle fibres. These

5.8A Diagram showing successive levels of organization within a skeletal muscle, from whole muscle, through fasciculi, fibres, myofibrils, myofilaments, down to molecular dimensions.

terminals are distributed within a fairly narrow transverse (motor) band near the centre of the muscle, whilst some of the afferents enter the muscle spindles often in much the same region. The autonomic fibres ramify in the endomysium throughout the whole muscle supplying its vasculature. (For the innervation of associated tendons *see* pp. 522, 855.)

The somatic motor axons break up into a number of branches, each of which terminates on an individual muscle fibre in the form of a specialized structure, the *neuromuscular termination* or *motor end plate*. In most muscles this, as its name suggests, is a plate-like ('*en plaque*') terminal but in some slow muscle fibres, such as those of the extrinsic ocular muscles (Namba *et al.* 1968), the motor terminal is itself branched. The latter are named '*en grappe*' terminals because of a supposed resemblance to a bunch of grapes. This arrangement may be necessary because the sarcolemma of such slow muscle fibres does not show large propagated changes of potential when stimulated locally.

A motor unit is a functional division of a muscle and is defined as a single alpha motor neuron together with the muscle fibres which it innervates. (The term *myone* has been proposed for the *group* of *structural units* or muscle fibres that form a *functionally contractile motor unit—see* MacConaill and Basmajian 1977.) The size of motor units varies between muscles, smaller units occurring where precise control of muscular action is required. In the extrinsic ocular muscles each motor neuron innervates only 6–12 muscle fibres (Bors 1926), whereas in large proximal limb muscles the ratio may reach 1 to 2,000. Consequently, the force generated by each motor unit is inversely related to the precision of control.

Physiological investigations have shown that the muscle fibres innervated by one motor neuron are often widely spread within a muscle and do not necessarily correspond to its myonemes or fascicular divisions (Burke and Tsairis 1973). Thus, even when only a few motor units are active, the force is generated diffusely. It has also been shown that each axon terminates within a round or oval territory, with considerable overlap between adjacent zones of innervation (Sissons 1969). (It should also be noted here, that in the terminology proposed by MacConaill and Basmajian (1977) the muscle fascicle or *myoneme* is defined by them as the *kinematic unit* of muscle. A further classification of various structural/functional types of myoneme has also been advanced, and some of these will be mentioned briefly below.)

CONTROL OF MUSCLE CONTRACTION

In considering the contraction of a muscle as a whole it is important to understand how its individual elements operate. As seen above, each fibre is in receipt of a single terminal branch of a motor axon. When this is active, volleys of nerve impulses pass along its membrane, and, reaching the terminal, cause the liberation of a chemical transmitter, *acetylcholine*, close to the adjacent muscle fibre membrane. The transmitter is then rapidly broken down by enzymic action so that it operates only briefly. Electrical recordings show that the transmitter causes changes in the permeability of, and hence the electrical potential across, the sarcolemma: in resting fibres the so-called *resting potential* has a steady value of about 80 mV, the interior of the cell being negative with respect to the exterior. When stimulated by low concentrations of acetylcholine, a small transient localized depolarization of the membrane, the *end plate potential* occurs. This does not itself cause contraction, but with increased concentrations of transmitter it builds up until a critical level is reached, at which point the neighbouring membrane abruptly undergoes a massive rapid depolarization, continuing to reversal of the membrane potential so that the interior becomes 20 mV positive relative to the exterior. This is known as the *action potential*; the swing rapidly reverts to the resting potential but it initiates a wave of depolarization, potential reversal and return to resting levels, which sweeps at a speed of 5 metres per second over the whole surface of the muscle fibre, and this causes its momentary contraction. The mechanical response is a single twitch lasting 25–75 msec. Repeated action potentials can be elicited from a single muscle fibre if the activity of its motor axon is maintained, but there is a maximum limit to this since, after a

single muscle action potential has occurred, there is a *refractory period* of about 10 msec. until another can be elicited.

Since all action potentials are identical, as are all isolated twitches of a given muscle fibre, they are said to show an 'all or none' response, i.e. if they contract at all, they contract maximally within the limits imposed by their initial length and conditions of loading. Whole muscles, however, exhibit considerable gradation in their contraction and this is achieved by differential activity of the motor units (p. 526). Individual units can vary greatly in their twitch frequency, and the number of units that are active also fluctuates. In small contractions only a few units are operative, but with increasing contraction more are recruited until many or all are active. The sum of these activities results in a steady contraction of the whole muscle even though the individual units are twitching repetitively (but in an asynchronous manner). *Experimentally*, above a certain frequency of stimulation, its rapidity outstrips the contraction-relaxation time of the fibre so that relaxation cannot occur before the next contraction is initiated. This results in a partial or complete fusion of twitches, or *tetanus*, but this does not occur under physiological conditions. The frequency of stimulation which produces tetanus differs with muscle type—slow muscles at 30 impulses per second, whereas fast muscles may need 100 impulses per second.

It must be noted, however, that since all forms of muscle contraction are the summation of individual twitches, even those that appear 'steady' on superficial examination, in fact show a fine oscillation on closer examination with sensitive recording devices. Thus, in the same sense as one regards the energetic states of subatomic particles, or the release of a neurotransmitter at an interneuronal synapse or neuromuscular junction as *quantal*, muscle contraction may also be regarded as quantal, and for some purposes, therefore, quantum mechanical physics may prove the most appropriate.

The Blood Vessels of Skeletal Muscle

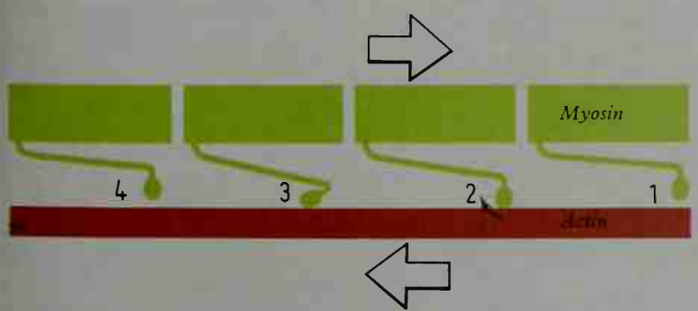
The blood supply of muscles is derived by muscular branches from the neighbouring arteries. In many the branches of the principal artery and nerve, as we have seen, enter together along a strip, often fairly constant in position, termed the neurovascular hilum. Subsidiary arteries are generally present and enter at the periphery or close to the ends of the muscle. These branch into smaller arteries and arterioles which ramify in the perimysial septa, and give off capillaries which serve the muscle fibres. These capillaries lie in the endomysium, mainly parallel with the muscle fibres, but they present frequent transverse anastomoses, forming a three-dimensional lattice. It has been shown in cats, that the capillary bed of predominantly red muscle is much denser than that of white muscle.

The supply and drainage of the capillary beds have been the subject of some controversy (*see* Zweifach and Metz 1955, and p. 625). Physiological studies with isotopic sodium as a tracer (Barlow *et al.* 1961), and microscopic examination (Grant and Payling Wright 1968), indicate that there are two distinct circulations in skeletal muscle. The *nutritive circulation* is derived from arteriolar branches of arteries entering by way of the neurovascular hilum. These penetrate to the endomysium where all the blood passes through the capillary bed before collection into venules and veins to leave again through the hilum. Alternatively, some of the blood passes into the arterioles of the epi- and peri-mysium in which few capillaries are present. Arteriovenous anastomoses are abundant here, and most of the blood returns to the veins without passing through capillaries; this circuit therefore constitutes a *non-nutritive* pathway through which blood may pass when the flow in the endomysial capillary bed is impeded, e.g. during contraction. (See also p. 632.)

The lymphatic drainage commences in lymphatic capillaries which lie in the epi- and peri-mysial sheaths, apparently not penetrating the endomysium, and these converge into larger lymphatic vessels which accompany the veins leaving the muscles.

The Connective Tissues of Skeletal Muscle

The general arrangement of the connective tissue as various so-called 'sheaths' has already been mentioned (p. 506). In fact these perform important roles in the organization of the muscle fibres since they give a degree of mechanical coherence to the muscle, whilst allowing a measure of relative movement within it. These connective tissue planes are, of course, the route whereby nerves and blood vessels penetrate to all parts of the muscle. The endomysium is of particular importance since it forms the external environment of the muscle fibres, and mediates the exchange of metabolites between them and neighbouring capillaries. Its mucopolysaccharide matrix is also important in the flow of ions during excitation of the membrane of the muscle fibre.

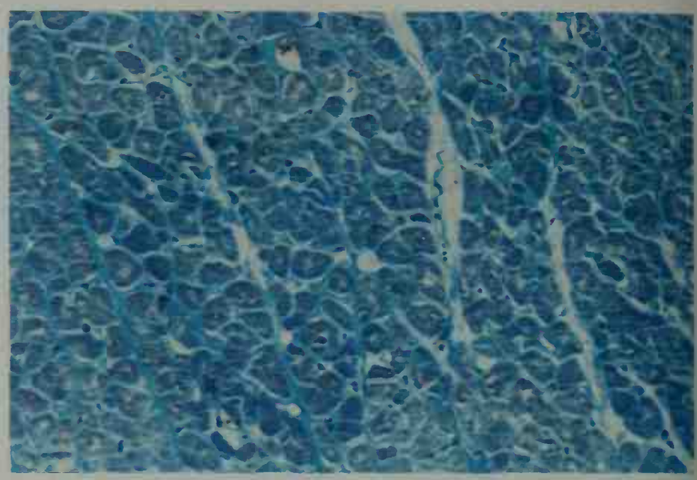


The collagen, reticulin and elastin fibres, and their associated ground substances, play a large part in determining the mechanical characteristics of muscle during contraction and passive extension (Hill 1970).

The manner in which muscle fibres transmit their contractile force to adjacent structures depends upon the interaction between muscle fibres and the surrounding connective tissue sheaths. Important in this regard is the junctional region between the ends of the muscle fibres and the tendinous attachments, loosely called the *myotendinal junction* (Schippel and Reissig 1968; Hanak and Böck 1971). Here, the connective tissue of the endo-, peri and epimysia become strongly fibrous and thicken to continue as the fibrous bundles of the tendon. The muscle fibres at this point may taper, be flat ended, or may show a terminal expansion. Electron microscopy shows these ends to have a highly indented sarcolemma with a dense internal layer of cytoplasm into which are inserted the actin filaments of the adjacent sarcomeres. Externally, the basement membrane is prominent, and collagen and reticulin fibres lie in close contact. There are, however, no indications of desmosomal attachments, and it seems likely that here, as along the whole length of the fibre, the contractile forces are transmitted from the cell surface to the matrix of the surrounding connective tissues primarily by viscous adhesion with its fibres and ground substance.

Cardiac Muscle

Heart muscle has structural and physiological properties which distinguish it from both skeletal and smooth muscle. Histologically, it is made up of tracts of cells (5.9) each about 80 μm long and 15 μm in diameter in man (resting length), containing a single centrally placed nucleus. Each cell may be partially divided into two or more branches at its ends and these abut against other cells: the appearance by light microscopy is of a network of branching and anastomosing cylinders, and indeed for many years cardiac muscle was, quite incorrectly as we shall see below, thought to be a syncytium. In the spaces between the cells lies an endomysium comprised of fibroblasts, collagen and reticulin fibres, ground substance, capillaries and nerves. The larger bundles or tracts of cells, varying in size from a few hundred to many thousands of cells in diameter, are encompassed and separated by perimysium in much the same fashion as skeletal muscle.



Each cardiac muscle cell (*cardiac myocyte*) shows striations which are identical in organization with those of skeletal muscle, with A, I, Z and H bands. In histological preparations these bands

are not as conspicuous as in skeletal muscle. At the ends of the cells are conspicuous cross striations, the *intercalated discs*. With the electron microscope the same pattern of actin and myosin filaments is seen, as in skeletal muscle (Fawcett and McNutt 1969; Page and Fozzard 1973). They are not, however, grouped into distinctive myofibrils, and the numerous mitochondria found in heart muscle cells, together with their various intracytoplasmic membranes, are closely surrounded on every side by myofilaments (**5**.11). T-systems are present (Forssmann and Girardier 1970), but they penetrate the cells at the level of the Z band rather than at the A–I band junction (**5**.11), possibly reflecting the relatively slower contraction time of cardiac muscle compared with skeletal muscle. The sarcoplasmic reticulum is present but not as abundant as in fast skeletal muscle. Glycogen and myoglobin are also prominent features of cardiac muscle, and histochemical studies show the cells to be rich in oxidative enzymes. These characteristics, somewhat similar to those of mammalian slow skeletal muscle, reflect the high oxygen demand and the constant rhythmic expenditure of energy which typifies heart muscle. The density of the vascular bed and blood flow to the heart also emphasizes these considerations.

Each cardiac myocyte shows a spontaneous rhythm of contraction and relaxation, even when isolated. This *myogenic rhythm* is accompanied by a parallel oscillation in membrane potential, but it is not known how this is achieved. The rhythm is slower than that of the heart as a whole, but can be synchronized with that of the other cells by the action of the pacemaker and conducting system (*vide infra*, and also p. 659).

5.10 Electron micrograph of cardiac muscle in longitudinal section showing abundant mitochondria and intercalated discs. × 4,000. Detail shows part of intercalated disc with gap junction in left half of field. × 15,000.

5.11 Three-dimensional reconstruction of cardiac muscle showing organization of myofibrils and membrane systems. As in previous diagrams, actin is shown *red* and myosin *green*; mitochondria are coloured *blue*; the sarcolemma and luminal surface of the invaginated transverse tubules are *purple*. The intracellular surface of the transverse tubule is *orange*, and the sarcoplasmic reticulum is coloured *yellow*. An intercalated disc with intermittent desmosomes and communicating junctions (nexuses) is depicted on the lower left of the picture. Compare with 5.6, and see text for further details. (Modified from a diagram by Professor D. Fawcett.)

Intercalated Discs

With the electron microscope these have been shown to constitute specialized regions of cytoplasm and cell membrane which mark the junctions between the ends of the cells. The cell membrane in such regions runs transversely across the end of the cell but often forms a series of steps (5.9, 10). The cytoplasm adjacent to the membrane is particularly dense and appears to form an anchor for the actin filaments of the adjacent sarcomere. Numerous desmosomes are scattered between the adjacent ends of cardiac myocytes, and amongst the line of attachments there are special regions where the cell membranes come to lie in close apposition; these regions are similar in structure to the specialized contacts (gap junctions) of epithelial cells and to the 'nexuses' of smooth muscle cells (*vide infra*). It has been shown by electrical recording and stimulation, that such regions permit the relatively unimpeded electrotonic flow of ionic current between cells and are thus of great importance in the dissemination of contraction within the heart. Because of these electrical contacts between cells, excitation, and therefore contraction, in one part of a muscle bundle can spread to all the cells of that bundle. For this reason the heart behaves *electrically* as a syncytium (i.e. as though there were no cell membranes separating its cells), and, as intimated above, before the advent of electron microscopy, it was regarded as structurally syncytial.

The Conducting Tissues of the Heart

These are also considered with the heart (*see* p. 659). Three major types of cell are found in the conducting system, namely *nodal myocytes*, *transitional myocytes*, and *Purkinje myocytes*, each present in particular regions (Sommer and Johnson 1968; James and Sherf 1974). (It should perhaps be noted here, that rows of Purkinje myocytes constitute the Purkinje 'fibres', and it seems less than appropriate that the official term Purkinje *fibre* has been taken as synonymous with single Purkinje myocytes.)

Nodal myocytes, which are responsible for pacemaker activities, are uninucleate, rounded, cylindrical, or polygonal cells, present in clusters or rows in both the sinu-atrial and atrioventricular nodes. They possess only a few randomly orientated myofibrils, lack a regular sarcotubular system, and have a pale organelle-free zone around their large central nuclei.

Transitional myocytes are also found in the nodes, and extend into the stem and principal branches of the conducting system; they form connecting pathways between the nodal myocytes and the final elements of the system, the Purkinje myocytes. Transitional myocytes are narrower than the general cardiac myocytes, but otherwise possess the same type of contractile apparatus. It is possible that these cells conduct more slowly than the larger fibres of the system, and are the basis of the delay in conduction which occurs at the atrioventricular node and in the principal bundles immediately distal to the node.

Purkinje myocytes are large uninucleate cells which are wider and shorter (30 μm in diameter and some 20–50 μm long) than the surrounding general cardiac myocytes. They also possess larger nexuses both laterally and at their ends. Internally they contain fewer myofibrils, many mitochondria, abundant glycogen, and a well developed sarcotubular system. All these features can be correlated with the rapid conduction velocities of impulses along Purkinje fibres, some 2–3 metres per second, compared with 0.6 metre per second in ordinary myocardium. Detailed analysis of the organization and three-dimensional distribution of Purkinje myocyte nexuses terminating in apposition to normal cardiac myocytes within the depths of the ventricular myocardium has not been achieved, at the time of writing.

As will be mentioned elsewhere (p. 663) electrophysiological evidence has been presented concerning the existence of *preferential conduction paths* from right to left atrium (*interatrial*), between the sinu-atrial and atrioventricular nodes (*internodal*), and also *accessory atrioventricular bundles*. However, whether any or all of these pathways consist of structurally specialized *conducting tissue*, or reflect the elongation and axial polarization of tracts of *ordinary cardiac myocytes*, remains controversial.

Innervation of Cardiac Muscle

Non-myelinated, post-ganglionic, sympathetic and parasympathetic nerves permeate the connective tissue septa and end in close proximity to the individual cardiac muscle cells. The quantitative aspects of the three-dimensional distribution of both autonomic efferent and afferent nerve terminals in the various localities of the myocardium (with its varieties of cardiac myocyte, including the conducting system), the valve annuli, cusps or leaflets, and chordae, the fibrous 'skeleton', endocardium, epicardium, and coronary vasculature is virtually an uncharted field.

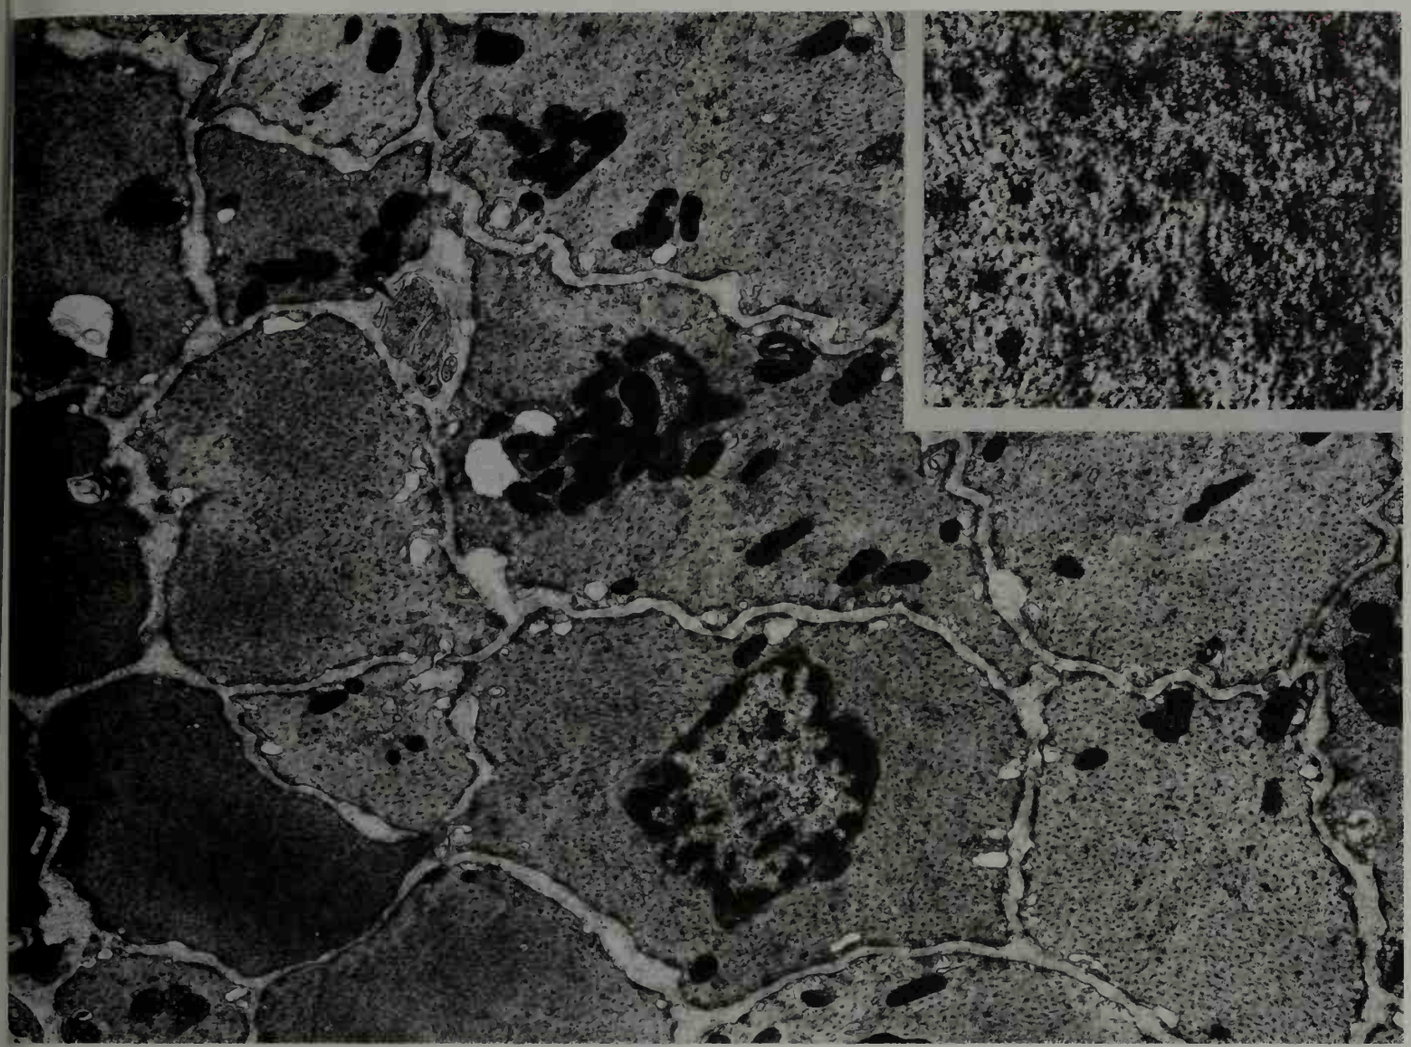
5.12 Longitudinal section of non-striated muscle from the ileum, showing groups of non-striated myocytes arranged in a fasciculus. Haematoxylin and eosin.

Blood Vessels of Cardiac Muscle

The myocardium has a dense vascular bed derived from the coronary vessels (p. 667). From the branches of these, capillaries arise and run in the endomysial septa to form a network of branching and anastomosing vessels so arranged that each cardiac muscle cell lies not more than about 8 μm away from a capillary (Wearn 1941). Vascular channels occupy about 60 per cent of the total interstitial space in the rabbits' myocardium (Frank and Langer 1974).

The lymphatic capillaries also penetrate the endomysium, in contrast to those of skeletal muscle.

Development, Growth and Regeneration of Cardiac Muscle



Cardiac muscle develops from the mesenchymal cells of the myo-epicardial mantle of the embryonic heart (p. 181). This source has recently been confirmed, with details, by Morris (1976) working on human embryos. The cardiac promyoblasts are at first stellate, adhering to each other by desmosomal attachments which later transform into intercalated discs (Challice and Virágh 1973; Morris 1976). They undergo repeated mitoses and synthesize myofilaments to become cardiac myoblasts, which begin rhythmic contraction early in fetal life. The multiplication of these cells continues into postnatal life, but gradually gives way to growth by hypertrophy of individual cells which is to some extent dependent upon the work load of the muscle.

Regeneration of damaged muscle does not occur to any noticeable extent; repair of the myocardium is by means of fibrous scar tissue (Hudson and Field 1973).

Non-striated Muscle

Non-striated muscle (**5**.12–15), sometimes known as smooth, involuntary or plain muscle, differs considerably from the previous two types of muscle tissue both in its structure and behaviour. It is made up of mononucleate fusiform myocytes, varying in length from 15 μm in small arterioles to 500 μm or more in the myometrium of the uterus during pregnancy (Csapo 1962; Huddart and Hunt 1975). They are disposed with their long axes parallel to the direction of contraction, and are usually arranged in small fasciculi. The latter are separated by loose connective tissue septa in which lie the afferent and efferent vessels and nerves. In regions where a concerted contraction in a particular direction occurs, these fasciculi lie parallel, as in the separate layers of the muscularis externa of the intestines; where contraction effects a reduction in surface area in a particular plane, the fasciculi interweave freely in all directions in that plane, as in the muscularis mucosae of the intestines and in the bladder. In muscular arteries non-striated muscle is present in thick sheets into which capillaries do not penetrate. Within a fasciculus much of the surface of each cell is covered by a prominent basal lamina (basement membrane), and between and inside the laminae fine elastin, reticulin, and collagen fibres abound, forming complex networks around each cell, which are separated therefore, except at the special points of contact described below, by a space of 40–80 nm. There is usually a lack of fibroblasts or other connective tissue cells within the fasciculi, and the extracellular fibres may be a product of the myocytes themselves at some stage in their development. At the boundaries of the fasciculi these connective tissue fibres interweave with those of the inter-fascicular septa, and presumably provide the means whereby the forces generated by the contraction of individual cells are transmitted throughout the tissue.

Two types of non-striated muscle have been distinguished on the basis of their innervation and behaviour, *multi-unit* and

5.13 Low-power electron micrograph of a group of non-striated myocytes in transverse section, showing a centrally placed nucleus in one of the cells, and numerous darkly staining mitochondria. An autonomic nerve fibre (arrow) is visible among the myocytes. Specimen taken from the ileum. Magnification × 6,000. unitary muscles (Bozler 1948; Burnstock 1970). In the former there are rich nerve plexuses so that many of the cells receive motor terminals; contraction is usually initiated by nervous action, it is *neurogenic*, rather than by stretching or arising spontaneously, and small groups of muscle cells may operate independently. The muscle of the iris and those of larger arteries and ductus deferens are of this type. Unitary muscles, in contrast, have relatively few motor nerves; their rhythmic contractions are spontaneous, i.e. *myogenic* in origin, and may be governed by *pacemaker regions* in the muscle, or may be elicited by previous stretching of the muscle. Typical examples are the muscle layers of the stomach, intestines, uterus, ureter and some of the smaller blood vessels. The function of the nervous control in unitary muscles is to enhance or depress the rate and force of the pre-existing rhythmic contraction. Intermediate types of muscle also exist and the two divisions outlined here probably represent the extremes of a wide spectrum of types and activities.

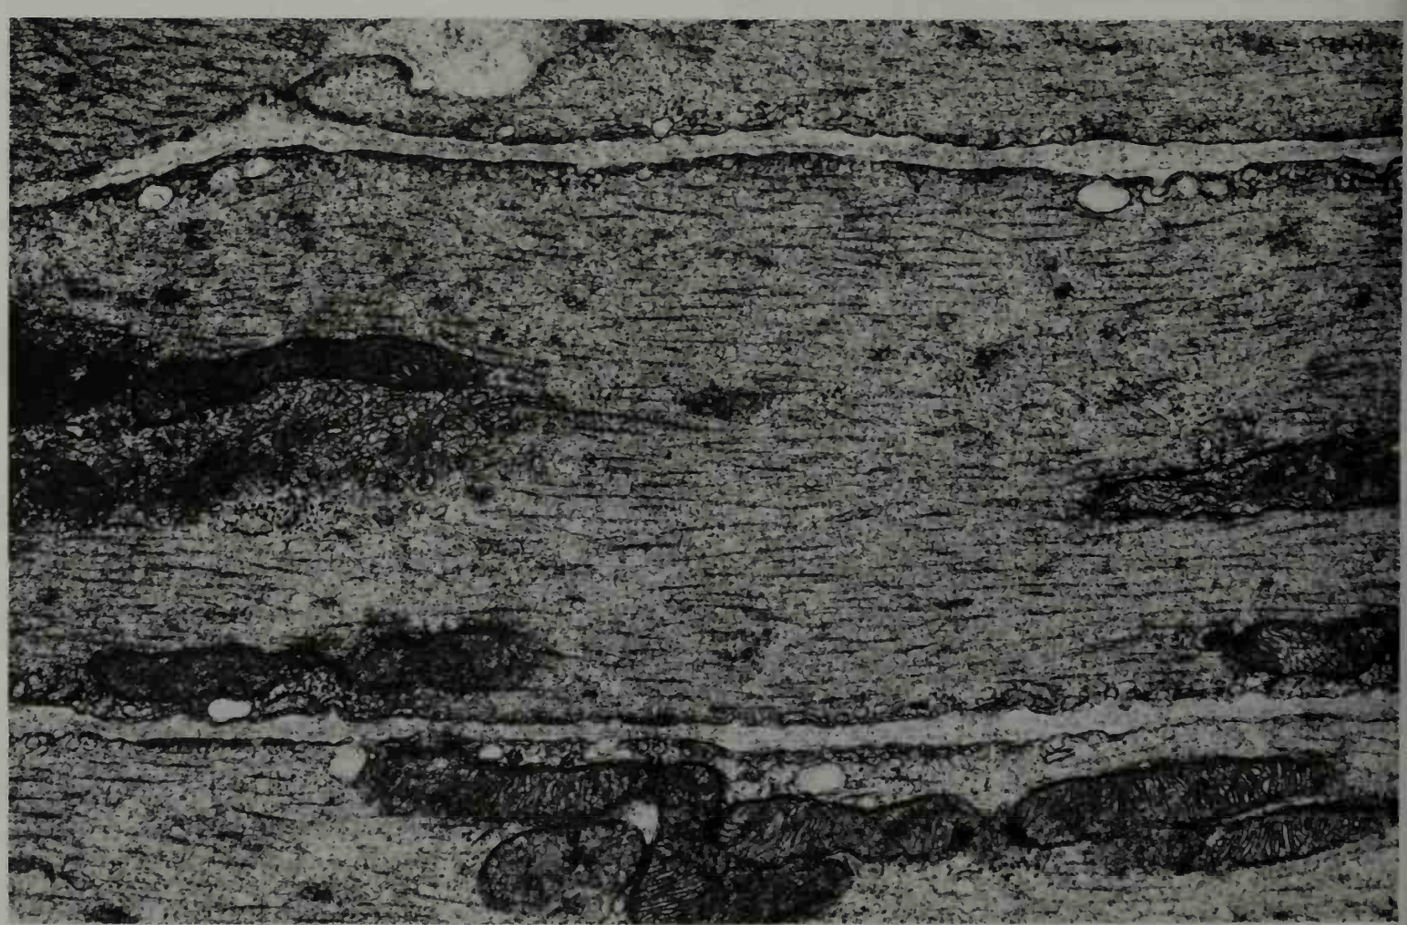
Individual non-striated myocytes when seen with the light microscope show a centrally placed nucleus, which may be highly elongated in stretched muscle, or ovoid with a crenated surface in contracted muscle. The cells are weakly birefringent, indicating some degree of longitudinal orientation of the cell components.

Ultrastructurally the cytoplasm of the non-striated myocyte is seen to consist mainly of closely-packed fine filaments lying parallel to the long axis of the cell (**5**.13, 14, 15B). Most of the usual cellular organelles including Golgi complexes, agranular and granular endoplasmic reticulum, free ribosomes, and lysosomes are positioned near both ends of the nucleus (the nuclear poles), but clusters of mitochondria are also found elsewhere in the cytoplasm, either peripherally or in deeply placed scattered groups, the site varying with different types of non-striated muscle (Gabella 1973; Huddart and Hunt 1975). A branched, irregular sarcoplasmic reticulum, capable of sequestering calcium ions, also ramifies within the masses of filaments (Popescu and Diculescu 1975), and its terminal sacs lie immediately beneath the myocyte's plasma membrane. Numerous small endocytotic vesicles line the cell surface, either in rows or distributed randomly, and the cell surface is also characterized by occasional projections (*see* **5**.13) and various specialized junctions with other cells.

The myofilaments are responsible for cellular contraction, but until recently the detailed organization of actin and myosin was unknown—only actin was visible in the earlier micrographs. Improvements in fixation resulted in the demonstration of myosin in the form of thick ribbons, or rod-like aggregates, of myosin molecules which are up to 15 μm long and some 0.1 μm wide (Somlyo *et al.* 1973). It is probable that the myosin molecules are arranged in non-parallel directions on the two sides of such assemblies, presumably allowing them to generate shearing forces in relation to adjacent actin filaments, thus shortening the myocyte, without the necessity for the sarcomeric arrangement of striated muscle. Each myosin aggregate, together with up to 15 surrounding actin filaments, forms an obliquely orientated '*contractile unit*' which can be visualized in glycerinated preparations with the light microscope (Small 1974). Actin filaments are also inserted into cytoplasmic densities associated with the inner surface of the plasma membrane (Cooke 1976). In addition to the myofilaments, bundles of '*intermediate filaments*',



5.14A A low-power electron micrograph of a longitudinal section through two non-striated myocytes, one showing a nucleus. Note the irregular outlines of the cells, and the endoplasmic reticulum and mitochondria within. Fine collagen fibrils lie in the intercellular spaces. Specimen from ileal wall. Magnification × 8,000.

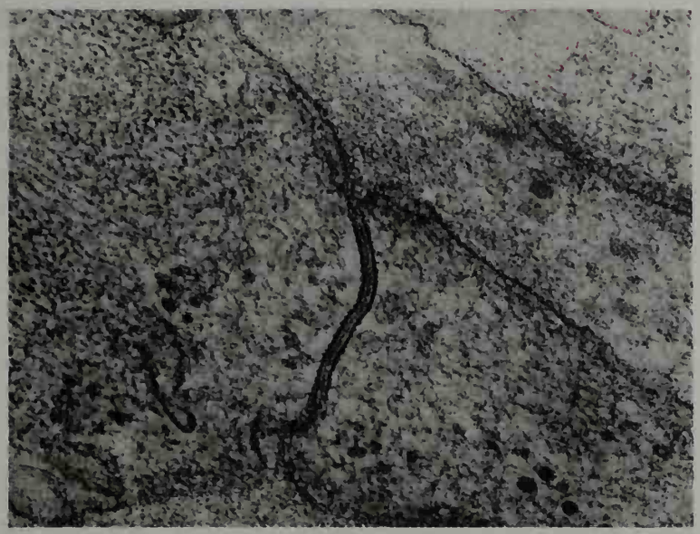
10 nm in diameter, traverse the cytoplasm becoming attached to the occasional dense bodies distributed throughout the cytoplasm. They resemble the tonofilaments of other cells, and may act as a cytoskeleton binding the various contractile units together.

Excitation of non-striated myocytes occurs when their plasma membranes are depolarized and calcium ions enter, thereby activating the actin-myosin systems. The myocytes can also excite each other directly by way of the nexuses (*maculae communicantes, communicating junctions, see* **5**.15A, B) which are present as small irregular patches distributed over the cell surfaces (Cobb and Bennett 1969; Lowry and Small 1970; Watanabe and Yamamoto 1974). It has been estimated that in some locations a few score such junctions are present on each cell. Individual nexuses are associated with an underlying expanded region of the sarcoplasmic reticulum; the latter may therefore be directly affected by signals from other cells (Fry *et al.* 1977) perhaps causing the mobilization of calcium stores during excitation. Electrical coupling ensures that a group of myocytes act in concert, and also enables a single nerve fibre to control many myocytes without exciting each individually. In addition to nexuses, myocytes are also interlinked by desmosomes, and to the surrounding basal lamina by surface specializations similar to zonulae adherentes (p. 7).

5.14B An electron micrograph of the cytoplasm of a non-striated myocyte in longitudinal section showing the irregularly distributed thick myosin and thin filaments. Note also the numerous endocytic vesicles and sarcoplasmic reticulum at the cell boundaries. Specimen from ileal wall. Magnification × 20,000.

Other Activities of Non-striated Muscle

As already mentioned, extracellular fibres are always present surrounding the muscle fasciculi, and it has been shown *in vitro* that non-striated myocytes can secrete elastin and other fibres. This resemblance to fibroblasts has called into question the sometimes rather arbitrary division between those two cell types. Certainly in the aorta, for example, non-striated myocytes generate large quantities of extracellular material including the elastic laminae, and are presumably limited in their contractile powers. Conversely, in regenerating connective tissue there are contractile fibroblast-like cells which are responsible, at least in part, for the movement that occurs during scar contracture. It is probable that both non-striated myocytes and fibroblasts arise from similar types of mesenchyme cells, and that in certain circumstances they develop some common features (*see* review by Ross 1971).



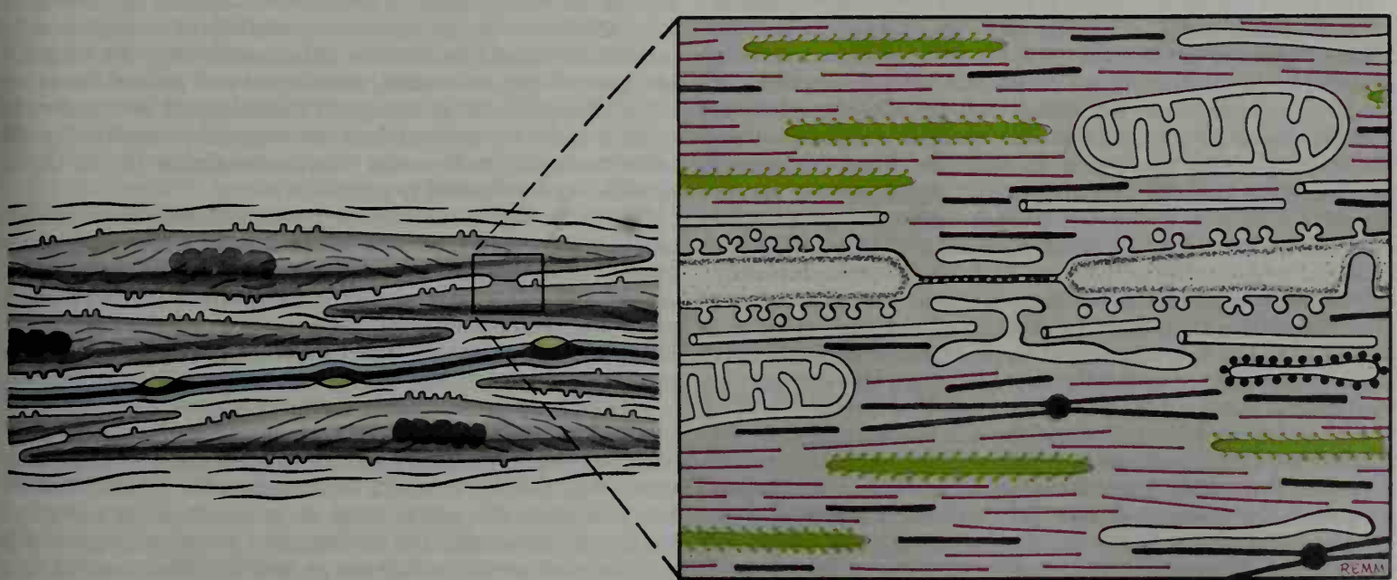
Development of Non-striated Muscle

The origins of non-striated muscle have already been outlined (p. 506). The mesenchyme cells involved become fusiform as the contractile proteins are synthesized, to form first myoblasts, and then mature myocytes which may continue to grow in size. New myocytes continue to originate, even in adult life, from mesenchymal cells, as in regenerating blood vessels, and there is evidence that non-striated myocytes are able to multiply mitotically, for example, in the myometrium after treatment with progesterone (Crandall 1938), although to what extent this occurs physiologically is uncertain. (For more recent studies of hormonal modification of myometrial growth, consult Ross and Klebanoff 1967.) Non-striated muscle can regenerate to a limited extent if damaged, by the multiplication and differentiation of mesenchyme cells, and by division of pre-existing muscle cells.

Innervation and Blood Supply of Smooth Muscle

Autonomic motor and sensory nerves form nonmyelinated plexuses of fibres which send branches to the muscle fasciculi—the nature of these will be considered elsewhere (pp. 847, 1136).

Capillary networks run in the connective tissue sheaths of the smaller fasciculi in most smooth muscles, but the vascularization is not as dense as in skeletal muscle. In some situations, e.g. the tunica media of muscular arteries, the capillaries may not penetrate the muscle blocks at all, reflecting their low energy requirements.



5.15A A gap junction (nexus) between two smooth muscle cells. × 70,000.

Myoepitheliocytes

These are contractile cells whose embryonic origin is believed to be ectodermal; they occur in association with several types of secretory tissue, either in close contact with the glandular part or the surrounding ducts. Myoepitheliocytes may be either *stellate*, with long dendritic extensions appearing to clasp an adjacent acinus, as in the submandibular gland, where they are known as basket cells, or *fusiform*, as in the intralobular ducts of salivary glands. They are also present around the acini of the mammary gland and the secretory portion of sweat glands. They are often under autonomic nervous control and their contraction initiates a rapid flow of secretion from the apical parts of the glands into the wider ducts.

With the electron microscope (Ellis 1965; Tandler *et al.* 1970), these cells are seen to have extensive desmosomal attachments with surrounding tissues, and internally there are large numbers of fine filaments, 5–10 nm in diameter, similar to the actin filaments of smooth muscle. Histochemically they are rich in alkaline phosphatase, ATPase, and adenyl cyclase (Han *et al.* 1976).

5.15B Diagram showing the principal features of organization of non-striated myocytes. On the left a group of myocytes shows the fusiform shape of the contracted cells, and the arrangement of the autonomic efferent innervation; on the right the main features of the cytoplasmic filaments and membrane systems is depicted. Thick myosin filaments (*green*) are surrounded by irregularly arranged actin filaments (*red*); microtubules, and intermediate filaments, some with associated dense bodies, are also illustrated. The elongated membranous cisternae correspond to the sarcoplasmic reticulum; endocytic vesicles, and a communicating junction between two adjacent myocytes are also visible.

ATTACHMENTS, GENERAL FORM AND ACTIONS OF SKELETAL MUSCLES

Tendons, Aponeuroses and Fasciae

Tendons are integral parts of muscles, forming a component which is for practical purposes often considered to be of unvarying length (but *vide infra*). Being largely composed of collagen fibres they are highly resistant to extension; but they are relatively flexible, and can therefore be angulated around bone surfaces or deflected beneath retinacula (*vide infra*) to change the final direction of pull. Since vascular networks are of low density in tendons, these appear white. Usually taking the form of cords or straps, they are round, oval or elongate in cross-sectional profile and consist of fascicles of collagen fibres, largely running parallel to the long axis but also partly interweaving to some degree. The fascicles may be large enough to give the tendon a longitudinally striated appearance visible to the naked eye, or even to form a duplicated or multiple structure. Some tendons are commonly doubled in this way, and some give rise to minor strands or slips which connect with adjacent tendons. In general the surface of tendons is smooth, but longitudinal ridging due to the arrangement of coarse fasciculi is quite common in large tendons, and may be marked, as on the osseous aspect of the angulated tendon of obturator internus (p. 602). The areolar connective tissue which permeates the tendon between its fascicles, providing a route for vessels and nerves, is condensed on its surface into a so-called sheath, or *epitendineum*; this usually contains elastic as well as irregularly arranged collagen fibres. Such a sheath does not provide a true free surface, being continuous with surrounding areolar tissue, the loose arrangement of which imposes minimal drag on the tendon in its movements. In many situations, however, tendons are separated completely or partially from their surroundings by synovial membrane (*vide infra*).

The tensile strength of tendon is similar to that of bone, i.e. about half that of steel. This is much in excess of ordinary demand. A tendon of cross-sectional area of 1 cm^2 will support 600–1000 kilograms. Although only slightly extensile, they *are* elastic, and considerable contractile energy is transferred to them when their muscles contract. Tendon tissue, in addition to its limited elasticity, also exhibits viscosity. Arnold (1974) has reviewed the literature of biomechanical and rheological properties of tendons, with special reference to the human foot. Certain avian wing tendons are highly elastic; the ultrastructural relations and interactions between collagen and elastin fibres in such structures have been investigated by Oakes and Bialkower (1977).

The blood supply of tendons is provided by a relatively sparse array of small arterioles which run longitudinally from the adjacent muscular tissue to ramify in the interfascicular intervals, where they intercommunicate freely and are accompanied by venae comitantes and lymphatic vessels. The longitudinal network in the tendon is augmented by small vessels from the surrounding areolar tissue or synovial sheath, where the latter is present (Edwards 1946). At their bony attachments the vessels appear to consist of no more than transversely arranged capillaries. There is no evidence of passage of vessels between bone and tendon at these sites, and the osseous surface is usually devoid of foramina (p. 297). The metabolism of tendon tissue is low, but must be increased in reaction to infection or injury. Repair is almost exclusively due to proliferation of connective tissue cells associated with collagen fibres, which take little part in the process (Potenza 1963).

The nerve supply of tendons appears to be largely, if not exclusively, afferent; no clear evidence of vasomotor control is available. Specialized afferent receptors, *neurotendinous endings* (p. 522), exist in tendons, especially near their junctions with muscle. The nerve fibres proceeding centrally from these receptors are carried partly in branches of the 'motor' nerves to the muscle, extending from these longitudinally into the tendon, and also in small branches which pass directly to neighbouring peripheral nerves (Stillwell 1957).

During postnatal growth tendons increase in length interstitially, but particularly at the musculotendinous junction, where there are concentrations of cells for rapid elaboration and deposition of collagen. From this point there is a decreasing growth gradient towards the osseous attachment.

Synovial sheaths and bursae occur in situations where structures which move relative to each other are in tight apposition. This applies particularly to sites where tendons are deflected around bones or under retinacula in the vicinity of joints; but the arrangement is seen at its simplest in a few locations such as the olecranon and the patella, where the skin must move freely over subcutaneous bony surfaces, usually under conditions of pressure. The *bursae* formed at such sites are simply flattened sacs of synovial membrane supported by dense irregular connective tissue; they are interposed in the loose areolar tissue (superficial fascia) between skin and bone, and because of their position are usually known as *subcutaneous bursae*. The degree of flattening of a bursa is obscured by the term 'sac'. Its opposed walls are separated merely by a film of fluid, and it is more of an enclosed cleft. These walls are to some extent tethered to periosteum and dermis, moving with these structures and hence sliding over each other. The whole arrangement is often described as a device to reduce friction, but its most fundamental characteristic is the creation of absolute discontinuity between tissues, yielding complete freedom of movement over a limited range. Each bursa contains a capillary film of synovial fluid acting as a lubricant and providing the cells of the synovial membrane with a wet environment on their free surfaces and a metabolic intermediary between tendons and their surroundings.

The majority of synovial bursae do in fact occur between tendons and bone, tendons and ligaments, or between one tendon and another, being then termed *subtendinous*. They may, however, be sited between muscle on the one hand and bone, tendon or ligament on the other—*submuscular synovial bursae*. They may also separate aponeurotic areas from bone (*subfascial bursae*), or are sometimes *interligamentous*. Not only are the majority of bursae near joints but may communicate with them, so that their synovial membranes are continuous. Such *communicating bursae* may develop separately and are only subsequently connected with the articular cavity; sometimes they ensheath a tendon for a short distance after it has emerged from an intracapsular attachment.

Tendon synovial sheaths occur where tendons pass under ligamentous bands, retinacula, through fascial slings or osseofibrous tunnels. They consist of two concentric layers, separated by a capillary film of synovial fluid and continuous at their extremities. The arrangement is thus a closed double-walled cylinder, the internal or *visceral layer* of which is attached to the tendon by loose areolar tissue, the external or *parietal layer* to neighbouring connective tissue structures or periosteum. Since the tendon is invaginated into the sheath, the visceral and parietal layers are often connected by an elongated mesentery or *mesotendon*. In some sheaths the mesotendons are reduced to localized cords, often multiple, such as the vincula tendinum of the digital synovial tendon sheaths (p. 577).

Where the skin is subjected to repetitive lateral displacement, associated with pressure, as in forearm or elbow in writing, or the buttock in certain sedentary occupations such as hand-weaving, *adventitious bursae* may appear, providing the skin with much more freedom of movement. This may throw some light on the factors involved in the evolution of bursae in general, but the established series develop during intrauterine life.

Some bursal arrangements are more elaborate and illustrate some of the characteristics of a synovial articulation (p. 424). Thus, osseous or cartilaginous sesamoids occur in some tendons, where they are bent around a bone surface, the apposed surfaces being cartilage covered, and the whole enveloped in a localized bursa, e.g. the sesamoid in the tendon of peroneus longus which articulates with the cuboid bone (p. 606), in effect constituting a synovial joint.

Aponeuroses are flat sheets of densely arranged collagen fibres, hence white and showing, like tendons, a surface iridescence, when exposed, due to the regular disposition of the fibres. They are frequently striated, the large fascicles of collagen

being separated by loose interfascicular connective tissue. Aponeuroses usually consist of several layers, the fasciculi being parallel within a layer but inclined in different directions in adjacent layers. In earlier usage the term aponeurosis was applied to any sheet of connective tissue spreading from ('apo-') the edge of a tendon ('neuron', a term originally used indiscriminately for tendons and peripheral nerves, which are not dissimilar in macroscopic appearance), and providing an extension of its attachment. Such an arrangement is exemplified by the levator palpebrae superioris and by the retinacula of the quadriceps extensor tendon, but the term is more widely used for any broad sheet of dense connective tissue associated with the attachment of muscle. Sometimes the whole attachment may be aponeurotic (e.g. obliquus externus abdominis); elsewhere aponeuroses provide extensive auxiliary areas from which muscle fibres arise (e.g. supra- and infra-spinous aponeuroses or fasciae). In these cases the aponeuroses are themselves attached to bone, often providing an additional attachment for muscles partly attached directly to bone.

Fascia is a term so wide and elastic in usage that it signifies little more than a collection of connective tissue large enough to be described by the unaided eye. The advent of tissue fixatives, and especially formalin, which preserve and accentuate areolar tissue, was a great stimulus to the regional naming of fasciae; and the habit of attaching a specific local term to any aggregation of connective tissue, sizeable enough to dissect, is still current, though perhaps on the wane. During development a large number of mesodermal cells are differentiated into bone, muscle, vessels, renal and splenic tissue, etc., but large amounts of mesoderm persist as less specialized connective tissues permeating all regions of the body, not only as the microscopic areolar component between, for example, the fibres of muscle, nerves and tendons, but also in larger macroscopic accumulations between whole muscles, viscera and other large structures. The arrangement of such connective tissue is highly variable. As a result of dissection it appears as condensations on the surfaces of muscles, etc. and is hence spoken of as *investing* fascia, though its function in such a situation is by no means so simple. Between muscles which move extensively upon each other it is usually in the form of very loose areolar tissue, presumably to facilitate movement. The peripheral nerves, blood and lymph vessels travel in the loose 'fascia' between other structures, often bound together as *neurovascular bundles*; and sometimes, in the case of larger vessels, such as the common carotid and femoral arteries, much denser sheaths of connective tissue exist, their precise functions being a matter of conjecture. They may aid venous return by surrounding large veins in company with the pulsating artery, but they may be no more than incidental growth patterns which result from the pulsatile tensions generated by the arteries.

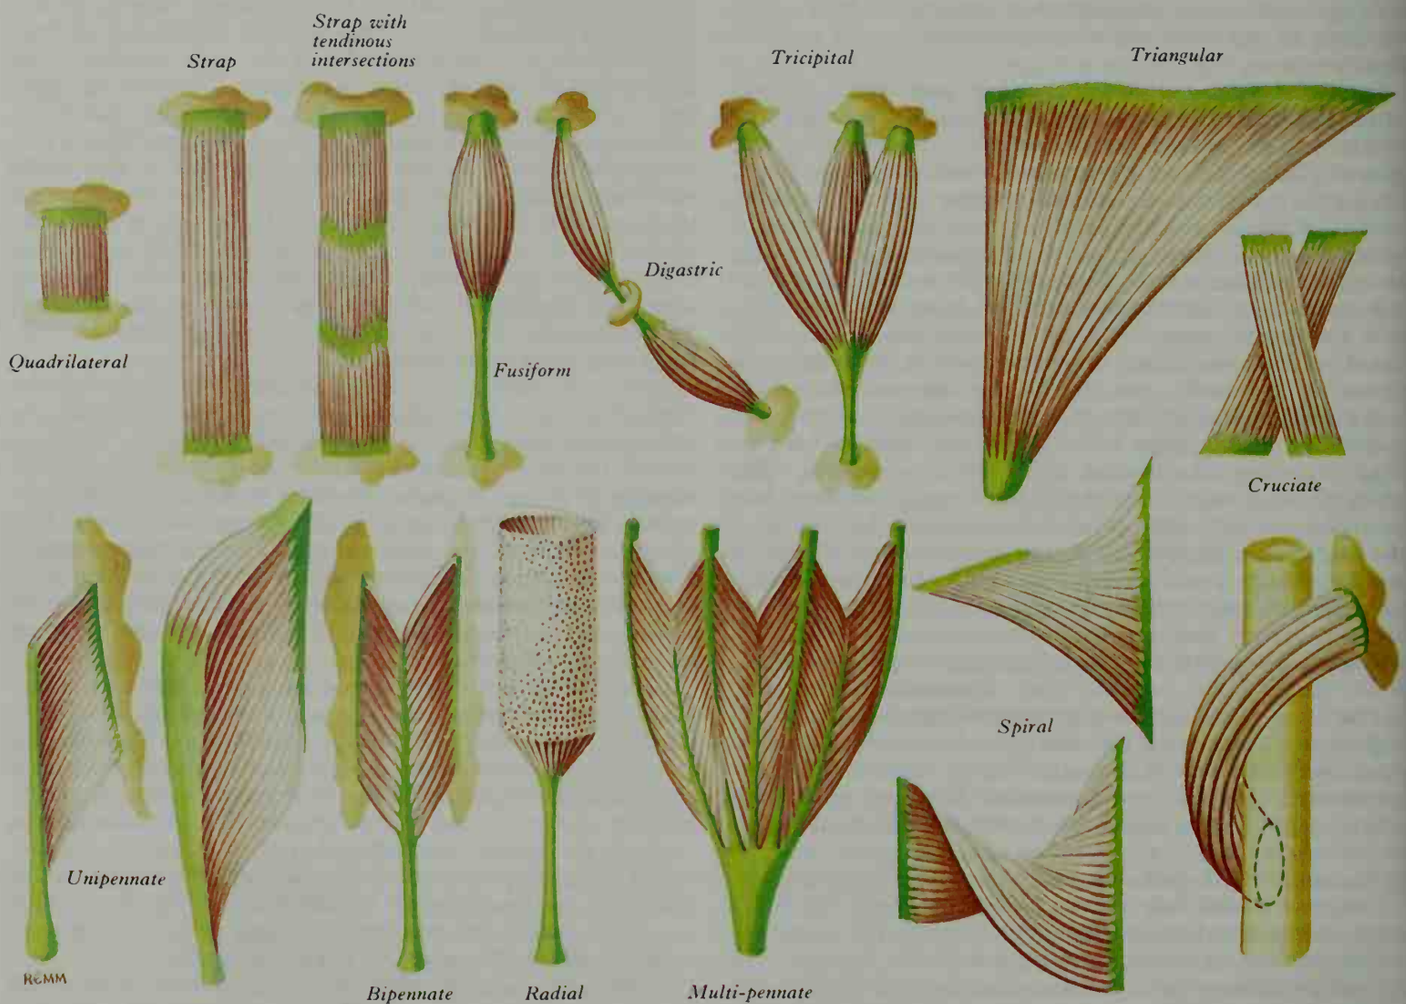
Fats may accumulate in the cells of fibro-areolar tissue wherever it occurs, forming adipose tissue, often well developed in the superficial region between muscles and skin. The dermis is, of course, compacted irregular connective tissue; and deep to this and continuous with it, loose areolar tissue, often adipose and of a variable thickness, is known as the **superficial fascia**. It allows the skin considerable freedom of movement and acts as a thermal insulator. Branches from the subcutaneous nerves, vessels and lymphatics travel in the superficial fascia, but their main trunks are in its deepest part where adipose tissue is scanty or absent. The superficial fascia also contains skin muscles, such as platysma, a representative of much more extensive sheets of skin-twitching musculature in other mammals. The quantity and distribution of its contained fat is different in the sexes. It is somewhat more abundant in females and more generally distributed; in males it diminishes from the trunk towards the extremities and this becomes more obvious in middle age when the total amount increases in both sexes. There is also an association with climate (rather than race), fat in the superficial fascia being more developed in the colder zones of the earth. Superficial fascia is most distinct over the lower part of the anterior abdominal wall, where it contains much elastic tissue and may present the appearance of several layers as it passes through the inguinal region into the thigh. It is also well differentiated in the limbs and perineum. It is thinnest over the dorsal aspects of the hands and feet, the side of the neck, face, around the anus, and especially over the penis and scrotum. It is practically absent from the external ears, or auricles. It is particularly dense in the scalp, the palms and the soles where it is permeated by numerous strong bands of connective tissue binding the superficial fascia and the skin to underlying fibrous structures, which come under the general term, *deep fascia*, but are known regionally as the aponeuroses of the scalp, palm, and sole.

Deep fascia is also composed chiefly of collagen fibres, but these are here arranged more compactly and with a high degree of regularity in their directions, so that deep fascia is often indistinguishable from aponeurotic tissue. As in the latter, the parallel fibres of one layer are usually set at an angle to those of another. In the limbs, where the deep fascia is particularly well developed, many fibres are longitudinal in arrangement, while others encircle the limb, binding the longitudinal fibres together into a tough, inelastic sheath for the musculature. In both arm and leg some of the muscles arise from the internal aspect of the deep fascia, which at these sites performs the same function as an aponeurosis and has the same appearance. Wherever the deep fascia comes into direct contact with bone, or rather its periosteum, it fuses with this and is hence well able to take the pull of attached muscles. A particularly powerful band of deep fascia exists in the thigh to transmit the tension of the tensor fasciae latae, and most of the gluteus maximus, to the tibia (p. 596)—the iliotibial tract. The biceps brachii is partly attached to the deep fascia of the forearm, while the palmar aponeurosis, which not only takes the pull of palmaris longus but also has the small intrinsic muscles of the thumb and minimus partly attached to it, is the deep fascia of the region.

Both in the neck and the limbs, laminae, continuous with the deep fascia and of identical structure, pass inwards between the groups of muscles and connect extensively with bone. These are termed *intermuscular septa*, and they do incidentally separate muscles, or groups of them, sometimes with somewhat different actions, developmental histories, and innervations. Except as a phenomenon of growth, however, most of the smaller resulting 'compartments' are of little significance, for the septa often serve to connect rather than separate muscles, in fact arising from both aspects of a particular septum, which thus functions as an *intermuscular aponeurosis*.

In some situations, the wrist and ankle being prime examples, localized transverse thickenings occur in the deep fascia and are attached at both ends to local bony prominences. These are the *retinacula*, thus termed because they retain tendons passing deep to them which would otherwise be dragged or 'bowed' out of position by the activities of their muscles. In their osseofibrous channels the tendons are deflected to work effectively, smooth action being aided by synovial sheaths. Similar arrangements of deep fascia and bone form the fibrous sheaths or tunnels in which the flexor tendons of the digits, in both hand and foot, are retained—again surrounded by synovial sheaths.

Additionally, and especially in the lower limb, deep fascia contributes to the efficiency of venous return, its contained muscles exerting a pumping effect upon the deep veins during contractions. Regurgitation in the deep veins, or backflow into the superficial veins, is largely prevented by venous valves.



Regional details of the deep and superficial fasciae, retinacula, intermuscular septa, aponeuroses, bursae and tendon sheaths, are included at the appropriate places throughout this section.

The Form of Muscles

There is, of course, a wide variation in the size, shape, complexity, fascicular architecture and, as we have seen, the form of attachment of muscles. Each, however, is well adapted to provide an appropriate range, direction and force of contraction, to meet the habitual requirements at the articulations over which it passes. In this section our particular concern is the general shape of whole muscles, how their fibres vary in number, size and direction relative to the ultimate 'line of pull' at their attachments, and certain aspects of muscle action in which these structural variants are involved.

Individual muscle fibres are by no means uniform in diameter, ranging from 10 to 60 μm, and in length, from a few millimetres in the shortest muscles to many centimetres (15–30 cm and even longer have been quoted for the sartorius muscle). The diametric distribution of the fibres varies considerably with the particular muscle and species under consideration, as does the grouping of fibres into fasciculi by perimysial septa (p. 506). The general texture of the muscle naturally reflects the proportion and distribution of its connective tissue elements, muscles with fine fasciculi often being associated with precision movement patterns (e.g. the extrinsic ocular muscles), whereas coarse fasciculation characterizes many of the larger limb muscles (e.g. gluteus maximus). However, much remains to be investigated concerning the biomechanical significance, morphogenesis, and relation to similar arrangement of fasciculi occurs in the 'bellies' of *fusiform* muscles, which may, however, be quite short, converging to a tendon, sometimes of considerable length at one or both ends. The tendon, of course, may concentrate the force of contraction on to a restricted area of bone surface, or alter the direction of pull, whilst the proportion of the total span of the muscle occupied respectively by belly and tendon is closely related to its maximal range of contraction, which is often quite limited.

The maximum *force* which a muscle can generate is finally dependent upon its effective *mass* of contractile tissue, which in turn reflects the number and dimensions of its contained fibres, whilst, as already implied, its maximum *range* of unrestrained contraction is a function of the *length* of its muscle fibres. Where the fasciculi are parallel to the line of pull at its attachments, full

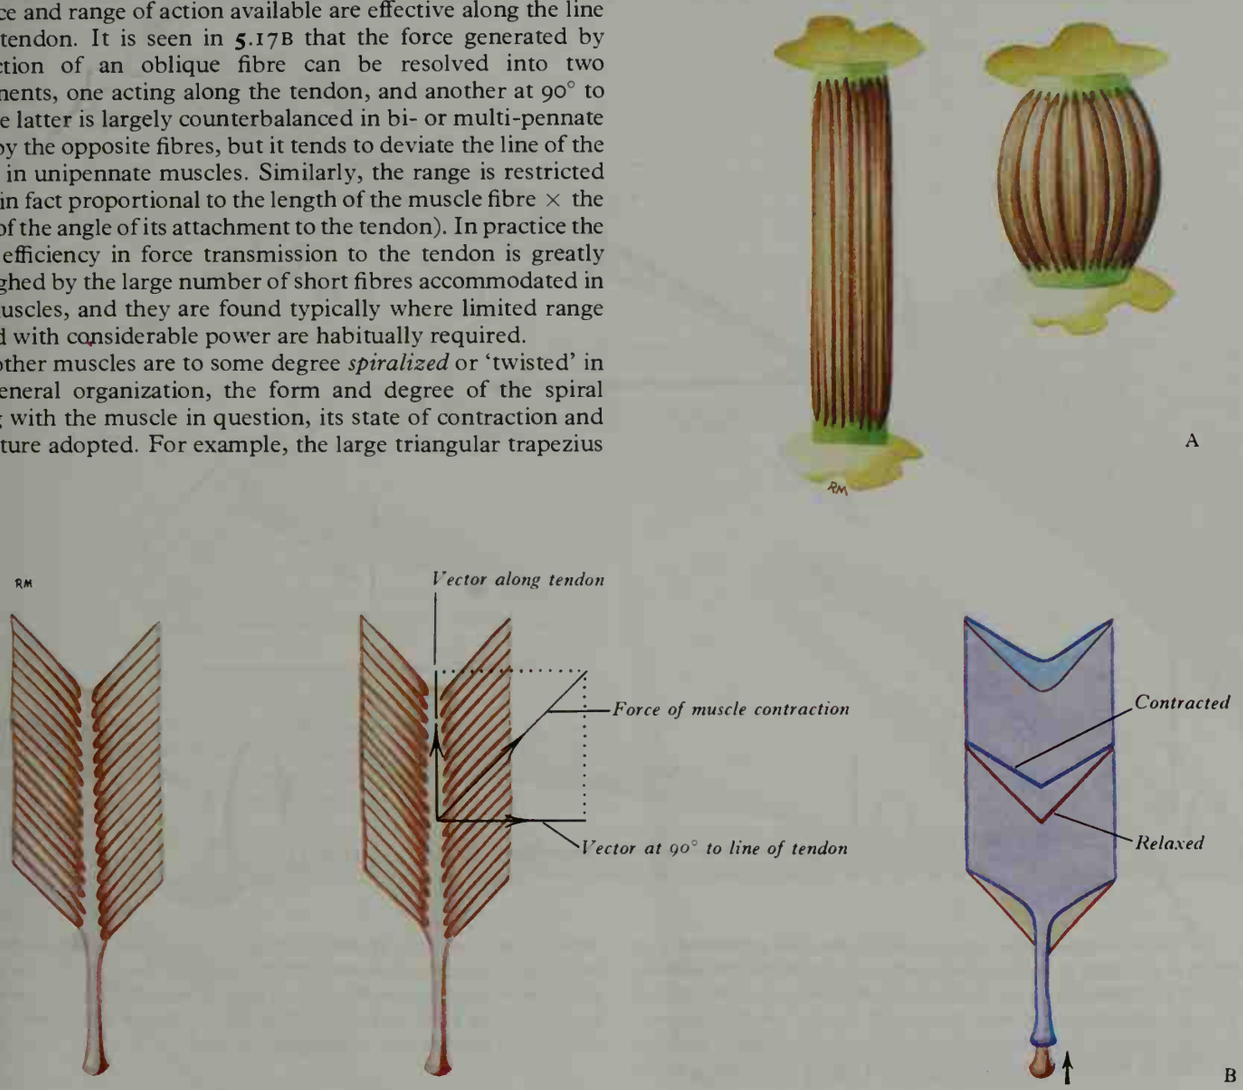
5.16 The morphological 'types' of muscle based upon their general form and fascicular architecture.

vascular and innervation patterns, of the fascicular units in muscles. They must also be carefully distinguished from the motor units which are the essential neuro-muscular functional divisions of a muscle, and which have a different distribution (p. 514), the interrelation of the two being at present obscure.

Broadly speaking, muscles may be grouped according to the orientation of their fasciculi, which may be *parallel*, *oblique*, or *spiralized* relative to the final direction of pull at their attachments (5.16).

Where the fasciculi are approximately parallel to the line of pull, they vary from flat, short and *quadrilateral* (e.g. thyrohyoid) to long and *straplike* (e.g. sternohyoid, sartorius), the individual muscle fibres often running almost the whole length of the muscle. Alternatively, the fibres may traverse shorter segments between irregular, transverse, tendinous intersections distributed at intervals along the muscle (e.g. rectus abdominis). A rather advantage can be taken of both the available force and range (5.17A). However, in straplike muscles, the fibres, although long, are often relatively few in number, and such muscles are particularly effective in circumstances demanding a considerable range of action, coupled with modest power. The bellies of fusiform muscles, however, may be slender or massive, long or short, with similar variations in the length and strength of their associated tendons, and these structural variations show corresponding grades of potential power and range.

Where the fasciculi are *oblique* to the line of pull (5.17B), muscles are variously classed as *triangular* (e.g. temporalis, adductor longus) or *pennate* (feather-like) in their construction. The latter vary in complexity (see 5.16). Examples are—*unipennate*, flexor pollicis longus; *bipennate*, rectus femoris and the dorsal interossei; *multipennate*, deltoid. A similar general architecture also obtains in certain other muscles, e.g. in the main



part of soleus, where the fasciculi pass obliquely between deep and superficial aponeuroses and the muscle when seen in sagittal section is therefore somewhat 'unipennate' in form; in other situations muscle fibres arise from around the walls of osteofascial compartments and converge obliquely towards a centrally sited tendon—these are sometimes termed *circumpennate*, e.g. tibialis anterior. (The terms unipennate and bipennate are unfortunate; feathers or *pennae*, rarely, if ever, consist of a one-sided set of plumules attached to a midrib, like a 'unipennate' muscle. They are almost invariably symmetrical, corresponding to a 'bipennate' muscle. More logical terms would be semipennate and pennate.)

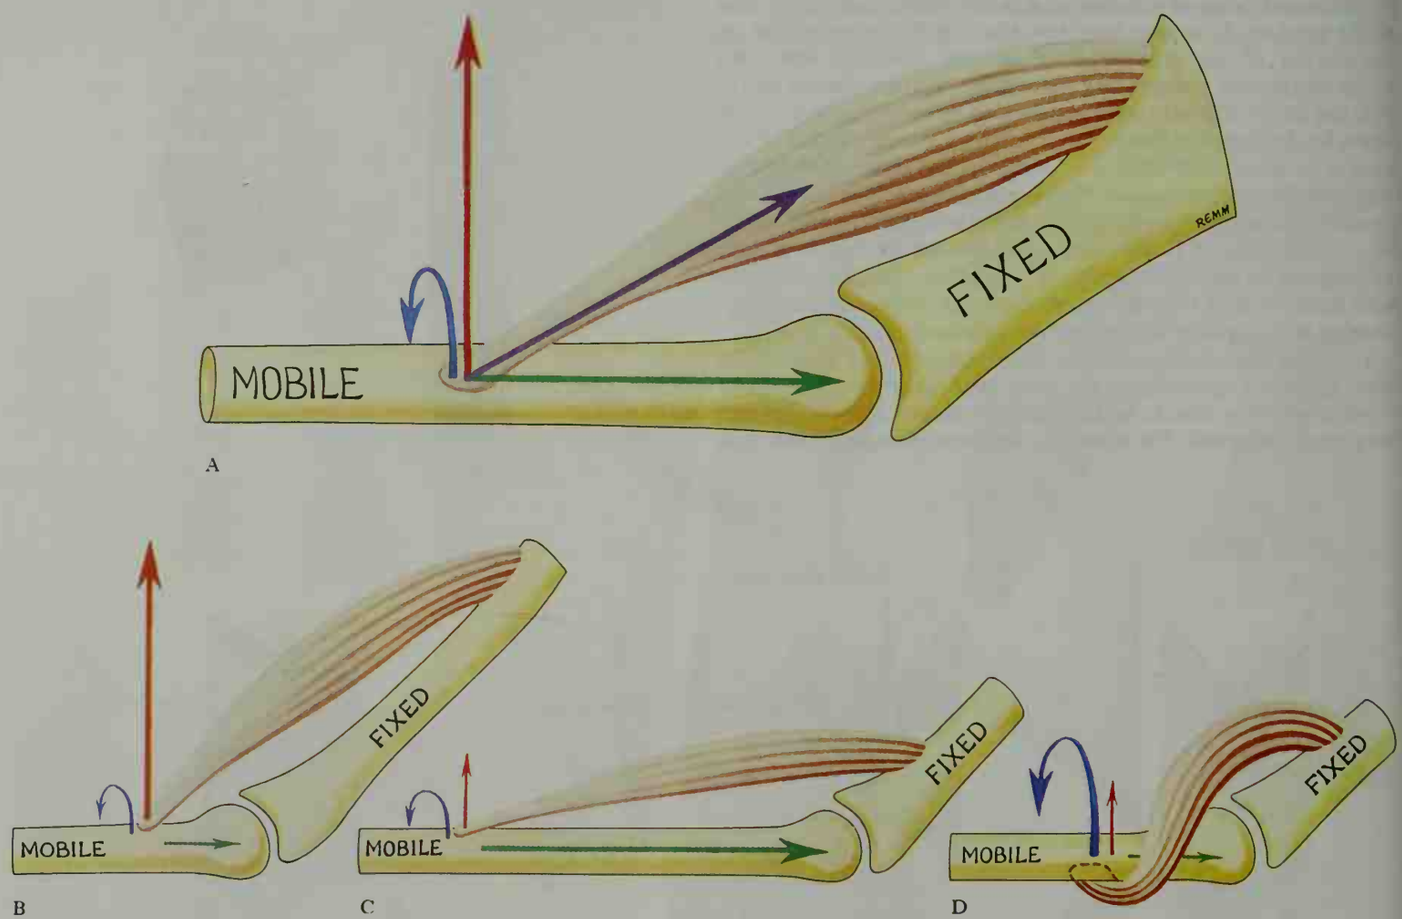
In all these muscle forms, it is evident that only a proportion of the force and range of action available are effective along the line of the tendon. It is seen in **5**.17B that the force generated by contraction of an oblique fibre can be resolved into two components, one acting along the tendon, and another at 90° to this; the latter is largely counterbalanced in bi- or multi-pennate forms by the opposite fibres, but it tends to deviate the line of the tendon in unipennate muscles. Similarly, the range is restricted (and is in fact proportional to the length of the muscle fibre × the cosine of the angle of its attachment to the tendon). In practice the loss of efficiency in force transmission to the tendon is greatly outweighed by the large number of short fibres accommodated in such muscles, and they are found typically where limited range coupled with considerable power are habitually required.

Yet other muscles are to some degree *spiralized* or 'twisted' in their general organization, the form and degree of the spiral varying with the muscle in question, its state of contraction and the posture adopted. For example, the large triangular trapezius muscle has a long linear *vertical* midline attachment, and a *horizontal* curved lateral attachment, the muscle having a 90° twist between the two, with the body erect and the arms pendent. Similar considerations apply to the clavicular head of pectoralis major, whereas its sternocostal fibres, and those of latissimus dorsi, undergo a 180° twist between their midline and lateral attachments. When such muscles contract they not only act to approximate their attachments, but also to bring them into the same plane, and in so doing undergo some 'despiralization' (**5**.20). Elsewhere, muscles are spirally wrapped around a bone which forms one of their attachments, e.g. the supinator, which winds obliquely around the proximal radial shaft; their contraction again involves a reduction of the spiral and the imparting of a strong rotational force to the bone (*vide infra*).

Allied to spiral muscles are those which consist of two or more planes in which the fasciculi run in different directions and are sometimes termed *cruciate* (**5**.16); examples are the sterno-cleidomastoid, masseter and adductor magnus, all of which are both partially spiral and cruciate in form.

Finally, it should be noted that many muscles exhibit regional variations in structure and are often compounded of more than one of the foregoing classical types, and this often reflects contrasting functional roles for the muscle. In this regard it should be emphasized that in some actions, only one region of a muscle may be active, and the remainder quiescent (e.g. see the action of trapezius in upward rotation of the scapula, p. 565).

5.17A and B Simple mechanical considerations related to the actions of A strap, and B bipennate muscles. (For details of the actions of these different muscle types consult text.)



The Actions of Muscles

The analysis of sarcomere construction and its relationship to muscle contraction has made rapid progress up to the present time, and the views current at the time of writing have been set out elsewhere (p. 506). The nature of a simple muscle twitch, the partial or complete fusion of the mechanical responses into a tetanic contraction upon repetitive stimulation, and the concept of the functional neuromuscular territories or motor units, have also been discussed (pp. 514, 894). Ideas of isotonic and isometric forms of contraction, and the varying relationships between sarcomere length and the tension developed on contraction under isometric conditions, and during lengthening, have also received consideration (p. 510).

All these approaches are, of course, essential stages in the development of our understanding of the biology of muscle, but

the distribution of such events in space and time within a whole intact muscle, whilst difficult to analyse experimentally, provides a much greater range and flexibility of response than might at first appear from the previous analysis.

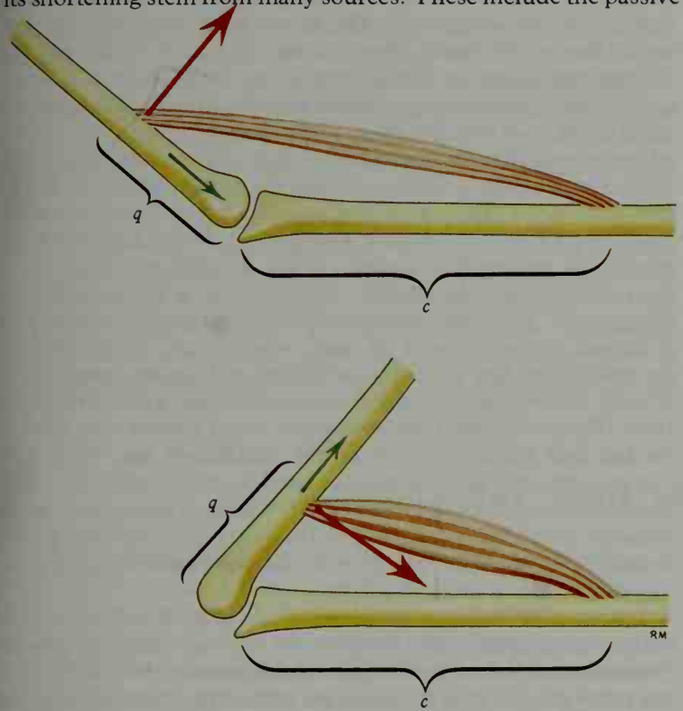
Rapid, repetitive, synchronous stimulation of all, or the majority of the motor units does not occur *in vivo*, and habitual physiological demands are met by the *asynchronous* contraction of only a proportion of the units available. During normal activities, therefore, at any instant in time, the muscle consists of an admixture of motor units in different states, some quiescent, some undergoing stimulation, some contracting and some relaxing, the overall state of the muscle being the integral of these activities.

5.18A–D A—Vectorial analysis of the *force* of contraction generated by a muscle which is attached to a fixed base, crosses a single multiaxial joint and is attached eccentrically to the shaft of a mobile bone. Colour code of arrows: *purple*—muscle force; *red*—transaxial 'swing' vector; *green*—paraxial 'shunt' vector; *blue*—tangential 'spin' vector. Similar analyses relating to muscles which are *predominantly*—B 'spurt', C 'shunt', and D 'spin' in their actions. It should be appreciated that these diagrams have been constructed to illustrate certain principles discussed in the text: they do *not* represent any specific human bone or muscle. It is also clear that, in B and C, if the fixity and mobility of the two bones were interchanged, B would now operate as a 'shunt' muscle, and C as a 'spurt' muscle.

With the passage of time there follows an ever-changing mosiac of active, relaxing and quiescent units. During such a rotation of states of activity between the available motor units, however, the *proportion* active may of course increase, decrease, or remain fairly constant with varying functional demands. Whether the muscle lengthens, shortens, or maintains its length, and what tension changes ensue depend upon many factors. These include the initial length of the muscle, the proportion of active motor units, or rate of change of this proportion, and the sum of the various forces both extrinsic and intrinsic to which the muscle is subjected, partly through its attachments. It must be emphasized that such a mechanism allows an infinite variety of possible quantitative responses of any particular muscle.

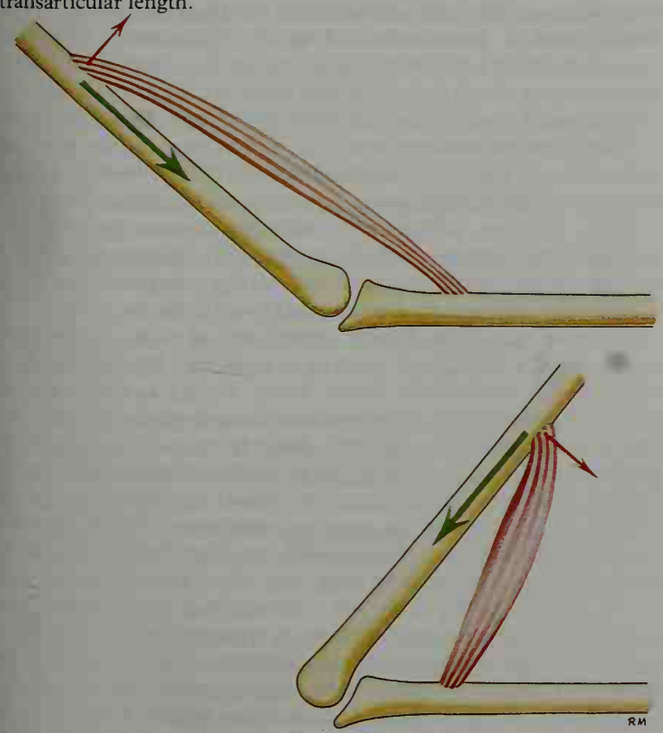
At one extreme, the muscle may be fully relaxed, and under such conditions much electromyographic evidence has accumulated to show that there is no motor-unit activity and the muscle is electrically silent (Joseph *et al.* 1955; Joseph 1960)—these views contrast with many earlier accounts of electrophysiologists who held that the nearest approach to full relaxation was still accompanied by slow 'background' activity rotating among a few motor units. On such accounts many misconceptions concerning the use of the term 'muscle tonus' were based. However, it must be realized that even a fully relaxed muscle is a highly complex three-dimensional structure endowed with *passive viscous, elastic* and other mechanical properties which provide some degree of resistance to deformation (e.g. by stretching). During activity also, such properties of the inactive motor units and their connective tissues provide an initial internal source of resistance, to be taken up and overcome by the active units, before external forces can be opposed and work performed. Such passive attributes of muscle, therefore, contribute greatly to the space-time-force relationship of muscles during the initiation, increase, and maintenance of particular states of activity; they are, of course, of equal importance during diminution and/or cessation of activity.

When an individual muscle fibre or motor unit contracts, it of course tends to approximate its points of attachment, but whether it in fact does so depends upon the force it is capable of generating (a function of its geometry, mass and initial average sarcomere length), balanced against the *extrinsic* and *intrinsic* forces which are transmitted to it through its connective tissues, and which oppose its shortening.



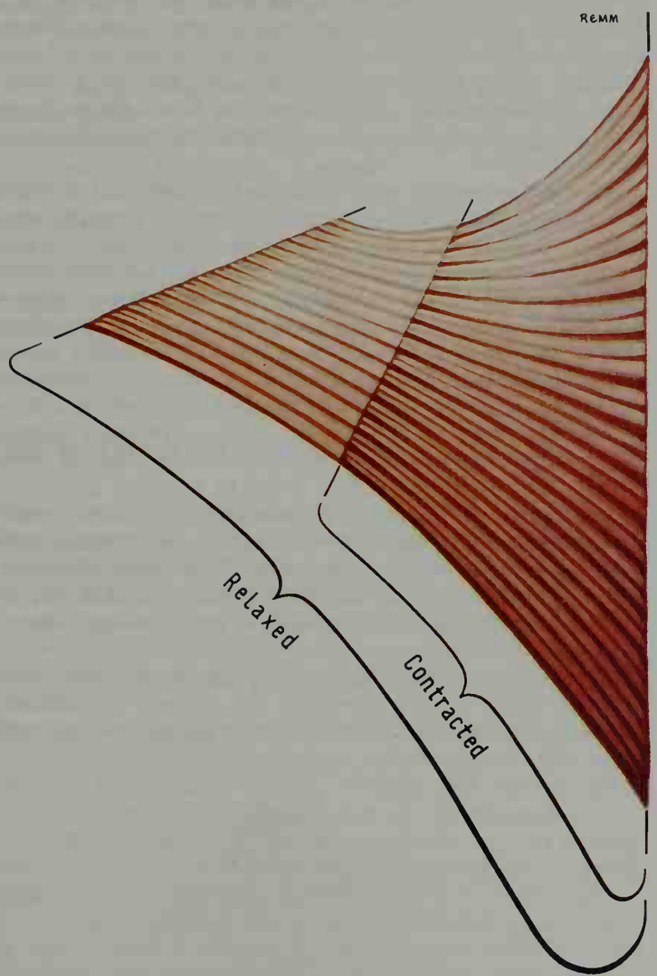
For an active whole muscle, therefore, the following variations in activity are possible. Its original length may be *maintained* (with, of course, slight fluctuations) and the tension generated at its attachments may persist approximately unchanged, or it may increase or decrease, depending upon external circumstances and the number and state of its active motor units. Similarly, the muscle may *shorten* but at the same time, its tension may increase, persist or even decrease with varying conditions. Finally, a muscle

may *lengthen*, and yet again it is particularly important to realize that its tension may decrease, persist or increase with varying demands. It should be clear from the foregoing that when considering whole muscles it is a naïve appraisal to simply correlate the term 'contraction' with only shortening or tension increases, and 'relaxation' with only lengthening or decreases of tension—many other subtle grades of combination are not only possible, but form the whole foundation for the infinitely varied patterns of activity in human behaviour.



When a muscle contracts to initiate a movement, for example a limb muscle across a single joint, the circumstances which oppose its shortening stem from many sources. These include the passive mechanical properties of the muscle itself mentioned above, similar properties of the articular tissues, opposing musculature, and the other soft tissues of the limb, any contractile activity of the opposing musculature, the inertia of the segment to be moved, together with any additional burden carried by it, and finally, the inescapable effect of gravity upon all the foregoing. In general, sufficient motor units are thrown into activity to overcome these resistances and to impart an angular acceleration on the limb segment until a required velocity has been reached, after which only sufficient units continue contracting to maintain this throughout the remainder of the movement.

In practice, the various movements at different joints are carried out by *ordered patterns of activity* in muscle groups and these have been classified according to their role.



Ignoring for a moment movements carried out with the assistance of gravity (*vide infra*), one or more muscles are constantly active in the initiation and maintenance of a particular movement, and these are classed as *prime movers* (e.g. brachialis in elbow flexion); and the muscle or muscles which can wholly oppose such a movement, or initiate and maintain its converse, are termed *antagonists* (e.g. triceps in the example quoted). However, views concerning the interrelation of the two have undergone extensive revision in recent years. For long it was widely held that at the outset of a particular movement, contraction of the prime movers was immediately accompanied by partial contraction of the antagonists, after which smooth continuation of the movement depended upon progressive contraction of the prime movers with simultaneous lengthening and relaxation of the antagonists, the latter finally increasing their contraction to decelerate and terminate the movement. The neural connexions presumed to be responsible for this coordinated activity were

5.19A Some features of a 'spurt' muscle—note that it has a large 'swing' component of its force which acts to impart an angular acceleration to the mobile bone. Its small 'shunt' component acts towards the joint up to 90° of flexion, and thereafter away from the joint. *c*—cisarticular length; *q*—transarticular length.

5.19B Some features of a 'shunt' muscle—the large shunt component of its force acts towards the joint in all positions. In figures 5.19A and B no specific human muscle or bone is intended; in each case it is clear that the right bone is regarded as fixed whilst the left bone is mobile. Clearly their mobilities (and designations) could be interchanged.

5.20 An illustration of the 'detorsion' or untwisting which follows the contraction of a spirally disposed muscle.

incorporated in a '*principle of reciprocal innervation*'. However, it has now been demonstrated that apart from a variable transient burst of activity in the antagonists at initiation of the movement, they then remain quiescent until the final brief deceleration. Nevertheless, the activity of the prime movers is not unrestrained, but is balanced against the various *passive*, *inertial* and *gravitational* effects mentioned above.

There are, however, occasions when prime movers and antagonists *contract together* as *fixators*, increasing the *transarticular compression* (*vide infra*), and *stabilizing* the position of a joint, often to provide an immobile base from which other prime movers can act. Sometimes this stability can be achieved by the effects of gravity alone, e.g. when the joint is in or near its close-packed position (cf. the knee and hip joints in the erect posture, pp. 438, 617), or by prime movers balancing the various passive forces (cf. the stabilization of the humeral head in the glenoid cavity by supraspinatus with a pendent upper limb, pp. 458, 569); when this is not the case or when powerful external forces are encountered, both groups of muscles contract together, holding the joint in any desired position.

It is important to emphasize that virtually all movements (except the theoretically possible, but highly improbable case of a uniaxial joint acting precisely in the horizontal plane), are either opposed or assisted by gravitational forces. This has a profound effect upon the play of musculature during various movements, and prime-mover activity is always replaced by gravity whenever this is appropriate—in such cases the conventionally described roles of muscles are often reversed. For example, the prime mover for extension of the forearm on the arm at the elbow joint is, of course, the triceps (e.g. when thrusting, or partially supporting body weight on the hands with semiflexed elbows). When a weight is lowered from face level to a table, however, the movement of extension is accompanied by active controlled lengthening of the joint flexors. Similar considerations apply in many other circumstances, for example, the increasing length and force of contraction in the hamstrings (extensors of the hip joint), during controlled forwards bending or flexion of the trunk at the hip joints.

In some cases the contraction of a prime mover, acting across a uniaxial joint, simply produces the desired movement; but elsewhere, particularly with multiaxial joints, or when muscles cross more than one joint, the unrestrained contraction of such prime movers may produce additional unwanted movements. The elimination of the latter is effected by the contraction of *synergic* muscles which are, in a sense, partial antagonists to the prime mover. For example, the prime movers of powerful flexion of the fingers at the interphalangeal and metacarpophalangeal joints are the long flexors, superficial and deep, which also cross the intercarpal and radiocarpal joints and which, with unrestrained contraction, would also flex with a loss of efficiency. However, simultaneous contraction of the synergic carpal extensors not only eliminates this, but often produces some degree of extension at the wrist, with further increase of efficiency. (For further examples of synergy, *vide infra*.) Electromyography is now showing that, wherever feasible, movements are effected without using energy-consuming, synergist-dependent muscles. However, the majority of complex movements are the outcome of a finely graded interplay between external forces including gravity, inertia of the masses involved, passive mechanical properties of the various tissues, and the integrated patterns of tension-length variations in prime movers, antagonists, synergists and fixators. These patterns, and the positions of the joints between the body segments are constantly monitored by afferent nerve terminals in the various connective, periarticular and muscular tissues, and are in turn controlled and welded into functionally organized sequences by mechanisms which involve the cooperation of all levels in the central nervous system.

In addition to the foregoing account of muscle action some further concepts and an accompanying terminology have emerged from parallel kinesiological studies of joint and muscle mechanics (MacConaill and Basmajian 1977). These are only touched on briefly here and for a more comprehensive treatment, the references quoted should be consulted.

Illustration **5**.18A shows two bones, one for our present purposes is considered mobile and one fixed in position, articulating at a joint. A muscle which is attached slightly eccentrically to the mobile bone is contracting and exerting a force along the line of its tendon. It can be seen that this *force* can, in relation to the mobile bone, be resolved vectorially into three components. One is *transaxial* acting at right angles to the bone, tending to change its angulation at the joint (i.e. a *swing component*), another is *paraxial* and acts along the shaft of the bone towards the joint and tends to compress the articular surfaces (i.e. a *transarticular* or *shunt component*), and the third acts tangentially around the long axis of the bone and tends to rotate it about this axis (i.e. a *spin component*). The terms spurt and shunt may be unfamiliar to the reader: they originated from terminology used by nineteenth-century British engineers—*see* MacConaill (1949).

The actual movement produced will of course depend upon any constraints built into the shape and ligaments of the articulation, adjacent musculature, and extrinsic and intrinsic forces opposing the movement. Nevertheless, each of the three components has its own functional importance and is enhanced in certain muscles, and less prominent in others (**5**.18B, C, D). For example, when a muscle is markedly eccentric in its attachment to, or even wrapped around the mobile bone, it has a prominent spin component. Thus, the transversely wrapped pronator quadratus is almost a pure muscle of spin, whereas the longer oblique pronator teres has spin, transarticular and swing components. Finally, in contrast, the hamstring muscles exert a powerful swing force (flexion) on the knee joint and a much weaker spin force in medial and lateral rotation of the semiflexed leg. Such spin components of the force may be used as prime movers, e.g. in pronation and supination of the forearm, medial and lateral rotation at the hip joint, etc., or they may be used synergically balancing an opposite spin force, so allowing pure swing to occur (*see* comments on *antispin* p. 437).

Ignoring any spin component, the relative values of the transarticular and swing components will vary according to the distances of the fixed and mobile attachments of the muscle from the joint (**5**.19). These distances are termed the *cisarticular* (*c*) and *transarticular* (*q*) *lengths* respectively, and c/q denotes the *partition ratio* (*p*). When the fixed attachment is distant from the joint and the mobile attachment close to it (**5**.19A), i.e. $p > 1$, there is a powerful swing component and only a modest transarticular (shunt) component, and such a muscle has been designated a *spurt* muscle (and is constructed of spurt myonemes). A typical example is the brachialis muscle acting on the elbow joint from a fixed humerus. Such muscles acting alone are the most effective in initiating and continuing relatively slow movements of swing whether these are weak or powerful, and in carrying out postural readjustments which demand graded alterations of tension and length. In these circumstances the shunt component of the muscle involved is often sufficient to maintain contact between the articular surfaces at the joint. However, it is to be noted that when the angulation of the joint passes 90° the component of force acting along the bone is now directed away from the joint.

In contrast, a *shunt* muscle (composed of shunt myonemes) arising from a fixed base close to a joint and having a mobile attachment at some more distant point, i.e. $p < 1$, shows a large persistent (shunt) force vector acting along the bone towards the joint in all its positions, but only has a trivial swing component (**5**.19B). An often quoted example is brachioradialis acting on the elbow joint from a fixed humerus. Shunt myonemes or whole muscles are necessary in any circumstances which operate strongly to distract the articular surfaces. Such forces may follow loading, e.g. of the pendent arm, but it was also proposed that during a *rapid* swing of a limb segment, e.g. the forearm, the centrifugal force generated tending to separate the joint surfaces, would be too great to be opposed by spurt musculature alone. The latter was therefore assumed to be supplemented synergically by appropriate shunt muscle contractions which provided an opposing centripetal force towards the joint. Evidently, the generation of a centrifugal force, and the need for its opposition, would be independent of the direction of the swing, and shunt activity of the brachioradialis has been demonstrated electromyographically in both rapid flexion and rapid extension of the

forearm (however, *vide infra*). In the foregoing brief discussion of spurt and shunt myonemes and whole muscles it will have become clear to the reader that in any particular instance under consideration, one of the attachments is regarded as fixed (i.e. the 'functional origin') while the other (the 'functional insertion') is attached to a mobile unit. In practice, of course, the relative fixity and mobility of the two attachments are often reversed: in such circumstances, for example, a spurt myoneme would now operate as a shunt myoneme (and *vice versa*). For such reasons the terms origin and insertion have been abandoned in the following pages devoted to descriptions of individual muscles, the more general term attachment being preferred.

Since its first proposal, subsequent refinement, and explicit mathematical statement (for literature *see* MacConaill and Basmajian 1977; and MacConaill 1978a, b, c), the anatomico-kinetic classification of myonemes and whole muscles into spurt and shunt varieties has prompted much discussion and, in some cases, adverse criticism (*see*, for example, the writings of Stern 1971; Rozendal and Molen 1972; Joseph 1973; Jackson *et al.* 1977; and Stanier 1977). In his most recent publications, however, the proposer has stoutly maintained the validity of his *classification* (*see* references above), but has withdrawn certain *hypotheses* based upon this classification. In an attempt to provide a comprehensive 'generalized mechanics of articular swing', the interesting proposal has been made that the centripetal force acting along a bone moving at *any* speed is a *consequence* of its curvilinear motion; not a *cause* of it.

Another absorbing problem which is currently engaging both thoretical and experimental kinesiologists is the analysis of the *patterns* of sequential muscle contractions that occur when two or more muscles are capable of producing the same movement at a particular joint (consult Joseph 1973; and Jackson *et al.* 1977). The latter contend that there is a 'primary' muscle which always initiates the movement, and that 'secondary' muscles are only recruited when a critical level of activity has been reached in the primary muscle. These findings are held to apply to both isotonic contraction and isometric contraction, and the authors emphasize the importance of variations in force and velocity as determinants of sequential patterning. However, the values of the various parameters which, in combination, constitute a critical level of 'activity' have not yet been determined in a wide range of human muscles. It is also of interest that few authors have discussed explicitly the phenomenon of *increasing length* accompanied by *increasing tension* of a myoneme, or a whole muscle—a combination which is commonplace in habitual movements, and clearly should *not* be termed 'relaxation'.

Finally, it must be emphasized that these more advanced considerations of the activities of living myonemes, muscles, and the interplay of groups of muscles, coordinated by a most complex hierarchy of central nervous control systems, render much of the customary myological nomenclature as sometimes redundant, often inaccurate, and frequently frankly misleading.

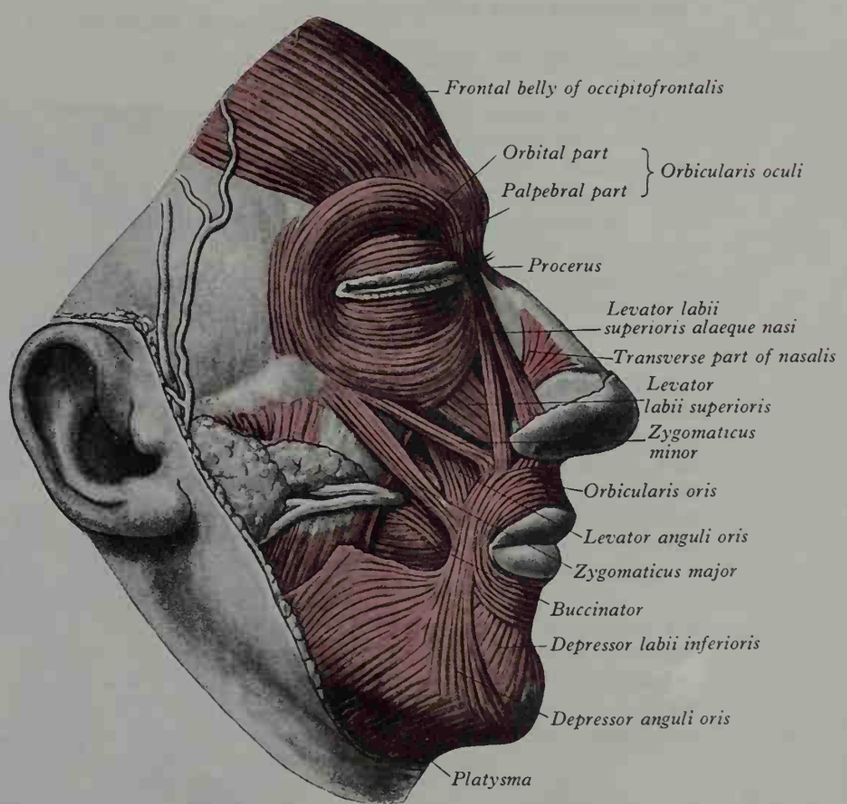
THE FASCIAE AND MUSCLES OF THE HEAD

These are habitually divided into the *facial muscles* which are in large measure related to the orbital margins plus eyelids, the external nose and nostrils, the lips, cheeks and mouth, the pinna, scalp and cervical skin (all, not entirely appropriately, often grouped as 'the muscles of facial expression'); and the *masticatory muscles* primarily concerned with movements of the temporo-mandibular joint. This dual division of head musculature reflects the different embryonic origins and innervations of the two groups, but it must be emphasized that in many functional activities, such as mastication, deglutition, vocalization, communicative and emotional expression, respiration, ocular, aural and nasal action, the two groups are closely cooperative and interdependent.

CRANIOFACIAL MUSCLES

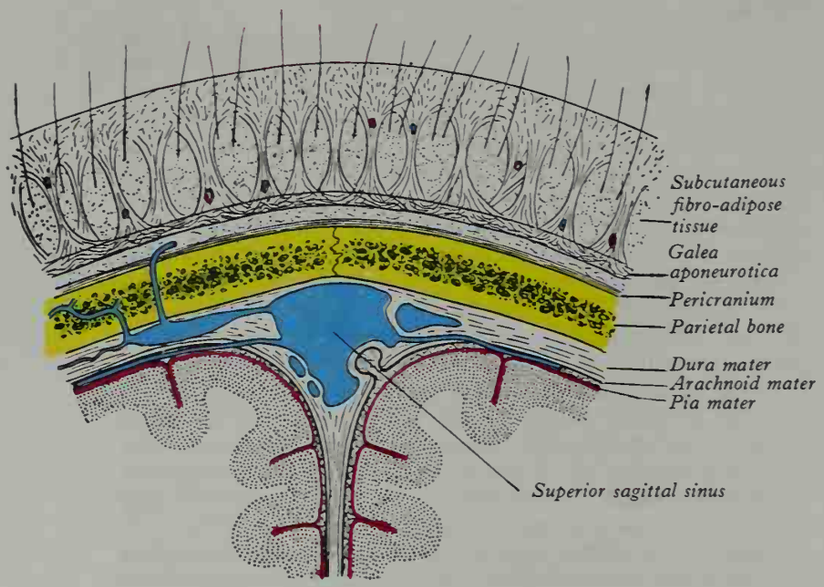
(A) Epicranial Musculature

The epicranius consists of two main parts: M. occipitofrontalis and M. temporoparietalis.



The superficial fascia in the scalp is firm and fibro-adipose, adherent to skin and to the underlying epicranius and its aponeurosis, the *galea aponeurotica* (epicranial aponeurosis); behind, it is continuous with the superficial fascia of the back of the neck; laterally, it is prolonged into the temporal region, where it is looser in texture.

The occipitofrontalis, a broad, musculofibrous layer, covers the dome of the skull, from the nuchal lines to the eyebrows. It consists of four parts—two occipital and two frontal—connected by the galea aponeurotica. (The osseous attachment necessarily interrupts the direct continuity of the galea aponeurotica and the cervical fascia, although, of course, the two are in a sense confluent, and *adherent to bone*, through the medium of the occipital periosteum.)



Each *occipital* part, thin and quadrilateral, arises by tendinous fibres from the lateral two-thirds of the highest nuchal line of the occipital bone and the mastoid part of the temporal bone. It ends in the galea aponeurotica.

Each *frontal* part (5.21) is thin, quadrilateral, and adherent to the superficial fascia. It is broader than the occipital part and its fibres are longer and paler. It has no bony attachments. Its medial fibres are continuous with those of the procerus; its intermediate fibres blend with the corrugator supercilii and orbicularis oculi; its lateral fibres are also blended with the latter muscle over the zygomatic process of the frontal bone. From these attachments the fibres are directed upwards to join the galea aponeurotica in front of the coronal suture. The medial margins of the frontal slips are joined together for some distance above the root of the nose; but between the occipital bellies there is a considerable, though variable interval, occupied by an extension of the galea aponeurotica.

The temporoparietalis is a variably developed sheet of

5.21 Muscles of the scalp and face. Right lateral aspect.

5.22 A coronal section through the scalp, skull and brain.

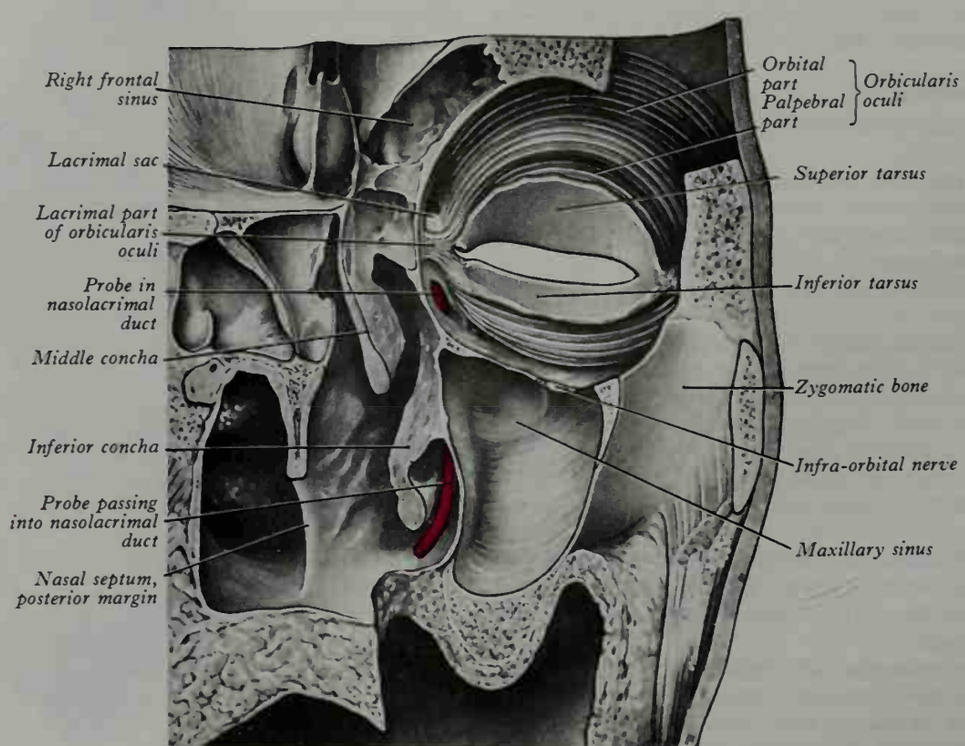
muscle which lies between the frontal part of the occipitofrontalis and the anterior and superior auricular muscles.

The galea aponeurotica (epicranial aponeurosis) covers the upper part of the cranium and forms with the epicranius a continuous fibromuscular sheet extending from the occiput to the eyebrows. Behind, in the interval between the occipital parts of the occipitofrontalis, it is attached to the external protuberance and highest nuchal line of the occipital bone. In front it splits to enclose the frontal parts and sends a short narrow prolongation between them. On each side the auriculares anterior et superior are attached to it; in this situation it becomes thinner, and is continued over the temporal fascia to the zygomatic arch. It is united to the skin by the firm, fibrous superficial fascia; it is connected to the pericranium by loose areolar tissue which allows it free movement, the latter carrying with it the skin of the scalp (5.22). Subdivision of this 'loose' subaponeurotic tissue into three layers has been described (Chayen and Nathan 1974), the intermediate of which is dense and resembles the galea aponeurotica in its attachments.

Nerve supply. The occipital part is supplied by the posterior auricular branch, and the frontal part by the temporal branches, of the facial nerve.

Actions. The occipital slips draw the scalp backwards; the frontal slips acting from above raise the eyebrows and the skin over the root of the nose; acting from below they draw the scalp forwards, throwing the integument of the forehead into transverse wrinkles. The occipital and frontal parts, acting alternately, move the entire scalp backwards and forwards. In the ordinary action of the frontal parts the eyebrows are elevated, a common accompaniment of glancing upwards. The action is also a part of expressions of surprise, horror, or fright, etc.

A thin muscular slip, termed the *transversus nuchae*, is present in about 25 per cent of people; it arises from the external occipital protuberance or from the superior nuchal line, either superficial or deep to the trapezius; it is frequently inserted with the auricularis posterior, but may join the posterior edge of the sternocleidomastoid.



Applied Anatomy. The scalp consists of five layers—skin, subcutaneous tissue, epicranius (and its aponeurosis), subaponeurotic areolar tissue, and pericranium (5.22). But it is better to regard the first three as a single layer, since when torn off in accidents, or turned down surgically, they remain firmly connected to each other. Because of the denseness of the subcutaneous tissue, any inflammatory swelling is slight and a wound which does not involve epicranius or the galea aponeurotica does not gape. Contraction and retraction of arteries is impeded by the dense nature of this tissue and therefore haemorrhage from scalp wounds is often considerable.

The subaponeurotic areolar tissue is surgically important. It is loose and lax, and is easily torn through; hence, it is this tissue which is torn when the scalp is avulsed. The vessels are in the avulsed tissue, and since they anastomose freely, necrosis is unusual.

(B) Circumorbital and Palpebral Musculature

Of the muscles to be considered in this connexion—orbicularis oculi, corrugator supercilii, and levator palpebrae superioris—the last is described with the adnexa of the eye, including the extra-ocular muscles (p. 1178).

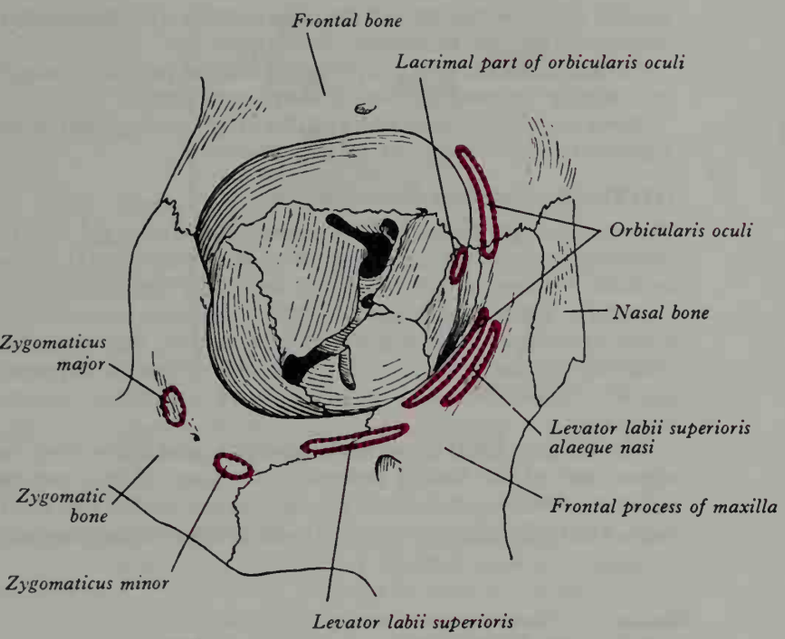
The orbicularis oculi (5.21, 23) is a broad, flat elliptical muscle which occupies the eyelids, surrounds the circumference

5.23 A dissection to expose the right orbicularis oculi from behind.

of the orbit, and spreads on the temporal region and cheek. It consists of orbital, palpebral and lacrimal parts.

The *orbital* part, reddish and thicker than the palpebral fasciculi, arises from the nasal part of the frontal bone, from the frontal process of the maxilla (5.24), and from the medial palpebral ligament, which interrupts the bony attachment. Its fibres form complete ellipses without interruption on the lateral side, the upper ones blending with the frontal part of occipitofrontalis and the corrugator. Many of the upper orbital fibres are inserted into the skin and subcutaneous tissue of the eyebrow. These constitute the *depressor supercilii*.

The *palpebral* part is thin and pale; it arises from the medial palpebral ligament, chiefly from its superficial but also from its deep surface, though not from its lower margin; it arises also from the bone immediately above and below the ligament. The fibres sweep across the eyelids in front of the orbital septum (p. 1185) and at the lateral commissure interlace to form the lateral palpebral raphe. A small group of fine fibres lies close to the margin of each eyelid, behind the eyelashes; it is named the *ciliary bundle*.



The *lacrimal* part lies behind the lacrimal sac, but is separated from it by the lacrimal fascia. It is attached to the lacrimal fascia, to the upper part of the crest of the lacrimal bone, and adjacent part of the lateral surface of the lacrimal bone (5.24). Passing laterally behind the lacrimal sac the muscle divides into upper and lower slips; some fibres are inserted into the tarsi of the eyelids close to the lacrimal canaliculi, but most continue across in front of the tarsi and interlace in the lateral palpebral raphe.

The *medial palpebral ligament*, about 4 mm in length and 2 mm in breadth, is attached to the frontal process of the maxilla in front of the nasolacrimal groove. Crossing the lacrimal sac, it divides into upper and lower parts, each attached to the medial end of the corresponding tarsus. It is separated from the lacrimal sac by the lacrimal fascia.

The *lateral palpebral raphe* is a much weaker structure, formed by the interlacing lateral ends of the palpebral fibres of the orbicularis oculi, strengthened on its deep surface by the orbital septum. A few lobules of the lacrimal gland or, more frequently, a small lobule of fat may lie between it and the more deeply placed lateral palpebral ligament.

Nerve supply. Temporal and zygomatic branches of the facial nerve.

Actions. The orbicularis oculi is the sphincter muscle of the eyelids. The palpebral portion can act under voluntary control, or reflexly, closing the lids gently, as in sleep or in blinking; the orbital portion is more frequently under voluntary control. It should be appreciated that during eye closure, although the major factor is lowering of the upper eyelid, there is also considerable elevation of the lower lid. Thus the palpebral part has upper *depressor* and lower *elevator* fascicles. When the entire muscle contracts, the skin of the forehead, temple and cheek is drawn *towards* the *medial* angle of the orbit, and the eyelids are not only firmly closed, but displaced *in toto* a little medially. The skin is thrown into folds, radiating from the lateral angle of the eyelids; these often become permanent—the so-called 'crow's feet'. The levator palpebrae superioris is an antagonist of the superior palpebral depressor fibres of this muscle since the former raises the upper eyelid and exposes the front of the bulb of the eye. The lacrimal part of the orbicularis oculi draws the eyelids and the lacrimal papillae medially; at the same time it exerts traction on the lacrimal fascia and is said to dilate the lacrimal sac (see also p. 1188). Thus the orbicularis oculi is importantly involved in tear transport. It may affect the disposition and pressure relationships of the palpebral part of the lacrimal gland, its ducts and their orifices; it assists in establishing the sinuous trajectories of the medially coursing tear film across the cornea; it adjusts the deep positioning of the puncta lacrimalia in the lacus lacrimalis, it may reduce pressure in the lacrimal sac, and possibly affects the operation of the ciliary and tarsal glands. The muscle is also an important element in facial expression and ocular reflexes. Partial closure of the palpebral fissure together with bunching and protrusion of the eyebrows diminishes the entry of light, into the eyes. The latter action of the upper orbital fibres, and their peripheral extensions, cause vertical furrowing above the bridge of the nose—features particularly well developed in inhabitants of the tropics. The protective value of the blink reflex is obvious.

5.24 Attachments of muscles around the right orbital opening.

The corrugator supercilii is a small pyramidal muscle, at the medial end of the eyebrow, deep to the frontal part of occipitofrontalis and the orbicularis oculi. From the medial end of the superciliary arch its fibres pass laterally and slightly upwards to the deep surface of the skin above the middle of the supra-orbital margin.

Nerve supply. The temporal branches of the facial nerve.

Actions. The muscle draws the eyebrow medially and downwards, producing, together with orbicularis oculi, the *vertical* wrinkles of the forehead. It assists in drawing the eyebrows downwards in bright sunlight, and is also involved in frowning.

(C) The Nasal Musculature

This group comprises the procerus, nasalis and depressor septi (5.21).

The procerus is a small pyramidal slip continuous with the medial side of the frontal part of the occipitofrontalis. It arises from the fascia covering the lower part of the nasal bone and the upper part of the lateral nasal cartilage; it is inserted into the skin over the lower part of the forehead between the eyebrows.

Actions. The procerus draws down the medial angle of the eyebrow and incidentally produces the transverse wrinkles over the bridge of the nose. It is active in frowning and 'concentration'. It also aids in reducing the glare of bright sunlight.

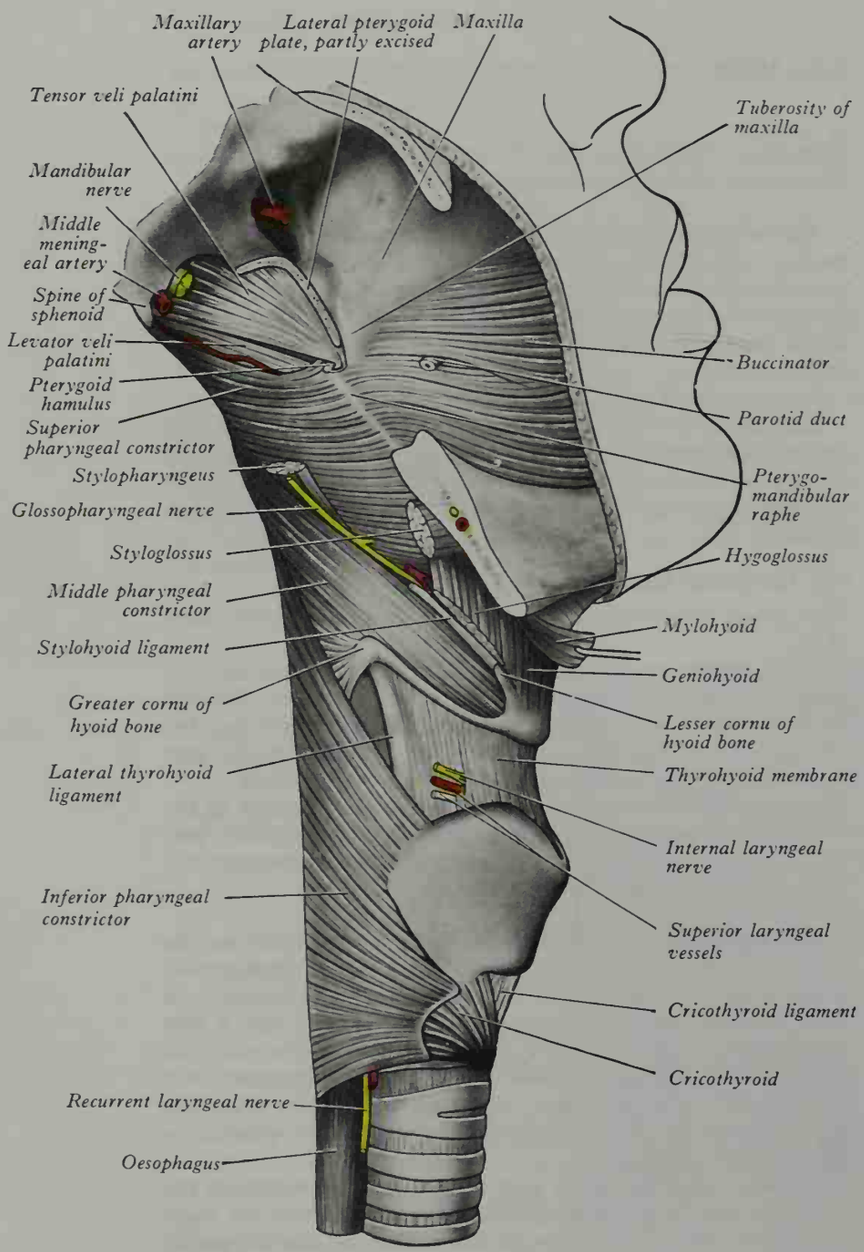
The nasalis consists of transverse and alar parts which may be continuous at their origins. The *transverse part* (compressor naris) arises from the maxilla just lateral to the nasal notch; its fibres proceed upwards and medially and expand into a thin aponeurosis, which is continuous on the bridge of the nose with that of the muscle of the opposite side, and with the aponeurosis of the procerus. The *alar part* (dilatator naris) arises from the maxilla, below and medial to the transverse part. It is attached to the cartilaginous ala nasi.

Actions. The transverse part of the nasalis compresses the nasal aperture at the junction of the vestibule with the nasal cavity. The alar part draws the ala downwards and laterally and so assists in widening the anterior nasal aperture. These actions are visible in deep respiration, especially its inspiratory phase, and they also accompany certain emotional states.

The depressor septi, often regarded as part of the dilatator naris, is attached to the maxilla above the central incisor tooth; it

ascends to the mobile part of the nasal septum. It is immediately deep to the mucous membrane of the upper lip.

Actions. The depressor septi assists the alar part of the nasalis in widening the nasal aperture in deep inspiration.



Nerve supply. All the muscles of this group are supplied by the superior buccal branches of the facial nerve.

(D) The Buccolabial Musculature

The shape of the buccal orifice and the posture of the lips are controlled by a complex assembly of muscular slips (5.21). These include elevators and retractors of the upper lip (levator labii superioris alaeque nasi, levator labii superioris, zygomaticus major and minor, levator anguli oris, and risorius), depressors and retractors of the lower lip (depressor labii inferioris, depressor anguli oris, and mentalis), and a sphincter (orbicularis oris and buccinator).

The levator labii superioris alaeque nasi arises from the upper part of the frontal process of the maxilla and, passing obliquely downwards and laterally, divides into medial and lateral slips. The medial slip is inserted into the greater alar cartilage and skin of the ala of the nose; the lateral slip is prolonged into the lateral part of the upper lip, and blends with the levator labii superioris and orbicularis oris.

Actions. The lateral slip raises and everts the upper lip; the medial slip acts as a dilatator of the nostril.

5.25 Buccinator and the muscles of the pharynx. The zygomatic arch, the masseter, the ramus of the mandible, the temporalis, and a large part of the lateral pterygoid plate and the pterygoids have all been removed. In addition, the upper parts of the stylopharyngeus and styloglossus have been excised, together with the postero-inferior part of the hyglossus and all the infrahyoid muscles.

The levator labii superioris starts from the lower margin of the orbital opening immediately above the infra-orbital foramen, arising from the maxilla and the zygomatic bone. Its fibres converge into the muscular substance of the upper lip between the lateral slip of the levator labii superioris alaeque nasi and levator anguli oris.

Actions. The levator labii superioris raises and everts the upper lip. Together with the zygomaticus minor it forms the nasolabial furrow, from the side of the nose to the upper lip. The furrow is often deepened in the expression of sadness or seriousness.

The zygomaticus minor arises from the lateral surface of the zygomatic bone immediately behind the zygomaticomaxillary suture, and passes downwards and medially into the muscular substance of the upper lip. It is separated from the levator labii superioris by a narrow interval (5.21).

Actions. The zygomaticus minor elevates the upper lip and also produces the nasolabial furrow. When the levator labii superioris alaeque nasi, the levator labii superioris and the zygomaticus minor are in action together, they express contempt and disdain.

The levator anguli oris arises from the canine fossa, just below the infra-orbital foramen, and is inserted into the angle of the mouth, intermingling with the fibres of zygomaticus major, depressor anguli oris, and orbicularis oris. Between the levator anguli oris and the levator labii superioris are the infra-orbital vessels and plexus of nerves (5.26).

Actions. The levator anguli oris raises the angle of the mouth and is instrumental in producing the nasolabial furrow.

The zygomaticus major extends from the zygomatic bone, in front of the zygomaticotemporal suture, to the angle of the mouth, where it blends with the fibres of the levator anguli oris, orbicularis oris, and depressor anguli oris. The zygomaticus major and minor and the levator labii superioris are sometimes more or less concealed by a thin sheet of muscle, named the *musculus malaris* and continuous with the orbicularis oculi (Lightoller 1925).

Actions. The zygomaticus major draws the angle of the mouth upwards and laterally as in laughing.

Nerve supply. All the five preceding muscles are supplied by the buccal branches of the facial nerve.

The mentalis is a conical fasciculus, at the side of the frenulum of the lower lip. It arises from the incisive fossa of the mandible and descends to be attached to the skin of the chin.

Actions. The mentalis raises and protrudes the lower lip, and at the same time wrinkles the skin of the chin, in drinking and also in expressing doubt or disdain. Electromyography shows, it is claimed, fairly continuous activity in mentalis, even to some extent in sleep. The finding is unexplained.

The depressor labii inferioris is quadrilateral and arises from the oblique line of the mandible, between the symphysis menti and the mental foramen, passing upwards and medially into the skin of the lower lip, blending with its fellow and orbicularis oris. At its origin it is continuous with platysma. Much fat is intermingled with the superficial fibres of this muscle.

Actions. The depressor labii inferioris draws the lower lip downwards and a little laterally in masticatory activity; it also contributes to the expression of irony.

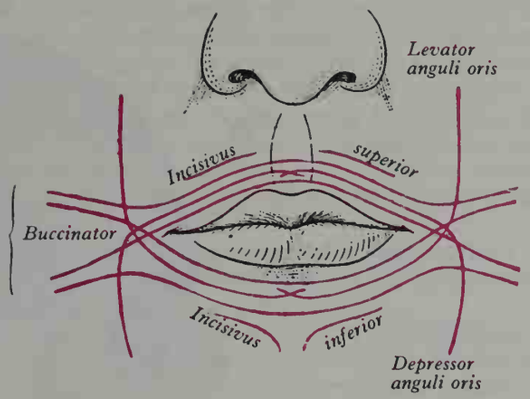
The depressor anguli oris arises from the oblique line of the mandible, below and lateral to the depressor labii inferioris; it converges into a narrow fasciculus blending with other muscles at the angle of the mouth. At its origin it is continuous with

platysma, and at its insertion with orbicularis oris and risorius; some of its fibres are directly continuous with those of levator anguli oris, and others occasionally cross to the muscle of the other side; these latter fibres constitute the *transversus menti*.

Actions. The depressor anguli oris draws the angle of the mouth downwards and laterally in opening the mouth and in the expression of sadness.

Nerve supply. The mentalis, depressor labii inferioris and the depressor anguli oris are all supplied by the mandibular marginal branch of the facial nerve.

The buccinator (5.25) is a thin quadrilateral muscle, occupying the interval between the maxilla and the mandible, in the cheek. It is attached to the outer surfaces of the alveolar processes of the maxilla and mandible, opposite to the three molar teeth and, behind, to the anterior border of the pterygomandibular raphe, which separates the muscle from the superior constrictor of the pharynx. Between the tuberosity of the maxilla and the upper end of the pterygomandibular raphe a few fibres spring from a fine tendinous band which bridges the interval between the maxilla and the pterygoid hamulus. The tendon of the tensor veli palatini on its way to the soft palate pierces the pharyngeal wall in the small gap which lies behind this tendinous band (5.25). The fibres of the buccinator converge towards the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the orbicularis oris, and those from above with the lower segment; the highest and lowest fibres are continued forward into the corresponding lip without decussation.



Relations. The buccinator is on the same plane as the superior pharyngeal constrictor and is covered by the buccopharyngeal fascia. *Superficially*, posteriorly, a large mass of fat separates it from the ramus of the mandible, masseter and a small portion of temporalis; this fat was originally named the suctorial pad, but its association with the act of sucking is not obvious. Anteriorly, the superficial surface of buccinator is related to zygomaticus major, risorius, levator and depressor anguli oris, and the parotid duct, which pierces it opposite the third upper molar tooth; the facial artery and facial vein cross it; it is also crossed by branches of the facial and buccal nerves. The *deep surface* is related to the buccal glands and mucous membrane of the mouth.

Nerve supply. The buccinator is supplied by the lower buccal branches of the facial nerve.

Actions. The buccinators compress the cheeks against the teeth, so that during the process of mastication the food is passed between them. Also when the cheeks have been previously distended with air, the buccinators expel it between the lips, as in any act of blowing; hence the name *buccinator*=a trumpeter.

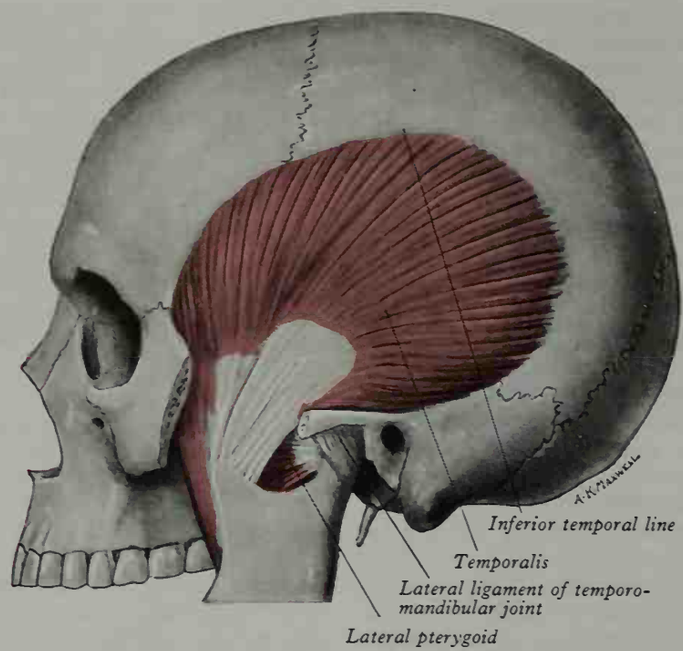
The pterygomandibular raphe is an interlacing of tendinous fibres stretching from the hamulus of the medial pterygoid plate down to the posterior end of the mylohyoid line of the mandible. *Medially* it is covered by the mucous membrane of the mouth. *Laterally* it is separated from the ramus of the mandible by a quantity of adipose tissue. *Posteriorly* it gives attachment to the superior constrictor of the pharynx, and *anteriorly* to a part of the buccinator (5.25).

The orbicularis oris (5.21, 25) is made up of several strata which surround the orifice of the mouth but have different directions. It consists partly of fibres derived from the other facial muscles which pass into the lips, and partly of fibres proper to them. Of the former, a considerable number are derived from the buccinator, and form the deeper stratum. Some of the buccinator fibres—namely, those near the middle of the muscle—decussate at the angle of the mouth; the uppermost and lowermost fibres pass across the lips from side to side without decussation. Superficial to this is a second stratum, formed by the levator and depressor anguli oris, which cross each other at the angle of the mouth; the fibres from the levator pass to the lower lip, and those from the depressor to the upper lip, along which they run to the skin near the anterior median line. Fibres are also derived from the levator labii superioris, the zygomaticus major and minor, and the depressor labii inferioris; these intermingle with the transverse fibres described above, and have principally an oblique

5.26 Arrangement of the fibres of the orbicularis oris.

direction. Some eight or nine muscles thus converge on each of the two angles of the mouth and interlace here at a palpable nodular mass, the *modiolus*. This can be fixed in a given position by the combined action of the zygomaticus major, levator anguli oris and the depressor anguli oris. These thus serve to fix the attachments of the orbicularis oris and the buccinator in this area. Within the lips the fibres of the orbicularis oris are divisible into two fasciculi, the *marginal* and *peripheral*. These combine laterally to form the *labial bands* which are traceable to the modiolus (Lightoller 1925; Burkitt and Lightoller 1926, 1927). The proper fibres of the lips are oblique, and pass from the deep surface of the skin to the mucous membrane, through the thickness of the lip. Finally, there are fibres by which the muscle is connected with the maxillae above, and with the mandible below. In the upper lip these constitute the *incisivus labii superioris*, which arises from the alveolar border of the maxilla, opposite the lateral incisor tooth, and arching laterally is continuous with the other muscles at the angle of the mouth. The additional fibres for the lower lip constitute a slip, *incisivus labii inferioris*, on each side; this slip arises from the mandible, lateral to the mentalis, and mingles with the other muscles at the angle of the mouth. In a study of a small number of fetal lips (14–25 weeks) Latham and Deaton (1976) concluded that orbicular fibres interlace and cross the midline to their cutaneous insertions, thus creating the ridges of the philtrum of the upper lip.

Nerve supply. The orbicularis oris is supplied by the lower buccal and the mandibular marginal branches of the facial nerve.



Actions. The orbicularis oris in its ordinary action effects the direct closure of the lips; by its deep, and oblique, fibres it compresses the lips against the teeth. The superficial part, consisting principally of the decussating fibres, brings the lips together and protrudes them. The orbicularis oris and other muscles of the lip play an important part in articulation, as well as in mastication (Duckworth 1947).

The risorius arises from the parotid fascia and is inserted into the skin at the angle of the mouth. It is a narrow bundle of fibres, broadest at its origin, but varying much in its size and form. The muscle may be absent or reduplicated; it may arise from the zygomatic arch, external ear, or the fascia over the mastoid process.

Nerve supply. The risorius is supplied by the buccal branches of the facial nerve.

Actions. The risorius retracts the angle of the mouth, and produces a sardonic expression.

Revelation of emotional state, intentions, and so forth by facial expression serves obvious social functions; but the facial musculature is even more frequently and usefully concerned in speech. There can be no doubt which is the more important form of communication. The niceties of speech immeasurably outstrip the repertoire of even the most expressive face. Nine muscles converge upon the mouth from each side to control the intricate labial movements of speech; occasionally they may curl the lips in irony or a sardonic grin. It is also important not to overlook the contribution of the facial musculature in feeding and drinking, in

5.27 Left temporalis. The zygomatic arch and masseter have been removed.

all their phases. Unfortunately, the individual activity of facial muscles has been little studied by experimental techniques and their participation in different movements is largely a matter of simple observation. Their role in mastication has been the subject of electromyographic study (Vitti *et al.* 1975).

MASTICATORY MUSCLES

The muscles immediately concerned with the movements of the mandible in mastication (and speech), are the masseter, temporalis and pterygoid muscles.

A strong layer of fascia, derived from the deep cervical fascia and named the **parotid fascia**, covers the masseter and is firmly connected with it. It is attached to the lower border of the zygomatic arch, and invests the parotid gland (p. 1272).

The masseter (5.34) is quadrilateral, and consists of three superimposed layers blending anteriorly. The *superficial layer*, the largest, arises by a thick aponeurosis from the zygomatic process of the maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch; its fibres pass downwards and backwards, to be inserted into the angle and lower half of the lateral surface of the ramus of the mandible. Intramuscular tendinous septa in this layer are responsible for the ridges on the bone. The *middle layer* arises from the deep surface of the anterior two-thirds of the zygomatic arch and from the lower border of the posterior third and is inserted into the middle of the ramus of the mandible. The *deep layer* arises from the deep surface of the zygomatic arch and is inserted into the upper part of the ramus of the mandible and into the coronoid process. The middle and deep layers together constitute the deep part of the masseter of the Nomina Anatomica (MacDougall 1955); these two layers form a *cruciate* muscle (p. 525). On account of its proximity to the skin, the masseter can be palpated when it is thrown into contraction vigorously, as in clenching the teeth. It has been stated (McConaill 1975) that the most superficial fibres of masseter are continued through their attachment at the lower border of the mandible, into the attachment of the medial pterygoid muscle. For more complex accounts of the lamination of the masseter consult Schumacher (1961), and Yoshikawa and Suzuki (1969).

Relations. *Superficial* to the muscle are the integument, platysma, risorius, zygomaticus major, and parotid gland; the parotid duct, branches of the facial nerve, and the transverse facial vessels cross the muscle. The *deep surface* overlies the insertion of temporalis and the ramus of the mandible; a mass of fat separates it in front from buccinator and the buccal nerve. The masseteric nerve and artery reach the deep surface of the muscle by passing through the dorsal part of the mandibular incisure. The *posterior margin* is overlapped by the parotid gland; the *anterior margin* projects over the buccinator and is crossed below by the facial vein.

Nerve supply. The masseter is supplied by a branch of the anterior trunk of the mandibular nerve. (See also medial pterygoid p. 536.)

Actions. The masseter elevates the mandible to occlude the teeth in mastication. Its activity in the resting position of the mandible is minimal. It has a small effect in side-to-side movements, protraction or retraction. An analysis of muscle fibre numbers and their diameter distribution, together with attempts to equate these data with dental occlusive forces, has been made by Rinqvist (1974).

The temporal fascia covers the temporalis. It is a strong, fibrous investment covered, laterally, by the auriculares anterior et superior, the galea aponeurotica and part of orbicularis oculi. The superficial temporal vessels and the auriculotemporal nerve ascend over it. Above, it is a single layer, attached to the whole of the superior temporal line; below, it has two layers, one attached to the lateral and the other to the medial margin of the upper border of the zygomatic arch. A small quantity of fat, the zygomatic branch of the superficial temporal artery, and the zygomaticotemporal branch of the maxillary nerve are between these layers. The deep surface of the fascia affords attachment to the superficial fibres of the temporalis.

The temporalis (5.27) is fan-shaped and arises from the whole of the temporal fossa (except the part formed by the zygomatic bone) and from the deep surface of the temporal fascia. Its fibres converge and descend into a tendon which passes through the gap between the zygomatic arch and the side of the skull, to be attached to the medial surface, apex, anterior and posterior borders of the coronoid process, and the anterior border of the ramus of the mandible nearly as far as the last molar tooth.

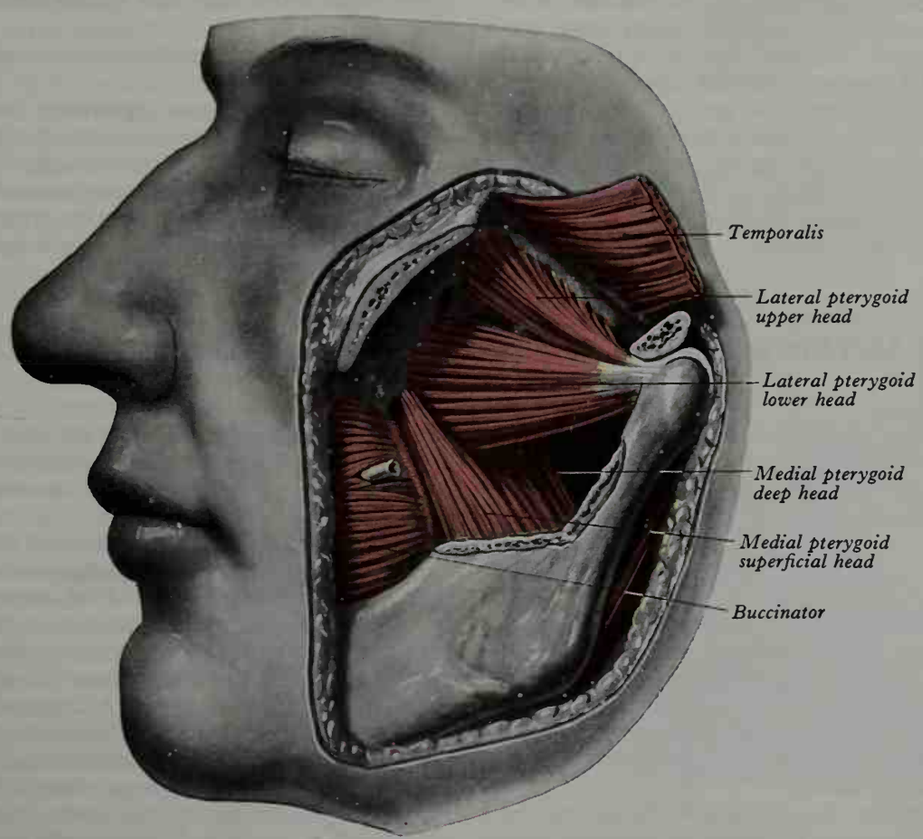
Relations. *Superficial* to the muscle are the skin, the auriculares anterior et superior, the temporal fascia, the superficial temporal vessels, the auriculotemporal nerve, the temporal branches of the facial nerve, the zygomaticotemporal nerve, the galea aponeurotica, the zygomatic arch, and the masseter. The *deep surface* is in relation with the temporal fossa, the lateral pterygoid, the superficial head of the medial pterygoid and a small part of the buccinator, the maxillary artery and its deep temporal branches, the deep temporal nerves, and the buccal vessels and nerve. *Behind* the tendon of the muscle the vessels and

masseteric nerve traverse the mandibular incisure. The *anterior border* is separated from the zygomatic bone by a mass of fat.

Nerve supply. The temporalis is supplied by the deep temporal branches of the anterior trunk of the mandibular nerve. (See also medial pterygoid p. 536.)

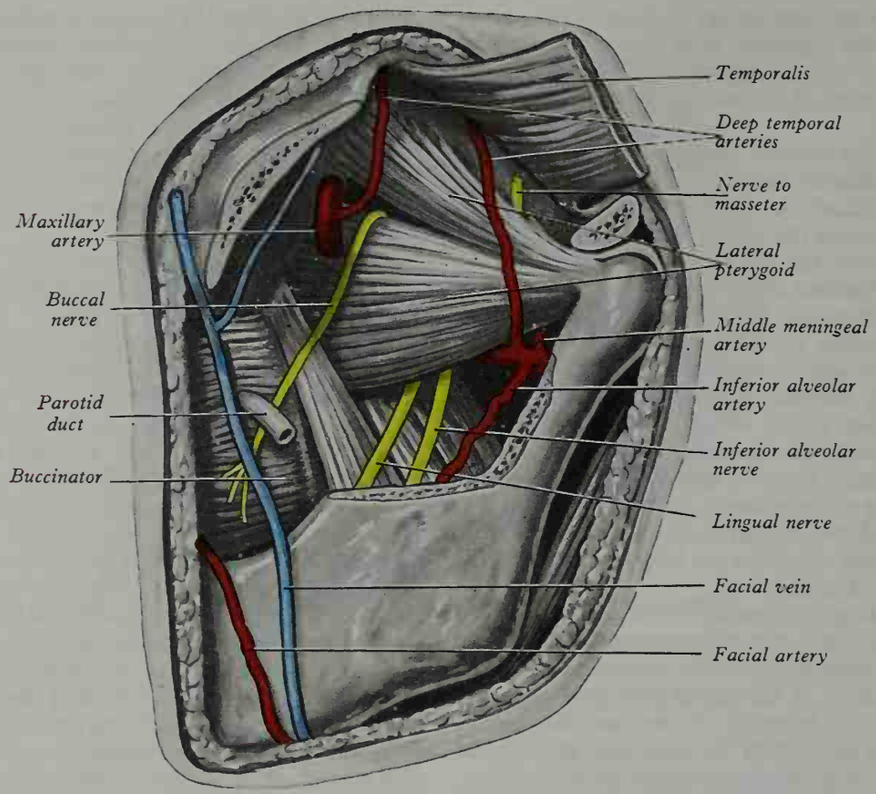
Actions. The temporalis elevates the mandible and so closes the mouth and approximates the teeth. This movement requires both the upward pull of the anterior fibres and the backward pull of the posterior fibres, because the head of the mandible rests on the articular eminence when the mouth is open. The posterior fibres draw the mandible backwards after it has been protruded. It is also a contributor to side-to-side grinding movements. Despite numerous electromyographic studies little can be added in further analysis of these activities, there being considerable unresolved disagreement between workers. The most recent study (Vitti and Basmajian 1977), however, suggests that the temporalis is active in forcible elevation, but not involved in slow elevation without occlusion: otherwise this study confirmed the above description. Owing to the strength of the temporal fascia, the muscle is not easy to palpate, but its contraction is easy to feel. Its upper limit can be made out along the inferior temporal line when the teeth are firmly clenched.

The lateral pterygoid (**5**.28), is a short, thick muscle with two parts or heads: an *upper* from the infratemporal surface and infratemporal crest of the greater wing of the sphenoid bone, and a *lower* from the lateral surface of the lateral pterygoid plate. Its fibres pass backwards and laterally, to be inserted into a depression on the front of the neck of the mandible, and into the articular capsule and disc of the temporomandibular articulation.



Early in the third month of intrauterine life the lateral pterygoid is inserted into the mesenchyme condensed around the developing condyle of the mandible, but a part of its tendon sweeps backwards above the condyle and gains insertion into that portion of Meckel's cartilage which later forms the head of the malleus (Harpman and Woollard 1938). This part of the tendon becomes incorporated into the articular disc of the temporomandibular joint, although its attachment to the malleus does not persist (Rees 1954).

Relations. Its *superficial surface* is related to the ramus of the mandible, the maxillary artery, which crosses it, either deep or superficial to it, the tendon of the temporalis and the masseter. Its *deep surface* rests against the upper part of the medial pterygoid, the sphenomandibular ligament, the middle meningeal artery, and the mandibular nerve; its *upper border* is in relation with the temporal and masseteric branches of the mandibular nerve, its *lower border* with the lingual and inferior alveolar nerves. The buccal nerve and the maxillary artery pass between the parts of the muscle (**5**.29).



Nerve supply. The lateral pterygoid is supplied by a branch from the anterior trunk of the mandibular nerve. (See also nerve supply of medial pterygoid p. 536).

Action. The lateral pterygoid assists in opening the mouth by pulling forward the condylar process of the mandible and the articular disc, while the head of the mandible rotates on the articular disc (Posselt 1952). In the reverse movement of closure the backward gliding of the articular disc and condyle of the mandible is controlled by the slow elongation of the lateral pterygoid, while the masseter and temporalis restore the jaw to the occlusal position. Acting with the medial pterygoid of the same side the lateral pterygoid advances the condyle of that side so that the jaw rotates about a vertical axis through the opposite condyle. When the medial and lateral pterygoids of the two sides act together they protrude the mandible so that the lower incisors project in front of the upper. Some authorities have ascribed different actions to the two parts of the lateral pterygoid muscle, the upper (superior) head being involved in chewing, the inferior in protrusion. Electromyographic records in rhesus monkeys (Macnamara 1972) favour this view. For a review and a mechanical assessment, consult Grant (1973).

The medial pterygoid (**5**.28), a thick, quadrilateral muscle, is attached to the medial surface of the lateral pterygoid plate and the grooved surface of the pyramidal process of the palatine bone; it also has a more superficial slip from the lateral surfaces of the pyramidal process of the palatine bone and tuberosity of the maxilla, and lies at first on the surface of the lower part of the lower head of the lateral pterygoid. Its fibres pass downwards, laterally, and backwards, and are attached, by a strong tendinous

5.28 The left pterygoid muscles. The zygomatic arch and part of the ramus of the mandible have been removed.

5.29 The structures related to the left pterygoid muscles.

lamina, to the postero-inferior part of the medial surfaces of the ramus and angle of the mandible, as high as the mandibular foramen and nearly as far forwards as the mylohyoid groove (3.81). This area is often rugged, due to the tendinous fasciculi in this attachment.

Relations. The *lateral surface* is related to the ramus of the mandible, from which it is separated, above, by the lateral pterygoid, the sphenomandibular ligament, the maxillary artery, the inferior alveolar vessels and nerve, the lingual nerve, and a process of the parotid gland. The *medial surface* is related to the tensor veli palatini, and is separated from the superior constrictor by the styloglossus, the stylopharyngeus and some areolar tissue.

Nerve supply. The medial pterygoid is supplied by a branch from the mandibular nerve. Schumacher and his colleagues (1976) have investigated the ramifications of the muscular nerves of the masticatory muscles in detail. They observed a very similar mode of branching in all these muscles.

Actions. The medial pterygoids assist in elevating the mandible. Acting with the lateral pterygoids they protrude it. When the two pterygoid muscles of one side are in action, the corresponding side of the mandible is swung forwards and to the opposite side, while the head of the mandible on the other side undergoes a slight degree of rotation (p. 440); by an alternating action of the muscles of the two sides, the side-to-side movements, which take place during trituration of the food, are effected.

For a further analysis of these activities *see* pp. 440–443 and references therein.

The pterygospinous ligament, which is occasionally replaced by muscle fibres, stretches between the spine of the sphenoid bone and the posterior border of the lateral pterygoid plate near its upper end. It is sometimes ossified and then helps to bound a foramen which transmits the branches of the mandibular nerve going to the temporalis, masseter and lateral pterygoid.

THE ANTEROLATERAL MUSCLES AND FASCIAE OF THE NECK

The anterolateral muscles of the neck will be described in the following groups:

I. Superficial and lateral cervical.
II. Suprahyoid and infrahyoid.
III. Anterior vertebral.
IV. Lateral vertebral.

The superficial cervical fascia is usually a thin lamina investing the platysma and is hardly demonstrable as a separate layer. It may, however, contain considerable amounts of adipose tissue, and usually does so to a greater extent in the female. Like all superficial fascia it is, of course, not a separate membrane, but merely a zone of loose connective tissue between dermis and deep fascia, to both of which it is united.

The deep cervical fascia (5.30) lies internal to platysma, and invests the muscles of the neck. It consists of the fibro-areolar tissue which exists between the muscles, viscera, vessels, etc., of the neck. In certain situations it forms well-defined fibrous sheets; elsewhere it is loosely arranged. It becomes condensed around the blood vessels, as fibrous sheaths which here, as elsewhere in the body, bind the arteries and their accompanying veins closely together.

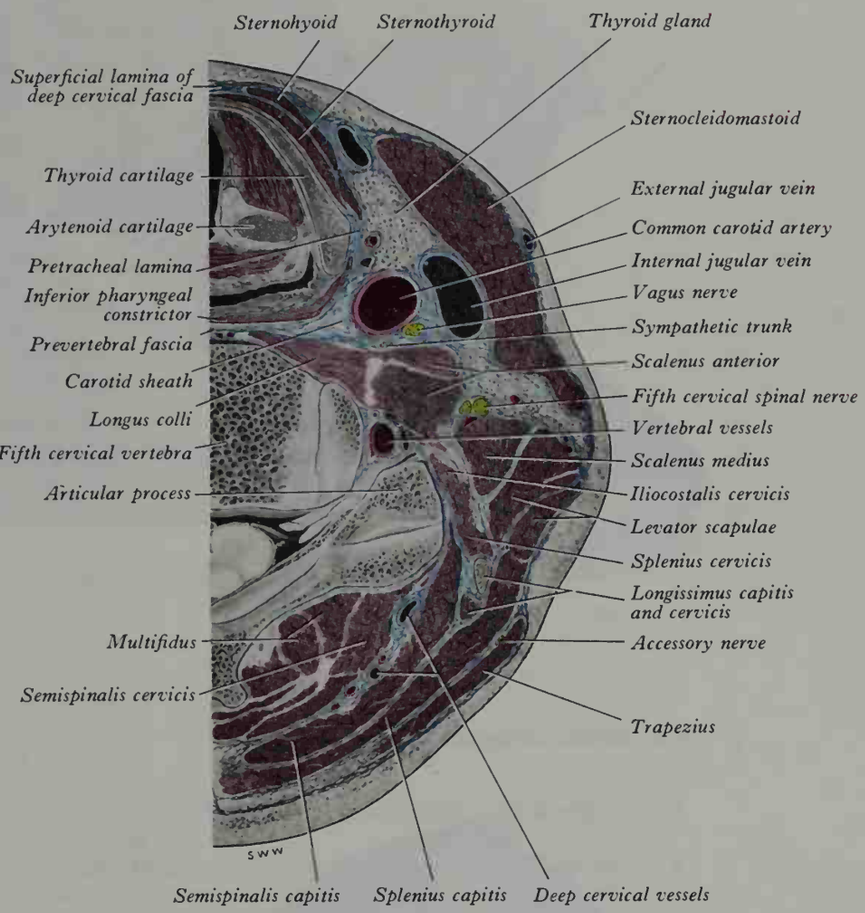
The *superficial (investing) lamina* of deep cervical fascia is continuous behind with the ligamentum nuchae and the periosteum covering the spine of the seventh cervical vertebra. It forms a thin investment for trapezius, and from the anterior border of this muscle is continued forwards, as a rather loose areolar layer covering the posterior triangle of the neck, to the posterior border of the sternocleidomastoid, where it becomes denser. Along the hinder edge of sternocleidomastoid it divides to enclose the muscle, and at the anterior margin again forms a single lamina, which covers the anterior triangle of the neck and reaches forwards to the median plane, where it is continuous with the corresponding lamina from the opposite side. In the median plane it is adherent to the symphysis menti and the body of the hyoid bone.

Above, the fascia is fused with periosteum along the superior nuchal line of the occipital bone, over the mastoid process, and along the whole of the base of the mandible. Between the mandibular angle and the anterior edge of the sternocleidomastoid it is particularly strong. Between the mandible and the mastoid process it ensheathes the parotid gland; the layer which covers the gland extends upwards under the name of the *parotid fascia* and is fixed to the zygomatic arch. From the part which passes deep to the parotid gland a strong band ascends to the styloid process, as the *stylomandibular ligament* (p. 440).

Below, the fascia is attached to the acromion, the clavicle and the manubrium sterni, fusing with their periostea. Some little distance above the last, it splits into superficial and deep layers. The former is attached to the anterior border of the manubrium, the latter to its posterior border and to the interclavicular ligament. Between these two layers there is a slit-like interval, the *suprasternal space*; it contains a small quantity of areolar tissue, the lower portions of the anterior jugular veins and the jugular arch, the sternal heads of the sternocleidomastoid muscles, and sometimes a lymph node. Over the lower part of the posterior triangle, between trapezius and sternocleidomastoid, the superficial lamina of deep fascia is also divided into superficial and deep layers. The superficial layer is attached below to the upper border of the clavicle. The deep layer surrounds the inferior belly of omohyoid and, deep to sternocleidomastoid, its intermediate tendon. Below, this deep layer blends with the fascia around subclavius and is attached to the back of the clavicle and anterior end of the first rib.

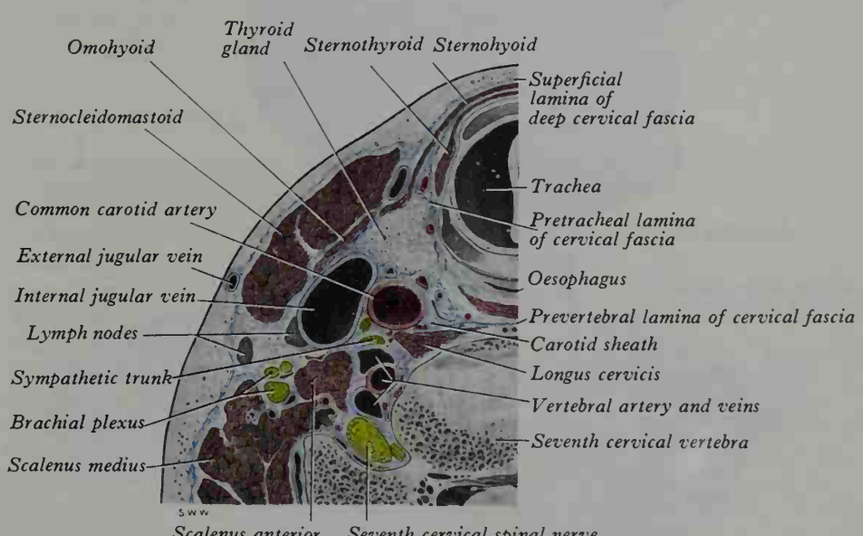
The *carotid sheath* is a condensation of the cervical fascia in which the common and internal carotid arteries, the internal jugular vein, the vagus nerve and the constituents of the ansa cervicalis are embedded. It is thicker around the arteries than the vein, and peripherally it is connected to the neighbouring layers by loose areolar tissue (5.31).

The *prevertebral lamina* of the cervical fascia covers the prevertebral muscles and extends laterally on the scalenus anterior, scalenus medius and levator scapulae, i.e. it forms a fascial floor for the posterior triangle of the neck. As the subclavian artery and the brachial nerves emerge from behind the scalenus anterior they carry the prevertebral fascia downwards and laterally behind the clavicle to form the *axillary sheath*. Traced laterally, the prevertebral fascia becomes thinner and areolar in character and is lost as a definite fibrous layer under cover of trapezius. Superiorly it is attached to the base of the skull, and inferiorly continues downwards in front of the longus colli muscles into the superior mediastinum, where it blends with the anterior longitudinal ligament. Anteriorly the prevertebral lamina is separated from the pharynx and its covering buccopharyngeal fascia by a loose cellular interval which is termed the *retropharyngeal space*. Further from the median plane, the same loose areolar tissue connects the prevertebral lamina to the carotid sheath and the fascia on the deep surface of the sternocleidomastoid. It should be observed that all the ventral rami of the cervical nerves lie at first behind the prevertebral lamina, and the nerve to the rhomboids, the nerve to serratus anterior and the phrenic nerve, retain this position throughout their course in the neck. However, the accessory nerve lies superficial to the prevertebral fascia (p. 1082).



The *pretracheal lamina* of the cervical fascia is very thin, but it provides a fine fascial sheath for the thyroid gland. Above, it is attached to the arch of the cricoid cartilage, and, below, it is continued into the superior mediastinum with the inferior thyroid veins.

Applied Anatomy. The superficial lamina of deep cervical fascia opposes the extension of abscesses towards the surface, and pus beneath it has a tendency to extend laterally. If the pus is in the anterior triangle, it may find its way into the mediastinum, in front of the pretracheal lamina of fascia; but owing to the thinness of the fascia in this situation it more frequently approaches the surface and points above the sternum. Pus behind the prevertebral lamina may extend towards the lateral part of the neck and point in the posterior triangle, or may perforate this layer of fascia and the buccopharyngeal fascia to bulge into the pharynx as a retropharyngeal abscess.

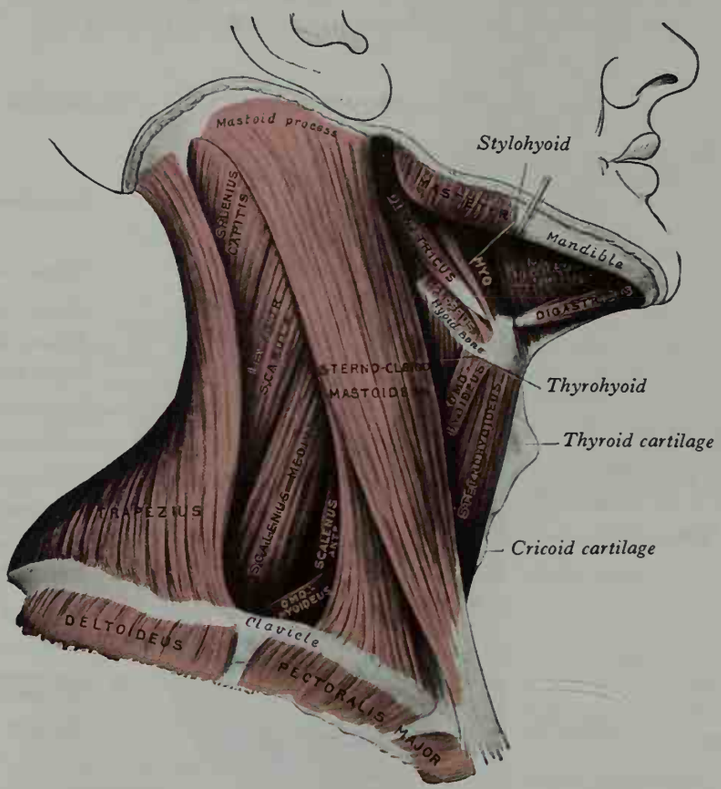


I. THE SUPERFICIAL AND LATERAL CERVICAL MUSCLES

These include the platysma, trapezius, and sternocleidomastoid muscles.

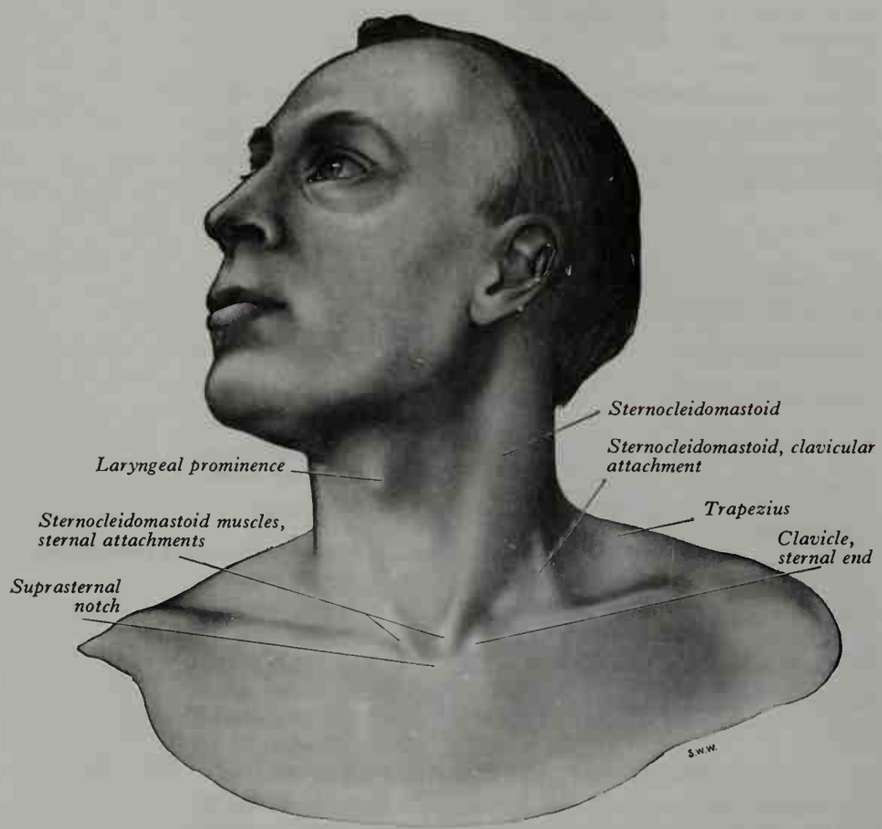
The platysma (5.21) is a broad sheet arising from the fascia covering the upper parts of the pectoralis major and deltoid; its fibres cross the clavicle, and proceed obliquely upwards and medially in the side of the neck. The anterior fibres interlace, below and behind the symphysis menti, with the fibres of the

5.30 A transverse section through the left half of the neck to show arrangement of the deep cervical fascia. (Specimen provided by Professor R. E. M. Bowden, Royal Free Hospital School of Medicine.)



5.31 Part of a transverse section through the lower part of the neck at the level of the seventh cervical vertebra to show the arrangement of the deep cervical fascia. (Specimen provided by Professor R. E. M. Bowden.)

opposite muscle; the succeeding fibres are inserted into the lower border of the body of the mandible, while the posterior fibres cross the mandible and the lower, anterior part of masseter to be attached to the skin and subcutaneous tissue of the lower part of the face, many blending with the muscles about the angle and lower part of the mouth. Under platysma the external jugular vein descends from the angle of the mandible to the middle of the clavicle. The platysma varies considerably in extent, and may even be absent on one side or both. It may be joined by slips from the mastoid process, the occipital bone or from the fascia over the upper part of trapezius (occipitalis minor).

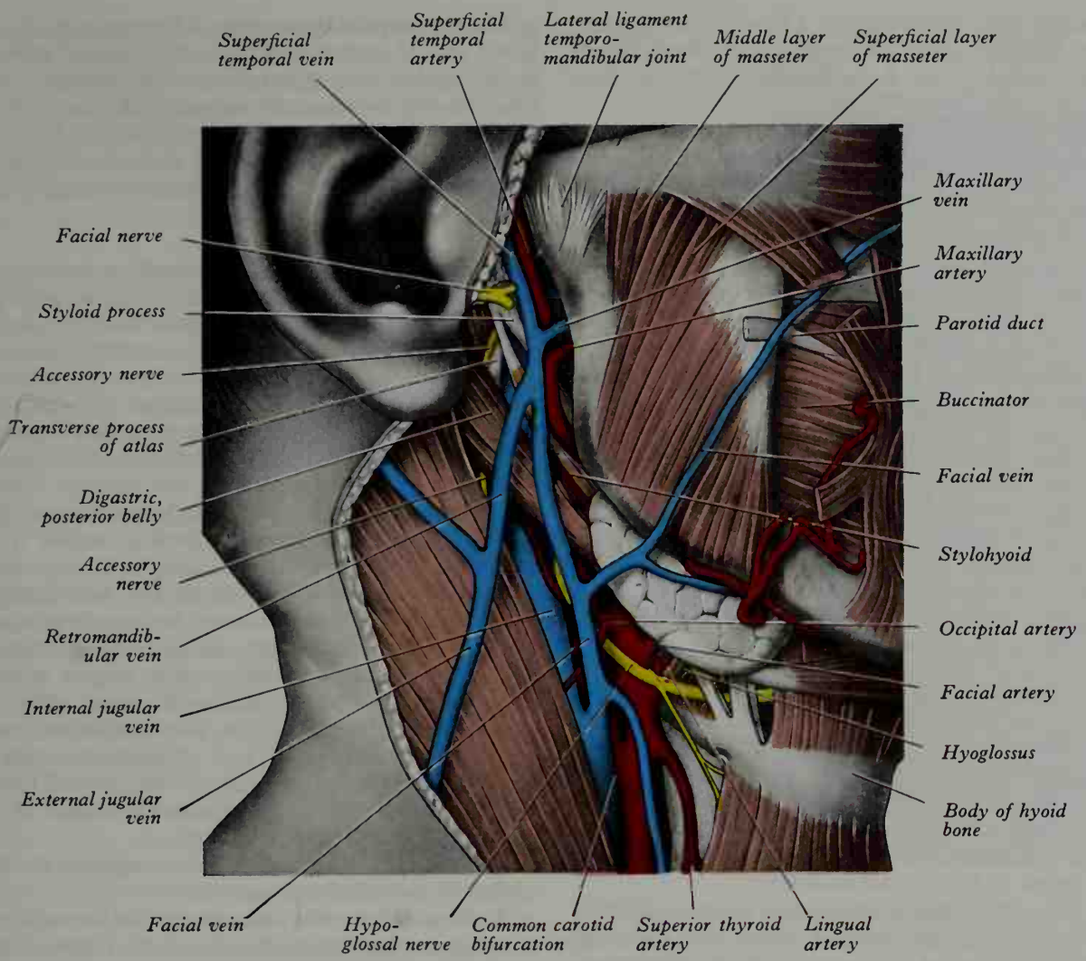


Nerve supply. The platysma is supplied by the cervical branch of the facial nerve.

Actions. When the entire platysma is in action it wrinkles the surface of the skin of the neck in an oblique direction, and tends to diminish the concavity between the jaw and the side of the neck. Its anterior portion, which is the thickest part of the muscle, may assist in depressing the mandible; it also serves to draw down the lower lip and angle of the mouth (as in the expression of horror or surprise).

Electromyographic studies show that the muscle is active in sudden deep inspiration (de Sousa 1964). Its action in widening the mouth and pulling down the angle is easily confirmed by mere palpation. The usefulness of platysma's activities are not clear. It is often very much contracted in situations of sudden and violent effort.

5.32 Muscles of the neck. Right lateral aspect.



5.33 Surface landmarks of the neck.

The trapezius is described on p. 564 with the scapular musculature.

The sternocleidomastoid (5.32) passes obliquely down across the side of the neck and forms a prominent landmark (5.33) especially when contracted. It is thick and narrow centrally, but broader and thinner at each end. *Below* it has two heads. The *medial* or *sternal head* is a rounded tendinous fasciculus, attached to the upper part of the anterior surface of the manubrium sterni, and passes upwards, laterally, and backwards. It can be seen and felt in the root of the neck. The *lateral* or *clavicular head*, which varies in width and is composed of muscular and fibrous fasciculi, passes almost vertically upwards from the upper surface of the medial third of the clavicle. The two heads are separated at their attachments by a triangular interval; but, as they ascend, the clavicular head spirals behind the sternal head and blends with its deep surface below the middle of the neck, forming a thick, rounded belly. *Above*, the muscle is inserted by a strong tendon into the lateral surface of the mastoid process, from its apex to its superior border, and by a thin aponeurosis into the lateral half of the superior nuchal line. The clavicular fibres are chiefly attached to the mastoid process; the sternal fibres are more oblique, superficial, and extend on to the occiput. The direction of pull of the two heads is therefore different, and the muscle may be classed as 'cruciate' and slightly 'spiralized' (*see* p. 525).

This muscle divides the side of the neck into two triangles, anterior and posterior. The boundaries of the *anterior triangle* are, in front, the median line of the neck; above, the base of the mandible, and a line continuing this from the angle of the mandible to the sternocleidomastoid; behind, the anterior border of the sternocleidomastoid. The apex of the triangle is at the upper border of the sternum. The boundaries of the *posterior triangle* are, in front, the posterior border of the sternocleidomastoid; below, the middle third of the clavicle; behind, the anterior margin of the trapezius. The apex corresponds with the meeting of the sternocleidomastoid and trapezius on the occipital bone. The subdivisions and contents of these triangles are given on pp. 685–686.

Relations. *Superficial* to the sternocleidomastoid are skin and platysma; it is separated from platysma by the external jugular vein, the great auricular and transverse cervical nerves, and the superficial lamina of the deep cervical fascia. Near its insertion the muscle is overlapped by a small portion of the parotid gland. The *deep surface* of the muscle is related at its origin to the sternoclavicular joint; it lies upon the sternohyoid, sternothyroid and the omohyoid, while the anterior jugular vein crosses deep to it, but superficial to the infrahyoid muscles, immediately above the clavicle. The carotid sheath and the subclavian artery are internal to these muscles. Between the omohyoid and the posterior belly of digastric the anterior part of sternocleidomastoid is superficial to the common, internal and external carotid arteries, internal jugular, facial and lingual veins, the deep cervical lymph nodes, the vagus nerve, and the rami of the ansa cervicalis. The sternocleidomastoid branch of the superior thyroid artery crosses deep to the muscle at the upper border of

5.34 Relations of the posterior belly of the digastric, exposed by the removal of skin, fasciae, parotid gland, and cutaneous branches of the cervical plexus.

the omohyoid. The posterior part of the muscle is related on its internal aspect to the splenius, levator scapulae and scaleni, the cervical plexus, the upper part of the brachial plexus, the phrenic nerve, and the transverse cervical and suprascapular arteries. The occipital artery crosses deep to the muscle at, or under cover of, the lower border of the digastric, where the accessory nerve, which pierces the muscle, runs downwards and laterally deep to it. At its insertion the muscle lies superficial to the mastoid process, and to the splenius, longissimus capitis, and the posterior belly of the digastric.

Nerve supply. The sternocleidomastoid is supplied by the accessory nerve, which usually traverses it, and by branches from the ventral rami of the second, third and sometimes the fourth cervical spinal nerves. Although long believed to be solely proprioceptive, clinical evidence now suggests that a proportion of these cervical fibres are motor.

Actions. When one sternocleidomastoid acts, it tilts the head towards the shoulder of the same side; it also rotates the head so as to carry the face towards the opposite side. The movement occurs in looking to the side and upwards, but more or less level rotation from side to side is a far more common visual movement and probably the most frequent in which the sternocleidomastoids (with, of course, other muscles) are involved. Acting together from below the sternocleidomastoid muscles draw the head forwards and so help the longi colli to flex the cervical part of the vertebral column. This is a common movement in feeding. The two muscles are also active when the head is raised while the body is supine. If the head is fixed, they assist in elevating the thorax in forced inspiration. Electromyographic observations (e.g. de Sousa 1973) suggest that the sternal fibres are more active in contralateral rotation, but that both parts of the muscle are involved to some extent in all the above movements. This study also indicated that the muscle is involved in cervical extension as well as flexion.

Applied Anatomy. The deformity termed *torticollis* is a contracture of the sternocleidomastoid. There is also a condition coming on in adult life (spasmodic torticollis) which begins with tonic or clonic spasm of one sternocleidomastoid muscle, soon followed by a spasm of the trapezius, particularly its clavicular portion. Such abnormal conditions illustrate the isolated muscle's action. It must be emphasized, however, that this is a caricature of its ordinary activities, which are invariably modified by synergists and antagonists, such as splenius capitis (p. 543), and many others.

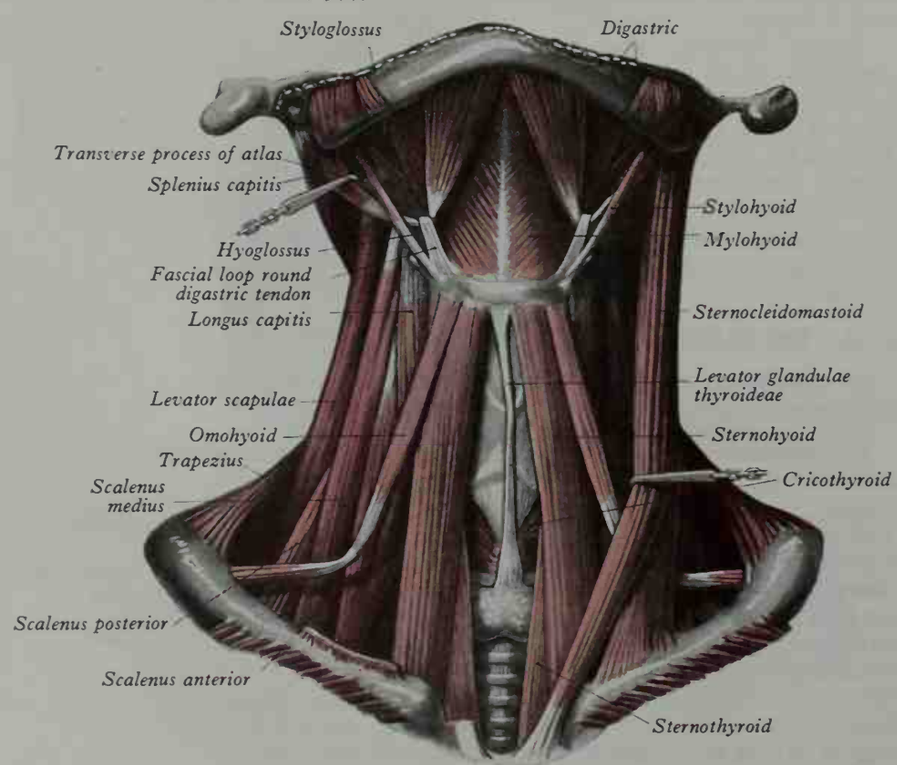
II (A). THE SUPRAHYOID MUSCLES

The *suprahyoid muscles* include the digastric, stylohyoid, mylohyoid and geniohyoid.

The digastric (5.34) has two bellies united by an intermediate rounded tendon. It lies below the body of the mandible, and extends, in an angled form, from the mastoid process to the chin. The *posterior belly*, longer than the anterior, is attached in the mastoid notch of the temporal bone and passes downwards and forwards. The *anterior belly* is attached to the digastric fossa on the base of the mandible close to the median plane, and passes downwards and backwards. The two bellies meet in an intermediate tendon, which perforates the stylohyoid. It is held to the side of the body and the greater cornu of the hyoid by a fibrous loop, sometimes lined by a synovial sheath. An aponeurotic layer is given off from the tendon of the digastric to the body and greater cornu of the hyoid bone. The digastric may lack its intermediate tendon and is then attached midway along the body of the mandible. The posterior belly may be augmented by a slip from

the styloid process or arise wholly from it. The anterior belly may cross the midline in part, and is not uncommonly more or less fused with mylohyoid. (*See* Lennartsson 1979 for proprioceptors.)

Relations. Its *superficial surface* is related to the platysma, sternocleidomastoid, part of splenius, longissimus capitis, mastoid process, stylohyoid, retromandibular vein and parotid and submandibular salivary glands. The *medial surface* of the anterior belly adjoins the mylohyoid, that of the posterior belly the superior oblique, rectus capitis lateralis, the transverse process of the atlas vertebra, the accessory nerve, internal jugular vein, occipital artery, hypoglossal nerve, the internal and external carotid, facial and lingual arteries and the hyoglossus (**5**.34).



Nerve supply. The anterior belly of digastric is supplied by the mylohyoid branch of the inferior alveolar nerve, the posterior belly by the facial nerve. These different supplies are, of course, associated with the separate derivation of the two parts of the muscle from first and second branchial arch mesenchyme (p. 150).

Actions. The digastric depresses the mandible and can elevate the hyoid bone. Electromyography indicates that the digastric muscles always act together and that they are secondary to the lateral pterygoids in mandibular depression, coming into play especially in maximal depression (Moyers 1950). The posterior belly is especially active in swallowing and chewing.

The stylohyoid (**5**.34, 35) arises by a small tendon from the posterior surface of the styloid process, near its base and, passing downwards and forwards, is inserted into the body of the hyoid bone, at its junction with the greater cornu, and just above the omohyoid. It is perforated, near its insertion, by the tendon of the digastric. Occasionally the muscle may be absent or double. It may be medial to the external carotid artery. It may end in the digastric or the supra- or infra-hyoid muscles.

Nerve supply. The stylohyoid is supplied by the facial nerve.

Actions. The stylohyoid elevates and draws back the hyoid bone. This elongates the floor of the mouth. With the other supra- and infra-hyoid muscles it can fix the hyoid bone as a basis for the action of tongue muscles attached to the bone. Its precise roles in masticatory and vocal movements have not been satisfactorily analysed (but *see* p. 1237). The roles of the stylohyoid muscle and the hyoid apparatus in speech and swallowing have, however, been investigated radiographically in mankind by Delmas and Senecail (1977).

5.35 Muscles of the front of the neck. On the right side the sternocleidomastoid has been removed. In this subject, the origin of the scalenus medius extended up to the transverse process of the atlas.

The stylohyoid ligament is a fibrous cord, attached to the tip of the styloid process and the lesser cornu of the hyoid bone. It gives origin to the highest fibres of the middle constrictor of the pharynx and is intimately related to the lateral wall of the oral pharynx (**5**.25). Below, it is overlapped by the hyoglossus. It is derived from the cartilage of the second branchial arch (p. 150) and may be partially ossified; in many mammals it forms a distinct bone, the *epihyal*.

The mylohyoid (**5**.32, 35) is superior or deep to the anterior belly of digastric, and forms, with its fellow, a muscular floor for the oral cavity. It is a flat, triangular sheet attached to the whole length of the mylohyoid line of the mandible. The posterior fibres pass medially and slightly downwards, to the front of the body of the hyoid bone near its lower border. The middle and anterior fibres from each side intersect in a median fibrous raphe which stretches from the symphysis menti to the hyoid bone. This raphe is sometimes wanting; if so, the two muscles form a continuous sheet. Sometimes it is fused with the anterior belly of digastric.

Relations. Its *inferior* or *superficial surface* is related to the platysma, the anterior belly of digastric, the superficial part of the submandibular gland, the facial and submental vessels, and the mylohyoid vessels and nerve. Its *superior* or *internal surface* is in relation with the geniohyoid, part of the hyoglossus, and the styloglossus, the hypoglossal and lingual nerves, the submandibular ganglion, sublingual gland, deep part of the submandibular gland and the submandibular duct, the lingual and sublingual vessels, and, posteriorly, with the mucous membrane of the mouth. In about one-third of subjects there is a hiatus in the muscle through which a process of the sublingual gland protrudes (Gaughran 1963).

Nerve supply. The mylohyoid is supplied by the mylohyoid branch of the inferior alveolar nerve.

Actions. The mylohyoid elevates the floor of the mouth in the first stage of deglutition (Whillis 1946). It also elevates the hyoid bone or depresses the mandible.

The geniohyoid (**5**.35) is a narrow muscle, above the medial part of mylohyoid. From the inferior mental spine on the back of the symphysis menti it runs backwards and slightly downwards to the anterior surface of the body of the hyoid bone; it is in contact with its fellow and may occasionally be fused with it, or with the genioglossus.

Nerve supply. The first cervical spinal nerve through the hypoglossal nerve (p. 1083).

Actions. the geniohyoid elevates the hyoid bone and draws it forwards, thus acting as a partial antagonist to stylohyoid. When the hyoid is fixed, it depresses the mandible.

II (B). THE INFRAHYOID MUSCLES

The *infrahyoid muscles* are the sternohyoid, sternothyroid, thyrohyoid and omohyoid. As a group they are antagonists to the suprahyoid group, in depressing the hyoid bone; but they may act as fixators of the hyoid, or cooperate in cyclic hyoid movements.

The sternohyoid (**5**.32, 35), a thin, narrow strap muscle, arises from the posterior surface of the medial end of the clavicle, the posterior sternoclavicular ligament, and the upper and posterior part of the manubrium sterni. Passing upwards and medially, it is attached to the inferior border of the body of the hyoid bone. Below, it is separated from its fellow by a considerable interval; but the two muscles usually come into contact in the middle of their course, and are contiguous above. The muscle may be absent or double, or augmented by a clavicular slip (*cleidohyoid*), or interrupted by a tendinous intersection.

Nerve supply. Branches from the ansa cervicalis (c. 1, 2, 3).

Action. the sternohyoid depresses the hyoid bone after it has been elevated in deglutition. It also doubtless plays a part in speech and mastication.

The sternothyroid (**5**.32, 35) is shorter and wider than sternohyoid, and lies internal to it. It passes from the posterior surface of the manubrium sterni below the origin of the

sternohyoid and the edge of the cartilage of the first rib to the oblique line on the lamina of the thyroid cartilage. In the lower part of the neck this muscle is in contact with its fellow, but it diverges as it ascends. It is applied to the anterolateral surface of the lobe of the thyroid gland.

Nerve supply. Branches from the ansa cervicalis (c. 1, 2, 3).

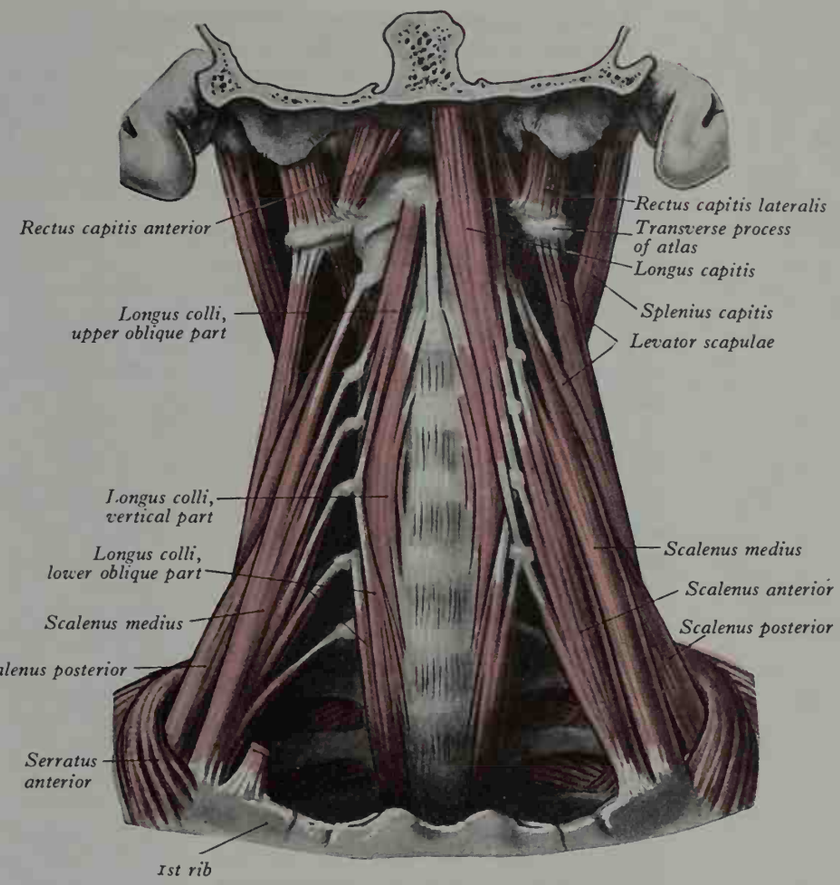
Action. The sternothyroid draws the larynx downwards after it has been elevated, as in swallowing or in vocal movements.

The thyrohyoid, a small, quadrilateral muscle, may be looked upon as an upward continuation of the sternothyroid. From the oblique line on the lamina of the thyroid cartilage it passes up to be attached to the lower border of the greater cornu and adjacent part of the body of the hyoid bone.

Nerve supply. The thyrohyoid is supplied by a branch from the hypoglossal nerve. Like the nerve to the geniohyoid, this branch contains fibres of the first cervical spinal nerve which supply the muscle.

Actions. The thyrohyoid depresses the hyoid bone, or raises the larynx.

The omohyoid (5.32, 35) consists of two fleshy bellies united at an angle by an intermediate tendon. It arises from the upper border of the scapula near the scapular notch, and occasionally from the superior transverse scapular ligament (p. 436). The *inferior belly* is a flat, narrow band, which inclines forwards and slightly upwards across the lower part of the neck; it then passes behind the sternocleidomastoid and there ends in the intermediate tendon. The inferior belly divides the posterior triangle of the neck into upper, *occipital* and lower, supraclavicular triangles (p. 686). The *superior belly* passes almost vertically upwards from this tendon, close to the lateral border of the sternohyoid, and is attached to the lower border of the body of the hyoid bone, lateral to the insertion of the sternohyoid. The intermediate tendon, which varies in length and form, usually lies adjacent to the internal jugular vein, opposite the arch of the cricoid cartilage. It is held by a band of the deep cervical fascia which ensheathes it and is attached below to the clavicle and the first rib; it is by this fascial process that the angular form of the muscle is maintained. A variable amount of striated muscle may occur in this fascial band. Either belly may be absent or double; the inferior may be attached directly to the clavicle, the superior is sometimes fused with sternohyoid. These variations have been confirmed by Buntine (1970).



Nerve supply. The superior and inferior bellies of the omohyoid are supplied respectively by branches from the ramus superior of the ansa cervicalis (c. 1), and from the ansa itself (c. 2, 3).

Actions. The omohyoid depresses the hyoid bone after it has been elevated. It has been suggested also in prolonged inspiratory efforts; by rendering tense the lower part of the deep cervical fascia they may lessen the inward suction of the soft parts, which would otherwise compress the great vessels and the apices of the lungs. Such interesting views are, of course, speculations. So far, sparse data in regard to the hyoid musculature as a whole have been contributed by electromyographers. However, a combined cineradiographic and electromyographic study of mastication (in the opossum, *Didelphys virginiana*) strongly suggests that the omohyoid muscles are involved in initiating hyoid movements in this activity (Crompton *et al.* 1975); see also p. 1313.

III. THE ANTERIOR VERTEBRAL MUSCLES

This group of muscles includes the longi colli et capitis and the recti capitis anterior et lateralis, all to some extent flexors of the head and neck (5.36).

The longus colli is applied to the anterior surface of the vertebral column, between the atlas and the third thoracic vertebra. It is divisible into three parts, inferior oblique, superior oblique, and vertical; its origin and insertion consist of tendinous slips. The *inferior oblique part*, which is the smallest, runs upwards and laterally from the front of the bodies of the first two or three thoracic vertebrae to the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebrae. The

5.36 The anterior and lateral vertebral muscles. On the right side the scalenus anterior and the longus capitis have been removed.

superior oblique part passes from the anterior tubercles of the transverse processes of the third, fourth and fifth cervical vertebrae upwards and medially, to be attached by a narrow tendon into the anterolateral surface of the tubercle on the anterior arch of the atlas. The *vertical* intermediate part ascends from the front of the bodies of the upper three thoracic and lower three cervical vertebrae to the front of the bodies of the second, third and fourth cervical vertebrae.

Nerve supply. The muscle receives branches from the ventral rami of the second, third, fourth, fifth and sixth cervical spinal nerves.

Actions. The longus colli bends the neck forwards; in addition, the oblique portions flex it laterally, and the inferior oblique portion rotates it to the opposite side. Despite its deep situation the muscle has been studied electromyographically (Fountain *et al.* 1966) largely in confirmation of the above, except that it is claimed that longus colli has little effect in lateral flexion. Its main antagonist is the longissimus cervicis.

The longus capitis, broad and thick above, narrow below, is attached below by tendinous slips to the anterior tubercles of the transverse processes of the third, fourth, fifth and sixth cervical vertebrae, and above to the inferior surface of the basilar part of the occipital bone.

Nerve supply. Branches from the ventral rami of the first, second and third cervical spinal nerves.

Action. The longus capitis flexes the head.

The foregoing anterior vertebral muscles vary chiefly in the number of their vertebral slips.

The rectus capitis anterior is a short, flat muscle situated behind the upper part of the longus capitis. From the anterior surface of the lateral mass of the atlas and the root of its transverse process, it ascends almost vertically to the inferior surface of the basilar part of the occipital bone in front of the occipital condyle.

Nerve supply. Branches from the loop between the ventral rami of the first and second cervical spinal nerves.

Action. The rectus capitis anterior flexes the head.

The rectus capitis lateralis is a short, flat muscle which arises from the upper surface of the transverse process of the atlas and is inserted into the inferior surface of the jugular process of the occipital bone. In view of its attachments and its relation to the ventral ramus of the first spinal nerve, the rectus capitis lateralis is regarded as homologous with the posterior intertransverse muscles.

Nerve supply. Branches from the loop between the ventral rami of the first and second cervical spinal nerves.

Action. The rectus capitis lateralis bends the head to the same side.

The actions of the above deep-seated muscles can only be deduced, and their precise roles in everyday activities await adequate technical appraisal.

IV. THE LATERAL VERTEBRAL MUSCLES

The scaleni, anterior, medius and posterior, extend obliquely like scaling ladders from the upper two ribs to the cervical transverse processes (**5**.36).

The scalenus anterior lies deeply at the side of the neck behind the sternocleidomastoid. From the anterior tubercles of the transverse processes of the third, fourth, fifth and sixth cervical vertebrae, it descends almost vertically, to be attached by a narrow, flat tendon to the scalene tubercle on the inner border of the first rib, and to the ridge on the upper surface of the rib in front of the groove for the subclavian artery.

Relations. In *front* of it are the clavicle, subclavius, sternocleidomastoid, and omohyoid, the lateral portion of the carotid sheath, the transverse cervical, suprascapular and ascending cervical arteries, the subclavian vein, the prevertebral fascia and the phrenic nerve. Its *posterior surface* is in relation with the suprapleural membrane (p. 1249), the pleura, the nerves forming the brachial plexus and the subclavian artery; the latter two separate it from the scalenus medius. *Below*, it is separated from the longus colli by an angular interval (**5**.36), in which the vertebral artery, with its companion vein on its lateral side, ascends to reach the foramen transversarium of the sixth cervical vertebra. The inferior thyroid artery crosses the interval from the lateral to the medial side near its apex. The sympathetic trunk and its cervicothoracic ganglion are closely related to the postero-medial side of this part of the vertebral artery (**6**.63). On the *left side* the thoracic duct crosses this interval at the level of the seventh cervical vertebra and usually comes into contact with the medial edge of the muscle. Above, it is separated from the longus capitis by the ascending cervical branch of the inferior thyroid artery.

Nerve supply. Scalenus anterior is supplied by branches from the ventral rami of the fourth, fifth and sixth cervical spinal nerves.

Actions. Acting from below, the scalenus anterior bends the cervical portion of the vertebral column forwards and laterally and rotates it towards the opposite side. When the muscle acts from above it assists in elevating the first rib.

The scalenus medius, the largest and longest of the scaleni, is attached above to the transverse process of the axis and the front of the posterior tubercles of the transverse processes of the lower five cervical vertebrae, and frequently extends upwards to the transverse process of the atlas (**5**.35); below it is attached to the upper surface of the first rib, between the tubercle of the rib and the groove for the subclavian artery.

Relations. Its *anterolateral surface* is related to the sterno-cleidomastoid; it is crossed by the clavicle and omohyoid: *anteriorly*, it is separated from the scalenus anterior by the subclavian artery and the cervical nerves. The levator scapulae and the scalenus posterior are posterolateral to it. The upper two roots of the nerve to serratus anterior and the dorsal scapular nerve (to the rhomboids) pierce the substance of the muscle and appear on its lateral surface.

Nerve supply. Branches from the ventral rami of the third to eighth cervical spinal nerves.

Actions. The scalenus medius, acting from below, bends the cervical part of the vertebral column to the same side; acting from above it helps to raise the first rib. The scalene muscles, in particular the scalenus medius, are active during inspiration, even during quiet breathing in the erect attitude (Campbell 1955).

The scalenus posterior, the smallest and most deeply situated of the scaleni, passes from the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebrae, to be attached by a thin tendon to the outer surface of the second rib, behind the tubercle for serratus anterior. It is occasionally blended with the scalenus medius. The scalene muscles vary a little in the number of vertebrae to which they are attached, in their degree of separation, and segmental innervation.

Nerve supply. Branches from the ventral rami of the lower three cervical spinal nerves.

Actions. The scalenus posterior bends the lower end of the cervical part of the vertebral column to the same side, when the second rib is fixed; when its upper attachment is fixed it helps to elevate the second rib.

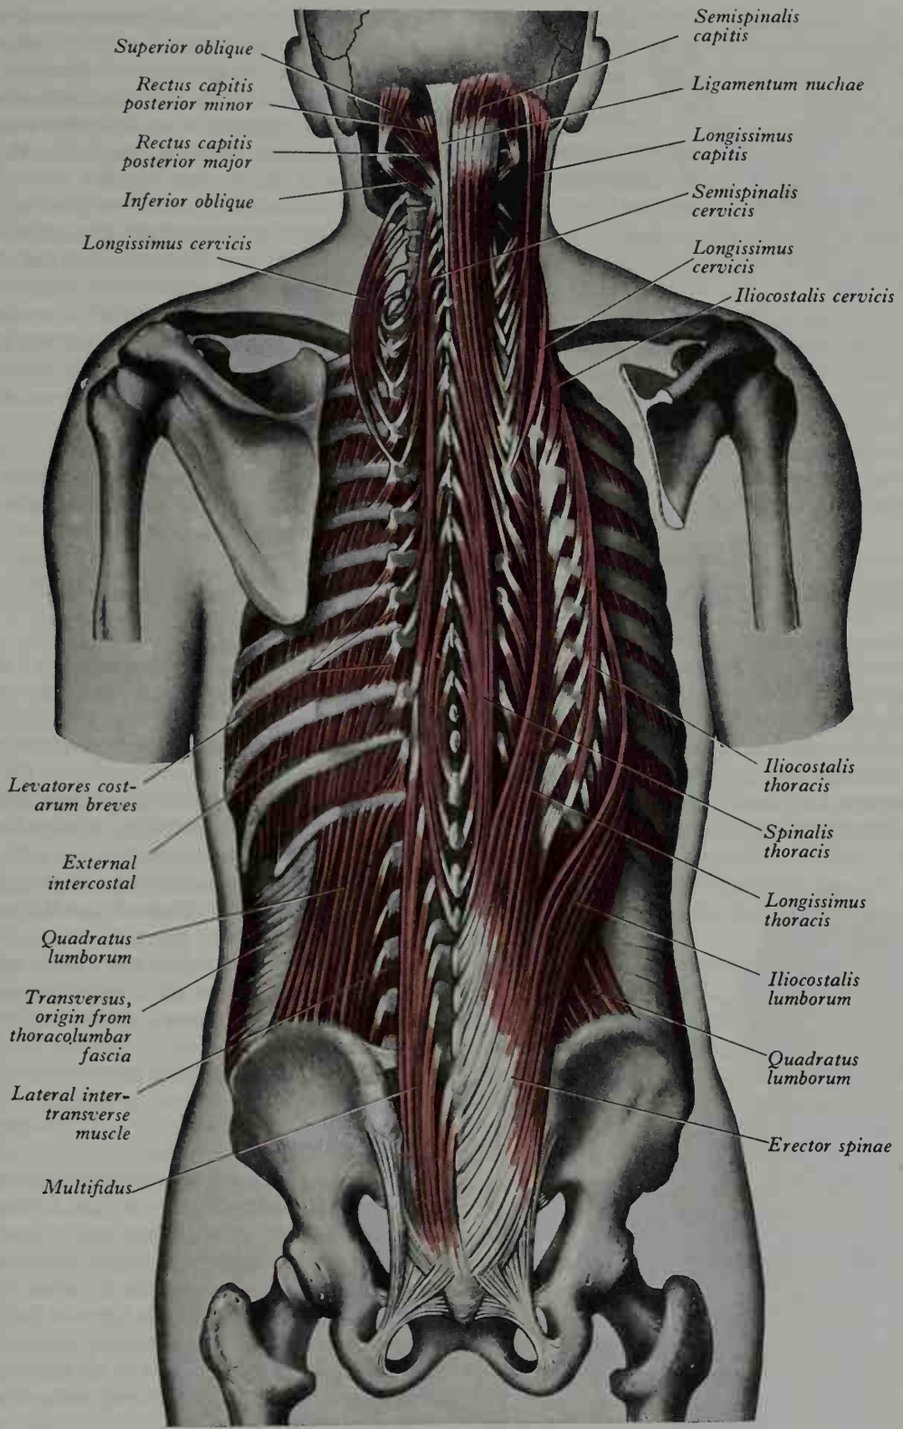
The scalenus minimus (pluralis) is associated with the suprapleural membrane, and cervical pleura, and is considered with them (p. 1249).

THE FASCIAE AND MUSCLES OF THE TRUNK

The muscles of the trunk may be arranged for convenience of description in six groups:

I. Deep muscles of the back.
II. Suboccipital muscles.
III. Muscles of the thorax.
IV. Muscles of the abdomen.
V. Muscles of the pelvis.
VI. Muscles of the perineum.

I. The Deep Muscles of the Back



The deep or intrinsic muscles of the back consist of a complex group of muscles extending from the pelvis to the skull. These include extensors and rotators of the head and neck (splenius capitis and cervicis), short segmental muscles (interspinales and intertransversarii), and the complex extensor and rotator masses (erector spinae and transversospinalis, the latter including the semispinales, rotatores, and multifidus). Collectively these muscles control the vertebral column (**5**.37).

The *superficial* and the *deep fasciae* of the back of the neck are described on p. 564.

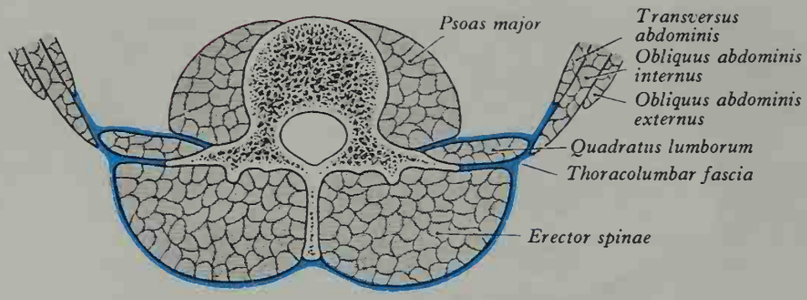
The thoracolumbar (lumbar) fascia covers the deep muscles of the back of the trunk. Above, it passes anterior to the serratus posterior superior and is continuous with the superficial lamina of the deep cervical fascia on the back of the neck.

In the thoracic region the thoracolumbar fascia is a thin fibrous lamina covering the extensor muscles of the vertebral column and separating them from the muscles connecting the vertebral column to the upper extremity. It is attached, *medially*, to the spines of the thoracic vertebrae; *laterally*, to the angles of the ribs.

In the lumbar region the thoracolumbar fascia is in three layers (**5**.38). The posterior layer is attached to the spines of the lumbar and sacral vertebrae and to the supraspinous ligaments; the middle layer is attached, *medially*, to the tips of the transverse

5.37 The deep muscles of the back. On the left side the erector spinae and its upward continuations (with the exception of the longissimus cervicis, which has been displaced laterally) and the semispinalis capitis have been removed.

processes of the lumbar vertebrae and the intertransverse ligaments, *below*, to the iliac crest, and *above*, to the lower border of the twelfth rib and the lumbocostal ligament (p. 451). The anterior layer covers the quadratus lumborum and is attached *medially* to the anterior surfaces of the transverse processes of the lumbar vertebrae behind the lateral part of the psoas major. *Below*, it is attached to the iliolumbar ligament and the adjoining part of the iliac crest; *above*, it forms the lateral arcuate ligament (p. 549). The posterior and middle layers unite at the lateral margin of the erector spinae, and at the lateral border of the quadratus lumborum they are joined by the anterior layer to form the aponeurotic origin of the transverse abdominis.



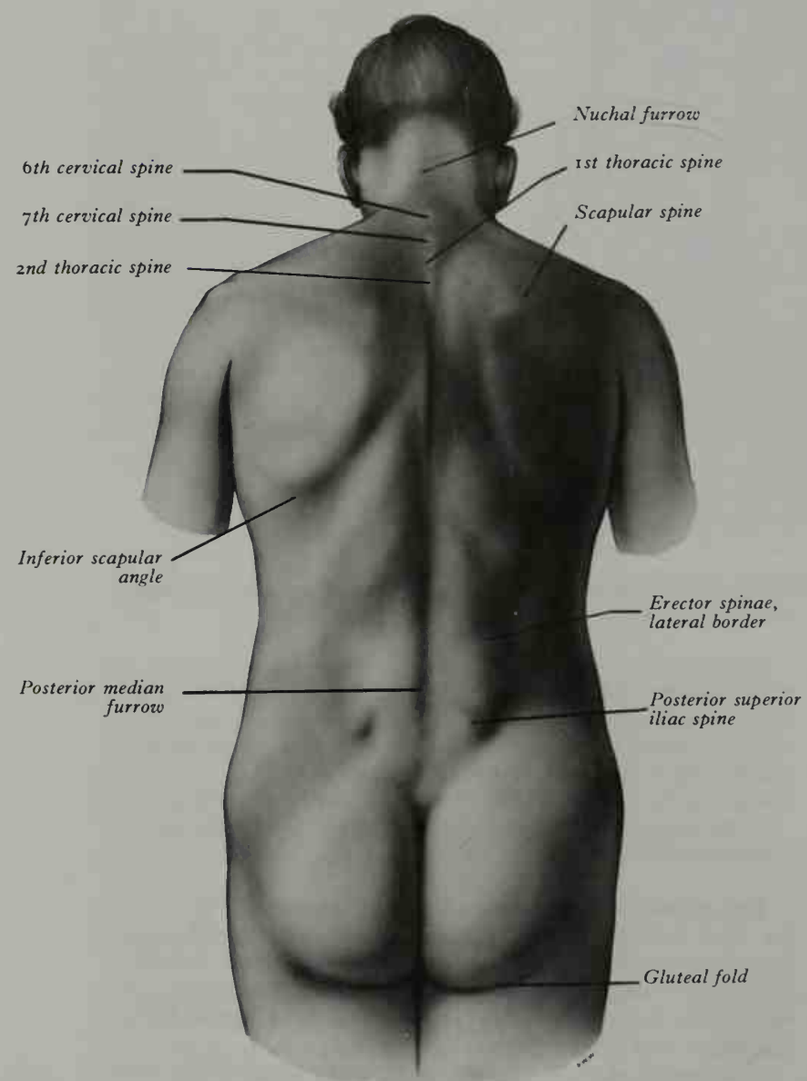
The splenius capitis (5.58) is attached below to the lower half of the ligamentum nuchae, the spine of the seventh cervical vertebra, and the spines of the upper three or four thoracic vertebrae, deep to the rhomboids and trapezius. The muscle passes upwards and laterally under cover of sternocleidomastoid, to the mastoid process of the temporal bone, and the rough surface on the occipital bone just below the lateral third of the superior nuchal line. The muscle forms a part of the floor of the posterior triangle of the neck, above and behind the levator scapulae.

Nerve supply. Lateral branches of the dorsal rami of the middle cervical spinal nerves.

The splenius cervicis ascends from the spines of the third to the sixth thoracic vertebrae to the posterior tubercles of the transverse processes of the upper two or three cervical vertebrae immediately anterior to the attachment of levator scapulae. The splenii may be absent or variable in their vertebral attachments. Accessory slips also occur.

Nerve supply. Lateral branches of the dorsal rami of the lower cervical spinal nerves.

Actions. The splenii of the two sides, acting together, draw the



5.38 Transverse section through the posterior abdominal wall, showing disposition of the thoracolumbar fascia. Note that all other connective tissue strata have been omitted.

head directly backwards; acting separately, they draw the head to one side, and slightly rotate it, turning the face to the same side. Thus they act as synergists with the opposite sternocleidomastoid.

THE ERECTOR SPINAE (SACROSPINALIS)

This muscle and its prolongations in the thoracic and cervical regions lie in the groove on the side of the vertebral column (5.37), covered in the lumbar and thoracic regions by the thoracolumbar fascia, the serratus posterior inferior below, and the rhomboid and splenius muscles above. It forms a large muscular and tendinous mass, which varies in size and composition at different levels of the vertebral column. In the sacral region it is narrow and pointed, and at its attachment chiefly tendinous. In the lumbar region it forms a thick fleshy mass which can readily be felt in the living subject. Its lateral border is flanked by a visible groove (5.39), and, traced upwards over the back of the thorax, it crosses the ribs at their angles, inclining medially as it ascends.

5.39 Dorsal aspect of the trunk, showing principal surface landmarks.

The erector spinae arises from the anterior surface of a broad and thick tendon, which is attached to the median sacral crest, to the spines of the lumbar and the eleventh and twelfth thoracic vertebrae, to their supraspinous ligaments, to the medial aspect of the dorsal part (p. 380) of the iliac crest, and to the lateral sacral crest (p. 280), where it blends with the sacrotuberous and dorsal sacroiliac ligaments; some of its fibres are continuous with the gluteus maximus. The muscular fibres form a large fleshy mass, which splits in the upper lumbar region into three columns: lateral, the *iliocostocervicalis*, intermediate, the *longissimus*, and medial, the *spinalis*. Each of these consists, from below upwards, of three parts as follows:

Lateral	*Intermediate*	*Medial*
Iliocostalis.	**Longissimus.**	**Spinalis.**
(a) I. lumborum.	(a) L. thoracis.	(a) S. thoracis.
(b) I. thoracis.	(b) L. cervicis.	(b) S. cervicis.
(c) I. cervicis.	(c) L. capitis.	(c) S. capitis.

Iliocostocervicalis

The iliocostalis lumborum is attached, by flattened tendons, to the inferior borders of the angles of the lower six or seven ribs.

The iliocostalis thoracis starts from the upper borders of the angles of the lower six ribs *medial* to the tendons of insertion of the iliocostalis lumborum; it ascends to the upper borders of the angles of the upper six ribs and the back of the transverse process of the seventh cervical vertebra.

The iliocostalis cervicis passes from the angles of the third, fourth, fifth and sixth ribs *medial* to the tendons of insertion of the iliocostalis thoracis to the posterior tubercles of the transverse processes of the fourth, fifth and sixth cervical vertebrae.

Nerve supply. These three muscles are supplied by the dorsal rami of the lower cervical, thoracic and upper lumbar spinal nerves.

Actions. These muscles are extensors of the vertebral column; they are also lateral flexors (p. 445).

Longissimus

The longissimus thoracis is the intermediate and largest of the continuations of the erector spinae. In the lumbar region, where it is as yet blended with the iliocostalis lumborum, some of its fibres are attached to the whole length of the posterior surfaces of the transverse processes and the accessory processes of the lumbar vertebrae, and to the middle layer of the thoracolumbar fascia. In the thoracic region it is attached, by rounded tendons, to the tips of the transverse processes of all the thoracic vertebrae, and by fleshy processes to the lower nine or ten ribs between their tubercles and angles.

The longissimus cervicis, situated medial to the longissimus thoracis, is attached by long thin tendons to the transverse processes of the upper four or five thoracic vertebrae, and also by tendons to the posterior tubercles of the transverse processes of the cervical vertebrae from the second to the sixth.

The longissimus capitis lies between the longissimus cervicis and the semispinalis capitis. It arises by tendons from the transverse processes of the upper four or five thoracic vertebrae, and the articular processes of the lower three or four cervical vertebrae, and is attached to the posterior margin of the mastoid process, deep to the splenius capitis and sternocleidomastoid. It is usually crossed by a tendinous intersection near its insertion.

Nerve supply. The longissimi are supplied by the dorsal rami of the lower cervical, the thoracic and the lumbar spinal nerves.

Actions. The longissimi thoracis et cervicis bend the vertebral column backwards and laterally; the longissimus capitis extends the head, and turns the face towards the same side.

Spinalis

The spinalis thoracis, the medial continuation of the erector spinae, is scarcely separable as a distinct muscle. It is situated at

the medial side of the longissimus thoracis, and is intimately blended with it; it is attached below by three or four tendons to the spines of the eleventh and twelfth thoracic, and first and second lumbar vertebrae; these, uniting, form a small muscle which is attached above by separate tendons to the spines of the upper thoracic vertebrae, the number varying from four to eight. It is intimately united with the semispinalis thoracis, which lies anterior to it.

The spinalis cervicis is an inconstant muscle, which ascends from the lower part of the ligamentum nuchae, the spine of the seventh cervical, and sometimes from the spines of the first and second thoracic vertebrae to the spine of the axis, and occasionally the spines of the two vertebrae immediately below it. This muscle is often absent.

The spinalis capitis is usually more or less blended with the semispinalis capitis.

Nerve supply. The spinales are supplied by the dorsal rami of the lower cervical and thoracic spinal nerves.

Actions. The spinales are extensors of the vertebral column.

TRANSVERSOSPINALIS

This consists of the the following muscles:

Semispinalis thoracis.	Multifidus.	Rotatores thoracis.
Semispinalis cervicis.		Rotatores cervicis.
Semispinalis capitis.		Rotatores lumborum.

These muscles run obliquely upwards and medially from the transverse processes to the spines of the vertebrae.

The semispinalis thoracis consists of thin, fleshy fasciculi, interposed between tendons of considerable length. It arises by a series of tendons from the transverse processes of the thoracic vertebrae from the sixth to the tenth inclusive, and is inserted, by tendons, into the spines of the upper four thoracic and lower two cervical vertebrae.

The semispinalis cervicis, thicker than the preceding, arises by a series of tendinous and fleshy fibres from the transverse processes of the upper five or six thoracic vertebrae, and is inserted into the cervical spines, from the axis to the fifth inclusive. The fasciculus connected with the axis is the largest, and is chiefly muscular in structure.

The semispinalis capitis (5.37) is situated at the back of the neck, under cover of the splenius, and medial to the longissimi cervicis et capitis. It arises by a series of tendons from the tips of the transverse processes of the upper six or seven thoracic and the seventh cervical vertebrae, from the articular processes of the fourth, fifth, and sixth cervical vertebrae and, occasionally, from the spine of the seventh cervical or first thoracic vertebra. The tendons are succeeded by a broad muscle, which passes upwards to the medial part of the area between the superior and inferior nuchal lines of the occipital bone. The medial part, usually more or less distinct from the rest of the muscle, is named the *spinalis capitis*; it is sometimes called the *biventer cervicis*, since it is transversed by an imperfect tendinous intersection.

Nerve supply. The semispinales are supplied by the dorsal rami of the cervical and thoracic spinal nerves.

Actions. The semispinales thoracis et cervicis extend the thoracic and cervical regions of the vertebral column, and rotate them towards the opposite side; the semispinalis capitis extends the head, and turns the face slightly towards the opposite side.

The multifidus consists of a number of fleshy and tendinous fasciculi, which lie deep to the foregoing muscles and fill the groove at the side of the spines of the vertebrae from the sacrum to the axis. Most caudally, its fasciculi arise from the back of the sacrum as low as the fourth sacrum foramen, from the aponeurosis of the erector spinae, posterior superior iliac spine and dorsal sacro-iliac ligaments; in the lumbar region, from all the mamillary processes; in the thoracic region, from all the transverse processes; in the cervical region, from the articular processes of the lower four vertebrae, Each fasciculus passes obliquely upwards and medially, and is attached to the whole length of the spine of one of the vertebrae above. The fasciculi vary in length; the most superficial pass from one vertebra to the third or fourth above; those next in depth run from one vertebra to the second or third above; while the deepest connect contiguous vertebrae.

Nerve supply. The dorsal rami of the spinal nerves.

Deep to the multifidus are the *rotatores* and these are best developed in the thoracic region.

The rotatores thoracis are eleven in number on each side, and are small and somewhat quadrilateral in form. Each connects the upper and posterior part of the transverse process of one vertebra to the lower border and lateral surface of the lamina of the vertebra next above, the fibres extending as far as the root of the spine. The first is found between the first and second thoracic vertebrae; the last, between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end of the series.

The rotatores cervicis et lumborum are represented only by irregular and variable muscle bundles with similar attachments to those of the rotatores thoracis.

Nerve supply. The dorsal rami of the spinal nerves.

The interspinales are short paired muscular fasciculi, between the spines of contiguous vertebrae, one on each side of the interspinous ligament. In the *cervical region* they are most distinct, and consists of six pairs; the first is situated between the axis and third vertebra, and the last between the seventh cervical and the first thoracic vertebrae. They are small narrow bundles, attached, above and below, to the apices of the spines. In the *thoracic region* they occur between the first and second vertebrae, and sometimes between the second and third, and the eleventh and twelfth vertebrae. In the *lumbar region* there are four pairs in the intervals between the five lumbar vertebrae. A pair is occasionally found between the last thoracic and first lumbar vertebrae, and another between the fifth lumbar vertebra and the sacrum. Sometimes the cervical interspinales span more than two vertebrae.

Nerve supply. The dorsal rami of the spinal nerves.

The intertransversarii are small muscles placed between the transverse processes of the vertebrae. They are best developed in the *cervical region* where they consist of anterior and posterior slips, which are separated by the ventral rami of the spinal nerves. The *posterior intertransverse muscles* are divisible into medial and lateral slips, which are supplied by the dorsal and ventral rami of the spinal nerves respectively. The *medial*, which is the proper intertransverse muscle, is often further subdivided into medial and lateral parts by the passage through it of the dorsal ramus of the spinal nerve. The *anterior intertransverse muscles* and the lateral parts of the posterior muscles connect the costal processes of contiguous vertebrae, and the medial parts of the posterior muscles connect the true transverse processes. There are seven pairs of these muscles, the highest between the atlas and axis, and the lowest between the seventh cervical vertebra and the first thoracic, but the anterior muscles between the atlas and axis is often absent. In the *thoracic region* they consist of single muscles, which are present between the transverse processes of the last three thoracic vertebrae only, and between the transverse processes of the last thoracic vertebra and the first lumbar. In the *lumbar region* they again consist of two sets of muscles, one named the *intertransversarii mediales*, connecting the accessory process of one vertebra with the mamillary process of the next, and the other named the *intertransversarii laterales*, which are really divisible into ventral and dorsal parts (Cave 1937; Morrison 1954). The ventral parts connect the transverse processes (costal elements) of the lumbar vertebrae, and each dorsal part connects the accessory process to the transverse process of the succeeding vertebra. The thoracic intertransverse muscles and ligaments are homologous with the medial slips of the proper posterior intertransverse muscles of the cervical region, and the *levatores costarum* are homologous with their lateral moieties. The lateral branch of the dorsal ramus of the spinal nerve separates the thoracic intertransverse from the levator costae muscle. In the lumbar region the levatores costarum are represented by the medial intertransverse muscles, while the lateral intertransverse are homologous with the intercostal muscles. For later views on the

homologies and classification of transversospinal musculature consult Sato (1973).

Nerve supply. The intertransversarii mediales lumborum, the thoracic intertransversarii and the medial parts of the posterior intertransversarii of the cervical region are supplied by the dorsal rami of the spinal nerves; the others are supplied by the ventral rami.

Actions. The short muscles of the back probably function, for the most part, as postural muscles. The vertebral column consists, in effect, of a series of short levers jointed together. A mechanical arrangement of this nature is unstable to compression forces and it will tend to buckle unless there is some mechanism by which the movements of the individual joints relative to one another can be controlled. This mechanism is provided by the short muscles of the back, which steady adjoining vertebrae and control their movements during motion of the vertebral column as a whole. In this way they ensure the efficient action of the long muscles.

Theoretically, these muscles are capable of producing extension (multifidi, spinales), lateral flexion (multifidus, intertransversarii), and rotation (multifidus and rotatores), but their detailed patterns of activity are not known.

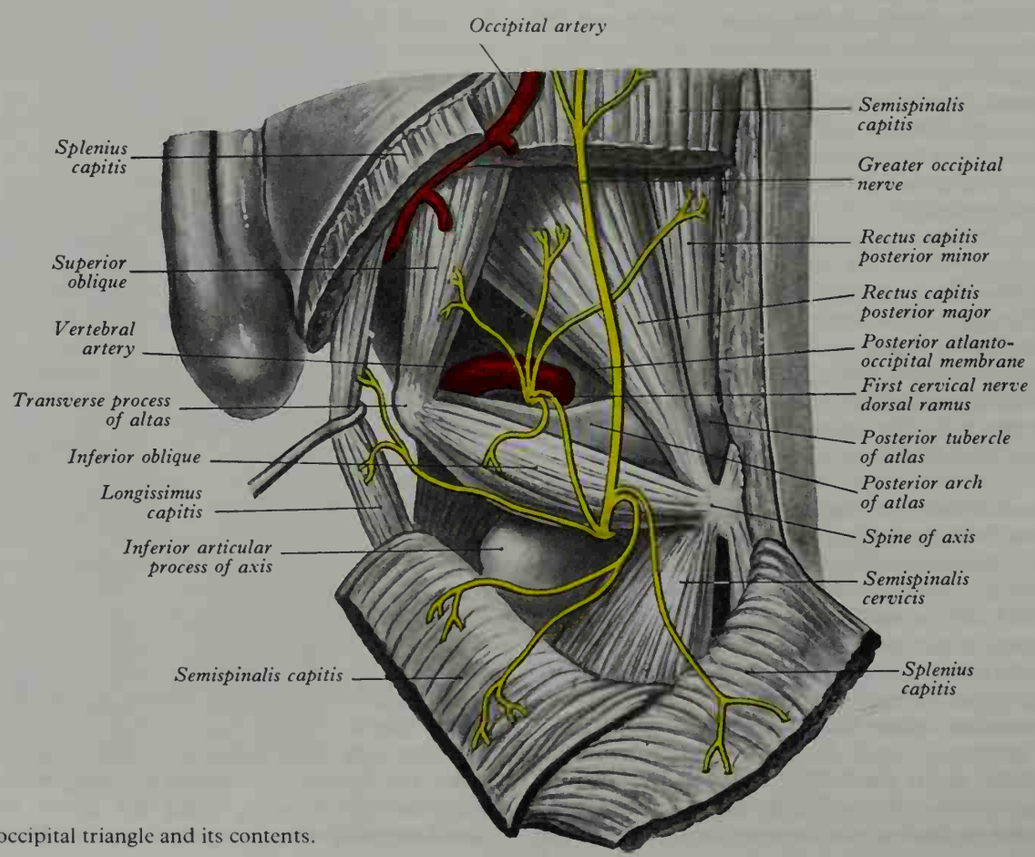
The deep muscles of the back are certainly involved in control of posture. They show intermittent contractions during the swaying movements which occur in the upright posture. Contraction of the erectores spinae extends the trunk, but the continued control of extension is to a large extent dependent on the activity of the rectus abdominis muscles. Conversely during flexion of the trunk, movement is initiated by the flexor muscles such as the recti abdominis, but as the centre of gravity moves forward control is by the erectores spinae. In lateral flexion the control is by the contralateral erector spinae. In the position of full flexion of the trunk the erectores spinae, however, are relaxed and electromyographically quiet. It is believed that this position is maintained by tension in the ligaments of the spine and by passive resistance to further deformation of the intervertebral disc (Floyd and Silver 1955; Joseph 1960). Jonsson (1974) has demonstrated that electromyographic activity in the erector spinae group is in most subjects greater in working postures assumed when they are working on lower surfaces from a standing position. This would be expected from the views expressed above.

II. The Suboccipital Muscles

This group of small muscles (5.40) is concerned in extension of the head at the atlanto-occipital joints (recti capitis posteriores major and minor), and rotation of the head and atlas on the axis (obliqui capitis superior and inferior).

The rectus capitis posterior major starts by a pointed tendon from the spine of the axis, and, becoming broader as it ascends, is attached to the lateral part of the inferior nuchal line of the occipital bone and the bone immediately below the line. As the muscles of the two sides pass upwards and laterally, they leave between them a triangular space, in which parts of the recti capitis posteriores minores are visible.

Actions. The rectus capitis posterior major extends the head, and turns the face towards the same side.



The rectus capitis posterior minor arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, widening as it ascends, is attached to the medial part of the inferior nuchal line of the occipital bone and also the bone between the line and the foramen magnum (p. 307). Either of the rectus capitis posterior muscles may be doubled longitudinally.

Action. The rectus capitis posterior minor extends the head.

The obliquus capitis inferior, the larger of the two oblique muscles, passes laterally and slightly upwards from the lateral surface of the spine and adjacent part of the upper part of the lamina of the axis to the lower and back part of the transverse process of the atlas.

Action. The obliquus capitis inferior turns the face towards the same side. Owing to the length of the transverse process of the atlas the muscle has considerable mechanical advantage.

The obliquus capitis superior, narrow below, wide and expanded above, arises by tendinous fibres from the upper surface of the transverse process of the atlas. It passes upwards and backwards, and is attached to the occipital bone, between the superior and inferior nuchal lines, lateral to the semispinalis capitis and overlapping the insertion of the rectus capitis posterior major.

5.40 The left suboccipital triangle and its contents.

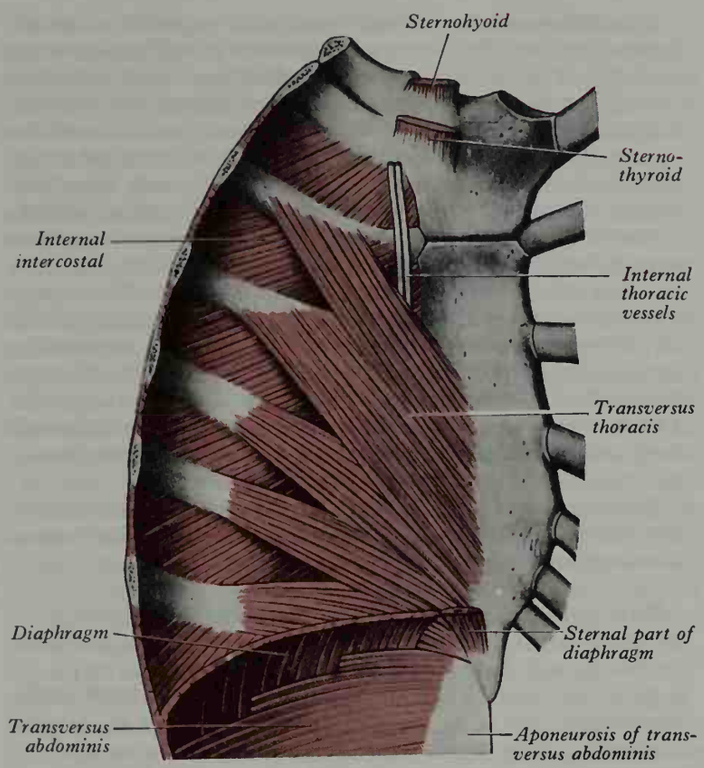
Actions. The obliquus capitis superior bends the head backwards and to the same side. This muscle and the two recti are probably employed more frequently as postural muscles than as prime movers, but direct observation is difficult.

Nerve supply. All the suboccipital muscles are supplied by the dorsal ramus of the first cervical spinal nerve.

The Suboccipital Triangle

This triangle is a region bounded, above and medially, by the rectus capitis posterior major, above and laterally, by the obliquus capitis superior, below and laterally, by the obliquus capitis inferior. Medially, it is covered by a layer of dense adipose tissue, situated deep to the semispinalis capitis, and, laterally, by the longissimus capitis and sometimes by the splenius capitis, which overlap the obliquus capitis superior. The 'floor' of the triangle is formed by the posterior atlanto-occipital membrane and the posterior arch of the atlas; the vertebral artery and the dorsal ramus of the first cervical nerve (**5**.40) lie in a groove on the upper surface of the posterior arch of the atlas.

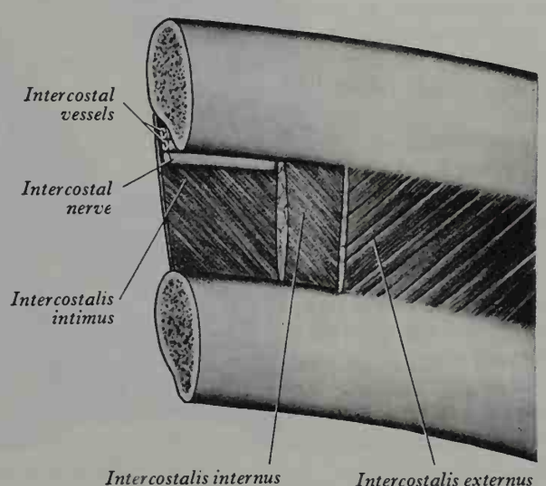
III. The Muscles of the Thorax



This group (**5**.41, 42, 43) consists of muscles which connect adjoining ribs (intercostales—externi, interni, et intimi), span several ribs between attachments (subcostales), connect ribs to sternum (transversus thoracis), or ribs to vertebrae (levatores costarum, serratus posterior superior et inferior) and the diaphragm. They are all concerned in the movements of ribs and hence, potentially, with respiration.

The intercostales (**5**.42) are thin superimposed layers of muscle and tendinous fibres occupying the intercostal spaces. They are named from their spatial relations—the intercostales externi are most superficial and the intercostales intimi are the innermost.

The intercostales externi are eleven in number on each side. Their attachments extend from the tubercles of the ribs, where they are blended with the posterior fibres of the superior costotransverse ligaments, almost to the cartilage of the ribs in front, where each is replaced by an aponeurotic layer named the *external intercostal membrane*, which is continued forwards to the sternum. Each muscle passes from the lower border of one rib to the upper border of the rib below. In the lower two spaces they extend to the ends of the costal cartilages, and in the upper two or three spaces they do not quite reach the ends of the ribs. They are thicker than the intercostales interni and their fibres are directed obliquely downwards and laterally at the back of the thorax, and downwards, forwards and medially at the front.



The intercostales interni are also eleven in number on each side. Their attachments commence anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and at the anterior extremities of the cartilages of the false ribs, and extend backwards as far as the posterior costal angles, where each is replaced by an aponeurotic layer named the *internal intercostal membrane*, which is continuous posteriorly with the anterior fibres of the superior costotransverse ligament and anteriorly with the fascia intervening between the internal and external intercostal muscles. Each muscle descends from the floor of the costal groove and the corresponding costal cartilage, and is inserted into the upper border of the rib below. Their fibres are also directed obliquely and nearly at right angles to those of the external intercostal muscles.

Actions. Opinions concerning the actions of the intercostals are not unanimous and at various times the following views have been maintained: that both the internal and external groups act as elevators of the ribs, that the external intercostals are elevators and the internal intercostals depressors of the ribs, that the intercartilaginous parts of the internal intercostals act with the external intercostals in inspiration and that both intercostals form strong elastic supports which prevent the contents of the intercostal spaces being drawn in or bulged out during

5.41 The left transversus thoracis, exposed and viewed from its posterior aspect. Note that, in the interval between the sternal and the costal origins of the diaphragm, the lower border of the transversus thoracis is in contact with the upper border of the transversus abdominis.

respiration. Experiment has shown that impulses pass along the nerves to the external intercostals of the lower intercostal spaces (5–9) in normal inspiration and that this activity is continued into the early part of expiration (Bronk and Ferguson 1935; Draper *et al.* 1960). With forced inspiration the contraction of these muscles is greater and more sustained. Electromyography has yielded some apparently divergent results. It has been claimed that the intercostals of the 6th, 7th and 8th spaces contract in the inspiratory phase of quiet breathing and are relaxed in expiration (Campbell 1958) and that in quiet breathing the intercostals of the upper four intercostal spaces show sustained and not rhythmic activity. In forced inspiration this activity is increased and continues at a diminished level in forced expiration (Jones *et al.* 1953). It is possible that the type and extent of activity in the intercostals varies with the depth of respiration (see also p. 550). These controversies have not yet been resolved (Hoshiko 1962; Basmajian 1967). The intercostals show constant activity during speech.

5.42 A dissection of a part of the thoracic wall, showing the position of the intercostal vessels and nerve relative to the intercostal muscles.

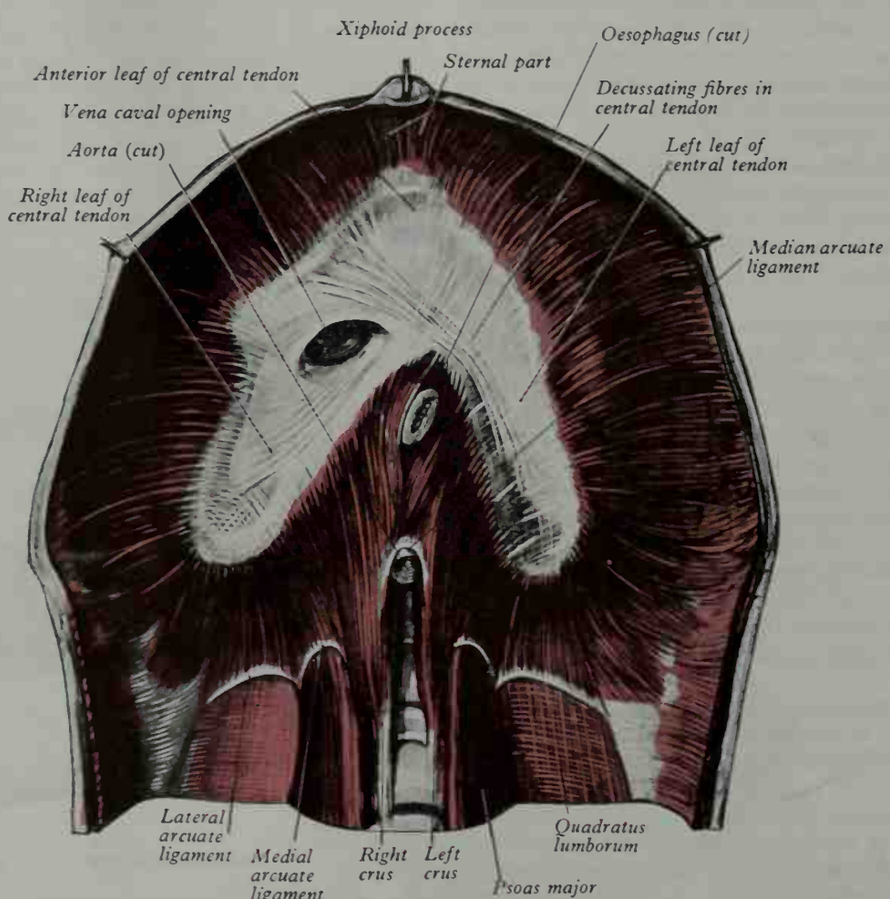
The intercostales intimi were once regarded as merely internal laminae of the internal intercostal muscles, with which their fibres do in fact coincide in direction. Each muscle is attached to the internal aspects of two adjoining ribs. They are insignificant and sometimes absent at highest thoracic levels, but become progressively more extensive below this, extending through about the middle two quarters of lower intercostal spaces. Walmsley (1915) considered them to correspond with the plane of the transversus abdominis and suggested the term musculi intracostales; his description was confirmed by Davies *et al.* (1931). Posteriorly the intercostales intimi, in those spaces where they are well developed, may become contiguous with the corresponding subcostales, which Davies *et al.* regarded as representing a fourth layer. The consensus of opinion, however, favours Walmsley's description of a three-layered arrangement. The intercostales intimi are related internally to the endothoracic fascia and parietal pleura, and externally to the intercostal nerves and vessels.

Actions. In the absence of specific information it can only be presumed that these muscles act in conjunction with the internal intercostal muscles (*vide supra*).

The subcostales consist of muscular and aponeurotic fasciculi, and are usually well developed only in the lower part of the thorax; each descends from the inner surface of one rib near its angle to the internal surface of the second or third rib below. Their fibres run in the same direction as those of the internal intercostals. Like the intercostales intimi they are between the intercostal vessels and nerves and the pleura. The incidence and distribution of these muscles have been recorded in detail by Eister (1912), and by Satoh (1974).

Actions. The subcostales probably depress the ribs.

The transversus thoracis (sternocostalis) is situated upon the internal surface of the anterior wall of the thorax (5.41). It arises from the lower third of the posterior surfaces of the body of the sternum, the xiphoid process, and the costal cartilages of the lower three or four true ribs near their sternal ends. Its fibres diverge as they pass upwards and laterally, to be attached by slips into the lower borders and inner surfaces of the costal cartilages of the second, third, fourth, fifth and sixth ribs. The lowest fibres of this muscle are horizontal, and are contiguous with the highest fibres of the transversus abdominis; the intermediate fibres are oblique, while the highest are almost vertical. This muscle varies in its attachments not only in different subjects but on opposite sides of the same subject. Like the intercostales intimi and subcostales, the transversus thoracis separates the intercostal nerves from the pleura.



Actions. The transversus thoracis draws down the costal cartilages to which it is attached.

Nerve supply. All the above muscles are supplied by the adjacent intercostal nerves.

The levatores costarum (5.37), twelve in number on each side, are strong bundles which arise from the ends of the transverse processes of the seventh cervical and 1st to 11th thoracic vertebrae; they pass obliquely downwards and laterally, parallel with the posterior borders of the external intercostals, and each is attached to the upper edge and external surface of the rib immediately below the vertebra from which it takes origin, between the tubercle and the angle (*levatores costarum breves*). Each of the four lower muscles divides into two fasciculi, one of which is attached as described above; the other passes down to the *second* rib below its origin (*levatores costarum longi*).

Nerve supply. The lateral branches of the dorsal rami of the corresponding thoracic nerves. (Consult Morrison 1954.)

Actions. The levatores costarum elevate the ribs but their importance in respiration is disputed (Primrose 1952); they are also said to act from their rib attachments as rotators and lateral flexors of the vertebral column.

548 5.43 The abdominal aspect of the diaphragm.

The serratus posterior superior is a thin, quadrilateral muscle, external to the upper and posterior part of the thorax. It arises by a thin aponeurosis from the lower part of the ligamentum nuchae, from the spines of the seventh cervical and upper two or three thoracic vertebrae and from their supraspinous ligaments. Inclining downwards and laterally it is attached by four fleshy digitations, into the upper borders and external surfaces of the second, third fourth and fifth ribs, a little lateral to their angles. It lies superficial to the thoracic part of the thoracolumbar fascia and anterior to the rhomboids. The number of slips may vary from three to six, and the muscle may even be absent.

Nerve supply. The second, third, fourth and fifth intercostal nerves.

Actions. By their attachments it is clear that this muscle could elevate ribs, but although experiments in dogs indicate that it is not a respiratory muscle (Ogawa *et al.* 1960), its role in man is not clear.

The serratus posterior inferior (5.58) is a thin irregularly quadrilateral muscle, situated at the junction of the thoracic and lumbar regions. It arises by a thin aponeurosis from the spines of the lower two thoracic and upper two or three lumbar vertebrae and from the supraspinous ligament; this aponeurosis is blended with the lumbar part of the thoracolumbar fascia. Passing obliquely upwards and laterally, it becomes fleshy, and is attached by four digitations into the inferior borders and outer surfaces of the lower four ribs, a little lateral to their angles. The number of slips may be reduced, and rarely the whole muscle is absent.

Nerve supply. The ventral rami of the ninth, tenth, eleventh and twelfth thoracic spinal nerves.

Actions. The serratus posterior inferior draws the lower ribs downwards and backwards, but perhaps not in respiration.

The Diaphragm

The diaphragm (5.43) is a dome-shaped, musculofibrous sheet which separates the thoracic from the abdominal cavity, its convex upper aspect facing the former, and its concave inferior surface directed towards the latter. Its periphery consists of muscular fibres attached to the circumference of the thoracic outlet and converging into a central tendon. The muscular fibres may be grouped into three parts—sternal, costal and lumbar.

The *sternal part* arises by two fleshy slips from the back of the xiphoid process, the *costal part* from the internal surfaces of the cartilages and adjacent parts of the lower six ribs on each side, interdigitating with the transversus abdominus (5.41), the *lumbar part* from two aponeurotic arches, the medial and lateral arcuate ligaments (sometimes termed lumbocostal arches) and from the lumbar vertebrae by two pillars or *crura*. The xiphoid slip is sometimes absent.

The *lateral arcuate ligament*, which is a thickened band in the fascia covering the quadratus lumborum, arches across the upper part of that muscle, and is attached, medially, to the front of the transverse process of the first lumbar vertebrae, and, laterally, to the lower margin of the twelfth rib near its mid point.

The *medial arcuate ligament* is a tendinous arch in the fascia covering the upper part of the psoas major; medially, it is continuous with the lateral tendinous margin of the corresponding crus, and is attached to the side of the body of the first or second lumbar vertebra; laterally, it is fixed to the front of the transverse process of the first lumbar vertebra.

The *crura* are tendinous in structure at their attachments, and blend with the anterior longitudinal ligament of the vertebral column. The *right crus*, broader and longer than the left, arises from the anterolateral surfaces of the bodies and intervertebral discs of the upper *three* lumbar vertebrae, while the *left crus* arises from the corresponding parts of the upper *two*. The medial tendinous margins of the crura meet in the median plane to form an arch across the front of the aorta, the *median arcuate ligament*; it is often poorly defined.

From this circumferential attachment the fibres of the diaphragm converge into a central tendon. The fibres from the xiphoid process are short, and occasionally aponeurotic; those from the medial and lateral arcuate ligaments, and more especially those from the ribs and their cartilages, are longer, and describe marked curves as they ascend and converge to their central attachment. The fibres from the crura diverge as they ascend, the most lateral being directed upwards and laterally to the central tendon. The medial fibres of the right crus ascend on the *left* side of the oesophageal opening, and occasionally a fleshy fasciculus from the medial side of the left crus crosses the aorta and runs obliquely through the fibres of the right crus towards the vena caval opening, but this fasciculus is not continued upwards around the oesophageal passage on the right side (Low 1907).

The *central tendon* of the diaphragm is a thin but strong aponeurosis of closely interwoven fibres situated near the centre of the dome formed by the muscle, but closer to the front of the thorax, so that the posterior muscular fibres are longer. It is immediately below the pericardium, with which it is partially blended. It is trifoliate in shape, consisting of three folia separated by slight indentations. The middle leaf has the form of an equilateral triangle, the apex directed towards the xiphoid process. The right and left folia are tongue-shaped and curve laterally and backwards, the left being a little narrower. The central area of the tendon consists of four well-marked *diagonal bands* radiating from a thick central point and expanding in a fan-shaped manner; the central point of decussation is a thick *node* of compressed tendinous strands situated in front of the oesophageal aperture, and to the left of the vena caval opening.

The Diaphragmatic Apertures

The diaphragm is pierced for the passage of structures between the thorax and abdomen: three large openings—the aortic, the oesophageal and the vena caval (5.43)—and a number of smaller ones exist.

The *aortic aperture* is the lowest and most posterior of the large openings; it is at the level of the lower border of the twelfth thoracic vertebra and the thoraco-lumbar intervertebral disc, slightly to the left of the median plane. Strictly speaking, it is an osseo-aponeurotic opening lying between the diaphragmatic crura laterally, the vertebral column posteriorly and the diaphragm anteriorly. It therefore lies *behind* the diaphragm and, more specifically, its median arcuate ligament when present. Occasionally some tendinous fibres from the medial parts of the crura also pass *behind* the aorta, and convert the opening into a fibrous ring. The aortic opening transmits the aorta and the thoracic duct and *occasionally* the azygos and hemiazygos veins (p. 754); some lymphatic trunks also *descend* through it from the lower posterior thoracic wall.

The *oesophageal aperture* is in the muscular part of the diaphragm at the level of the tenth thoracic vertebra; it is elliptical in shape, and is formed by the splitting of the medial fibres of the right crus (Low 1907). It is above, in front, and a little to the left of the aortic opening, and transmits the oesophagus, the complex vago-sympathetic gastric nerves, oesophageal branches of the left gastric vessels, and some lymphatic vessels. There is no direct continuity between the oesophageal wall and the muscle around the oesophageal opening. The fascia on the inferior surface of the diaphragm, which is continuous with the transversalis fascia (p. 559), and is rich in elastic fibres, extends upwards into the opening in a conical fashion to be attached to the wall of the oesophagus about 2 cm above the gastro-oesophageal junction. Some of its elastic fibres penetrate to the submucosa of the oesophagus. This fascial expansion is sometimes termed the *phreno-oesophageal ligament*; it constitutes a flexible connexion between the oesophagus and diaphragm, permitting some freedom during swallowing and respiration and at the same time limiting upward displacement of the oesophagus (Allison 1951; Hayward 1961).

The *vena caval aperture*, the highest of the three large openings, is at about the level of the disc between the eighth and ninth thoracic vertebrae. It is quadrilateral, and at the junction of the right leaf with the central area of the tendon so that its margins are aponeurotic. It is traversed by the inferior vena cava, which is adherent to the margin of the opening, and some branches of the right phrenic nerve.

There are two *lesser apertures* in each crus; one transmits the greater and the other the lesser splanchnic nerve. The ganglionated trunks of the sympathetic usually enter the

abdominal cavity behind the diaphragm, deep to the medial arcuate ligament. Openings for minute veins frequently occur in the central tendon.

On each side there are two small areas where the muscular fibres of the diaphragm are deficient and are replaced by areolar tissue. One, between the sternal and costal parts, contains the superior epigastric branch of the internal thoracic artery and some lymph vessels from the abdominal wall and convex surface of the liver. The other, between the costal part and the fibres springing from the lateral arcuate ligament, is less constant; when it exists, the posterosuperior surface of the kidney is separated from the pleura only by areolar tissue.

Relations. The upper surface of the diaphragm is in relation with three serous membranes, viz. on each side with the pleura which separates it from the base of the corresponding lung, and over the middle folium of the central tendon with the pericardium, which intervenes between it and the heart. The central area lies on a slightly *lower* level than the summits of the lateral regions, which are usually termed the *cupolae*. The greater part of the inferior surface is covered by peritoneum. The right side is accurately moulded over the convex surface of the right lobe of the liver, the right kidney, and right suprarenal gland; the left over the left lobe of the liver, the fundus of the stomach, the spleen, the left kidney, and the left suprarenal gland.

Nerve supply. The diaphragm is supplied with motor fibres by the phrenic nerves. The lower six or seven intercostal nerves distribute sensory fibres to the peripheral part of the muscle. There has been some controversy concerning the motor supply to the crural fibres stemming from a suggestion that these are supplied by intercostal nerves. However, Collis *et al.* (1954) and Bottia (1957) have described a supply by the phrenic nerves, and this has been confirmed by Shehata (1966). All three observers state that the crural fibres (irrespective of their origin) on the right and left aspects of the oesophageal hiatus are supplied by the ipsilateral phrenic nerve.

Actions. The diaphragm is the essential muscle of inspiration. Its dome presents a concave surface towards the abdomen. The central part of the dome is tendinous, with the pericardium attached to its upper surface; the circumferential part muscular. During inspiration the lowest ribs are fixed, and from these and the crura the muscular fibres contract and draw the central tendon downwards and forwards with the attached pericardium. In this movement the curvature of the diaphragm is scarcely altered, the dome moving downwards nearly parallel to its original position and pushing before it the abdominal viscera. The descent of the abdominal viscera is permitted by the extensibility of the abdominal wall, but the limit of this is soon reached. The central tendon, applied to the abdominal viscera, then becomes a fixed point for the action of the diaphragm, the effect of which is to elevate the lower ribs and through them to push forwards the body of the sternum and the upper ribs. The right cupola of the diaphragm, lying on the liver, has a greater resistance to overcome than the left, which lies over the stomach, but to compensate for this the right crus and the fibres of the right side are more substantial than those of the left. The balance between descent of the diaphragm and protrusion of the abdominal wall ('abdominal' breathing) and elevation of the ribs ('thoracic' breathing) varies in different individuals and with the depth of respiration. The thoracic element is usually more marked in females and in both sexes in deep inspiration.

In all expulsive acts the diaphragm is called into action to give additional power to each effort. Thus, before sneezing, coughing, laughing, crying, or vomiting, and previous to the expulsion of urine, or faeces, or of the fetus from the uterus, a deep inspiration takes place. A relatively deep inspiration, followed by closure of the glottis, is a common preliminary to powerful action of the trunk muscles, as in lifting heavy weights.

It has been suggested that the fibres of the right crus exert a sphincteric action on the lower end of the oesophagus in man. The act of expiration, which immediately succeeds the act of swallowing, relaxes these fibres and allows the contents of the oesophagus to pass into the stomach (*see* Whillis 1931; and p. 1318). In recent years less emphasis has been placed on this action of the right crus, and the intrinsic muscle of the lower 2 cm of the oesophagus below the attachment of the phrenoesophageal ligament is considered to have some effective sphincteric action. (See also p. 1336.)

The level of the diaphragm varies continuously during respiration; it is also affected by the degree of distension of the stomach and intestines and the size of the liver. After a forced expiration the right cupola is level in front with the fourth costal cartilage, at the side with the fifth, sixth and seventh ribs, and behind with the eighth; the left cupola is a little lower. The excursion of the diaphragm is about 1·5 cm during quiet breathing; in deep respiration the maximum movement ranges from 6 to 10 cm (Campbell 1958).

Radiographs show that the level of the diaphragm in the thorax also varies considerably with posture. It is highest when the body is supine, and in this position it performs the largest respiratory excursions with normal breathing. When the body is erect the dome of the diaphragm is lower, and its respiratory movements become smaller. The dome is still lower when the sitting posture is assumed, and respiratory excursions are smallest. When the body is horizontal and on one side, the two halves of the diaphragm do not behave alike. The uppermost half sinks to a level lower even than in sitting, and moves little with respiration; the lower half rises higher in the thorax than it does in the supine position, and its respiratory excursions are much increased.

It appears that the position of the diaphragm in the thorax depends upon three main factors: (1) the elastic retraction of the lung tissue, tending to pull it upwards; (2) the pressure exerted from below by the viscera: this naturally tends to be a negative pressure, or downward suction, when the patient sits or stands, and a positive, or upward pressure, when he is lying down; (3) the intra-abdominal pressure due to the abdominal muscles. These muscles are in a state of contraction in the standing position but not in the sitting; hence the diaphragm is pushed up higher in the former position.

Applied Anatomy. Abdominal organs, usually the stomach, occasionally herniate through the diaphragm into the thorax, either alongside the oesophagus or between the fibres arising from the lateral arcuate ligament and the costal fibres.

The Movements of Respiration

The rhythmic movements of respiration produce alterations in the capacity of the thoracic cavity which in turn bring about the inflow and expulsion of air in the lungs to ventilate the alveoli, where the gaseous exchanges between the blood and alveolar air occur. The capacity of the thoracic cavity can be increased, either independently or in combination, in the transverse, anteroposterior and vertical dimensions.

The transverse and anteroposterior dimensions are increased by movements of the ribs. When elevated, the anterior ends of the vertebrosternal ribs are thrust forwards and upwards with some slight movement at the sternal angle, thereby increasing the anteroposterior dimension of the cavity. At the same time these same ribs, rotating around an anteroposterior axis through their ends (p. 453), are everted, thereby increasing the transverse diameter. Elevation of the vertebrochondral ribs (**4**.35) results in an outward and backward movement to produce an increase in the transverse diameter. This is associated with some widening of the infrasternal angle and an increase in the capacity of the upper part of the abdominal cavity. The vertical dimension of the thoracic cavity is increased by contraction of the diaphragm. This presses on the abdominal viscera, which are permitted to descend by relaxation of the abdominal wall, during inspiration. When the limit of this descent is reached the abdominal viscera provide resistance for the central tendon of the diaphragm from which its muscle fibres elevate the lower ribs.

Each respiratory cycle consists of an inspiratory and an expiratory phase. When the body is at rest the former is of about 1 second and the latter about 3 seconds duration. The increased thoracic capacity in inspiration reduces the intrapleural pressure with consequent expansion of the lung, decreasing intrapulmonary pressure and entry of air through the respiratory passages. The expiratory phase is largely passive, the recoil of the

chest wall and lungs raising the intrathoracic pressure and expelling air.

In *quiet respiration* about 500-750 ml of *tidal air* are inspired or expired in each respiratory cycle. About one-third of this occupies the '*anatomical dead space*'. This space extends from the nostrils to the terminal bronchioles, its epithelium is not respiratory, and practically no gaseous exchanges with the blood can occur. The remainder of the inspired air is available for ventilation of the alveoli. The inspired air is warmed, humidified and filtered in the nasal cavity.

In *quiet inspiration* the principal and often the sole muscle concerned is the diaphragm. In an average adult the right cupola descends to the level of the disc between the tenth and eleventh thoracic vertebrae and the left cupola descends to the level of the disc between the eleventh and twelfth. The dome descends about 1·5 cm. This diaphragmatic movement is responsible for the greater part and perhaps sometimes the whole of the tidal volume of about 500 ml of air inspired. There is little or no alteration in the position of the bony boundaries of the thoracic inlet. Electromyography, however, shows rhythmic activity of the scalene muscles (anterior and medius). They serve to fix the upper ribs, while the intercostal muscles of the upper six intercostal spaces may show continuous activity, thereby preventing the sucking in or blowing out of the tissues of these spaces with changes in the intrapleural pressure. At the same time in quiet respiration the intercostals of the lower spaces may undergo rhythmic contraction, thereby contributing to the increase of the transverse diameter at this level in the thoracic cavity. These muscles may also resist pressure changes.

In inspiration the intrapleural and the intrapulmonary pressure fall below atmospheric. At the end of inspiration the intrapulmonary pressure is equal to the atmospheric. During inspiration the air which flows into the lung is not evenly distributed. Regional differences occur in both the ventilation and blood flow. The ventilation is greater in the lower than in the upper lobes of the lung. This accords with the fact that the movement of the upper chest in quiet respiration is inconspicuous, whereas that of the lower chest is greater, affecting principally the transverse diameter. These regional differences may also be related to the varying elasticity of different parts of the lungs and the dimensions of the air passages leading to them. It has been suggested that the alveoli which expand earliest in inspiration receive more of the air lying in the dead space.

In *quiet expiration* the elastic recoil of the lungs and chest wall is graduated by the slow relaxation of the inspiratory muscles. Electromyography demonstrates that the diaphragm and intercostals continue contracting but with progressively decreasing intensity well into the expiratory phase. Another component believed to be important in the recoil of the lungs is the thin film of surface-active material at the interphase between the alveolar air and the surface of the alveolar epithelium (*see* p. 1258). Provided the ventilation rate is below 40 litres/min there is no active participation of the intercostal or abdominal muscles in expiration.

In *deep inspiration* the movements already described are increased and additional muscles are brought into action. The muscles contract with greater force, the number of motor units called into action increases, the discharges along their nerves are of longer duration and the contribution of the different motor units is better synchronized.

The intercostal muscles become active in a progressively increasing number of intercostal spaces to produce movements of the upper ribs and sternum. The first rib is elevated by the scaleni, anterior and medius, and by the sternocleidomastoid indirectly through the clavicle and costoclavicular ligament and directly through the manubrium sterni. For each 1 cm increase in the circumference of the chest the capacity increases by about 200 ml.

The twelfth rib is fixed by the quadratus lumborum so that the diaphragm is able to exert a more powerful downward thrust on the abdominal viscera (Boyd *et al.* 1965). It has also been suggested that this action might provide a fixed basis for controlled relaxation of the diaphragm in the nice adjustment of expiration necessary to speech and singing (Taylor 1960). In addition, the erectores spinae come into action and the concavity of the thoracic part of the vertebral column is diminished, a movement which results in a slight increase in the width of the intercostal spaces and allows the ribs a greater range of movement. The intrapulmonary pressure at the beginning of *deep expiration* may rise to 30 mm of mercury above the atmospheric pressure.

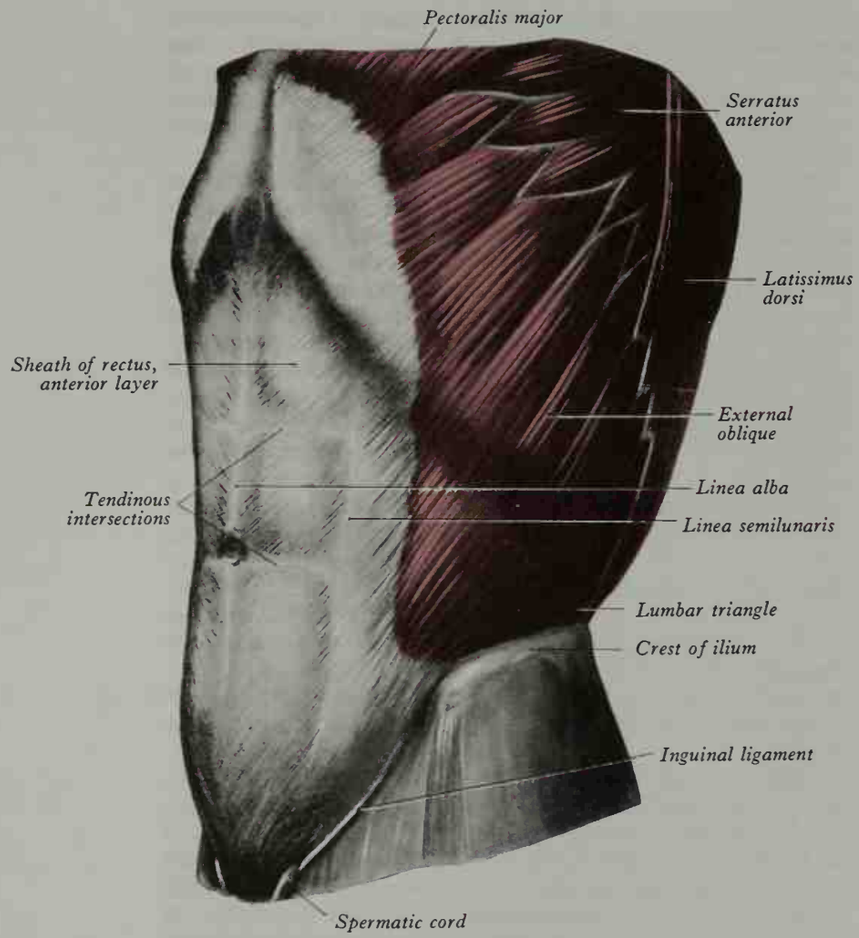
In *forced respiration*, as in breathing against resistance, further muscles are called into action. In forced *inspiration* the diaphragm contracts maximally, the right cupola descends to about the level of the eleventh thoracic vertebra, while the left cupola may reach the level of the body of the twelfth. Such maximal excursions of the diaphragm correspond to a maximal change in level of 9 to 10 cm. The action of the erectores spinae is appreciably augmented and muscles connecting the upper limb to the trunk may show some activity. In forced *expiration* additional expulsive factors are provided by the strong contraction of the muscles of the abdominal wall, particularly the oblique and transverse muscles, and by both the latissimi dorsi, which contract suddenly and energetically with such efforts as coughing and sneezing. The muscles of the abdominal wall raise the intra-abdominal pressure, forcing the relaxing diaphragm upwards and drawing the lower ribs downwards and medially.

The range and character of the movements of the thoracic parietes exhibit very striking individual variations, which may be dependent on the conformation of the thoracic skeleton, on habit or on other factors, and this extreme variability must be borne in mind when the movements are being analysed in any particular subject.

In all these phases of respiration it must be remembered that there are changes in the nostrils, larynx, trachea and bronchial tree. The actions of the dilators of the nostrils become evident in forced respiration. During quiet respiration the rima glottidis (p. 1237) is widened by lateral rotation of the vocal processes abducting the vocal cords and this is widened even further in forced inspiration by increasing abduction of the vocal cords and by abduction of the arytenoid cartilages. The calibre of the trachea, bronchi and bronchioles can be changed passively by distension or actively by alteration of the tone of the smooth muscle in their walls mediated through their parasympathetic (vagus nerve) and sympathetic nerve supplies, so that they dilate in inspiration and contract during expiration. The precise role of these antagonistic influences is not yet certain.

Applied Anatomy. The changes in the height of the diaphragm during alterations in posture explain why patients suffering from severe dyspnoea are most comfortable and least short of breath when they sit up. In unilateral disease of the pleura or lungs interference with the position or movement of the diaphragm can generally be observed on X-ray examination.

IV. The Muscles of the Abdomen



The muscles of the abdomen may be conveniently divided into anterolateral and posterior groups.

THE ANTEROLATERAL MUSCLES OF THE ABDOMEN

This group consists of four large flat muscular sheets forming the abdominal wall (obliqui externus and internus, transversus and rectus abdominis), and two smaller elements (cremaster and pyramidalis) concerned with suspension of the testis and tensing of the midline tendinous raphe of the abdominal wall.

The superficial fascia of the abdominal wall consists, over the greater part of it, of a single layer containing a variable amount of fat; but over the lower part, particularly in obese individuals, the fascia differentiates into layers. The extent and significance of these layers is disputed (Tobin and Benjamin 1949), but in practice the following obtains. The superficial fascia is divisible into two layers, between which are superficial vessels, nerves and the superficial inguinal lymph nodes.

The superficial layer (or layers) of the fascia is thick, areolar in texture, and contains in its meshes a varying quantity of fat. Below, it passes over the inguinal ligament, and is continuous with the superficial fascia of the thigh. In the male this layer is

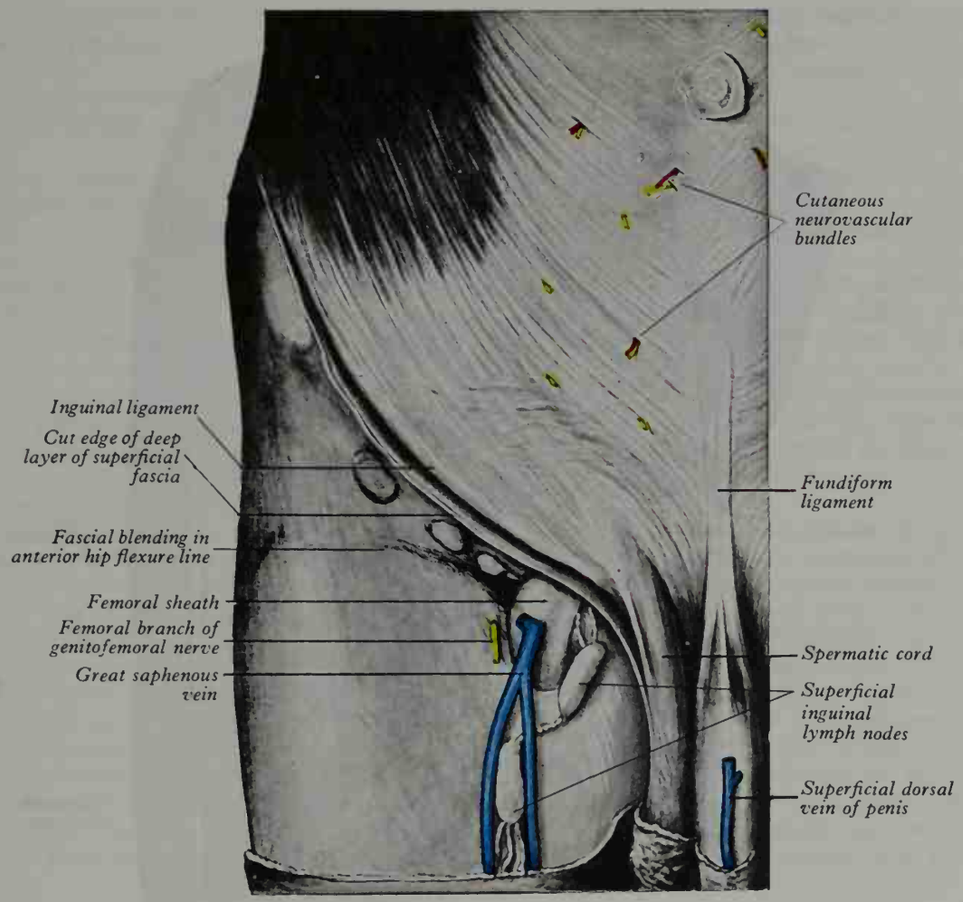
5.44 The left obliquus externus abdominis.

continued over the penis and outer surface of the spermatic cord into the scrotum, where it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish colour. In the scrotum it also contains non-striated muscular fibres, forming the *dartos* muscle, which is supplied by the genitofemoral nerve. From the scrotum it may be traced backwards into continuity with the superficial fascia of the perineum. In the female it is similarly continued from the abdomen into the labia majora and perineum.

The deep layer (or layers) of the fascia, more membranous than the superficial, contains elastic fibres. It is loosely connected by areolar tissue to the aponeurosis of the external oblique; but in the median plane it is intimately adherent to the linea alba and symphysis pubis, and is prolonged on the dorsum of the penis, contributing to the *fundiform ligament* (**5**.45). Above, it is continuous with the superficial fascia over the rest of the trunk; below and laterally, it passes over the inguinal ligament and blends with the overlying superficial layer and the underlying fascia lata in the flexure line or skin crease of the thigh (**5**.45); below and medially, it is continued over the penis and spermatic cord to the scrotum, and from there may be traced backwards into continuity with the membranous layer of the superficial fascia of the perineum (p. 561). In the female it is continued into the labia majora and thence to the fascia of the perineum.

In the child the testis can frequently be retracted out of the scrotum into the interval occupied by loose areolar tissue between the external oblique and the deep layer of superficial fascia over the inguinal canal. This interval is sometimes called the *superficial inguinal pouch* (Browne 1938).

The obliquus externus abdominus (**5**.44), curved round the lateral and anterior parts of the abdomen, is the largest and the most superficial of the three flat muscles in this region. It arises, by eight fleshy slips, from the external surfaces and inferior borders of the lower eight ribs; these slips interdigitate with the digitations of serratus anterior and latissimus dorsi, and are arranged in an oblique line which extends downwards and backwards, the upper ones being attached close to the cartilages of the corresponding ribs, the lowest to the apex of the cartilage of the last rib, the middle ones to the ribs at some distance from their cartilages. From these attachments the fibres diverge as they pass to their insertions. Those from the lower two ribs pass nearly vertically downwards, and are attached to the anterior half or more of the outer lip of the ventral segment of the iliac crest (p. 379); the middle and upper fibres, directed downwards and forwards, end in an aponeurosis, opposite a line drawn vertically from the ninth costal cartilage to a little below the level of the umbilicus, and then inclining laterally to the anterior superior iliac spine. The muscle fibres rarely descend beyond a line from the anterior superior iliac spine to the umbilicus. The posterior border of the muscle is free (**5**.58).



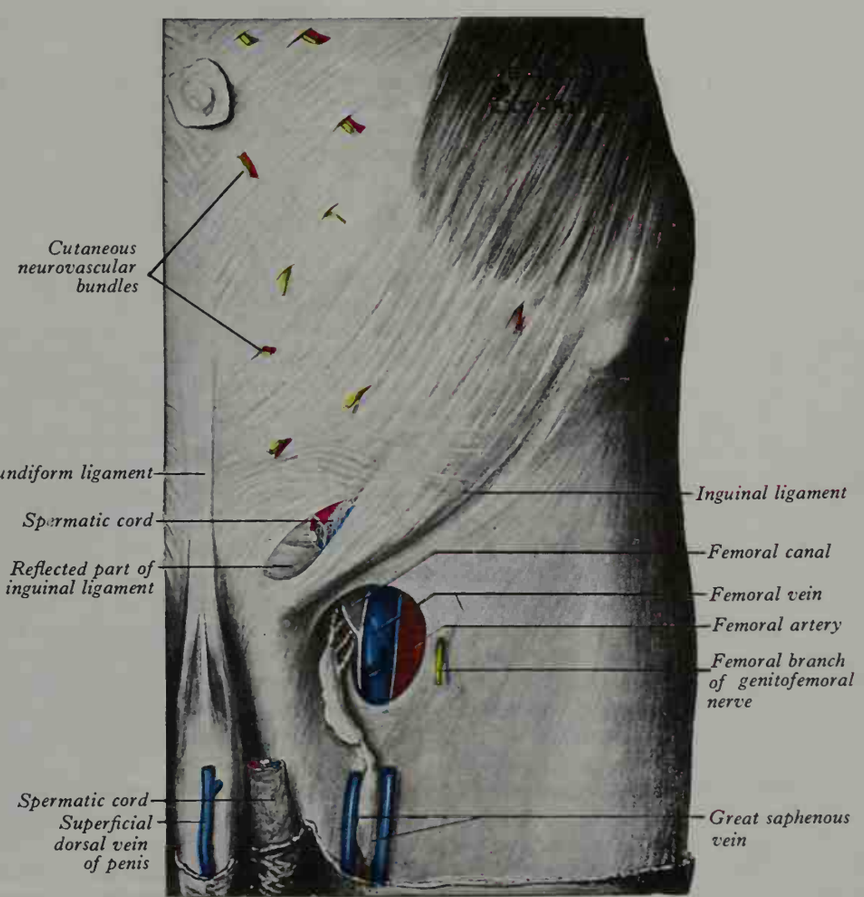
The *aponeurosis* of the external oblique is a strong tendinous sheet, the fibres of which are directed downwards and medially. In the median plane its fibres end in the *linea alba* (**5**.44), a tendinous raphe which stretches from the xiphoid process to the symphysis pubis. At the raphe it is continuous with the aponeurosis of the opposite muscle and the two together cover the front of the abdomen. Below and medially the aponeurosis is attached to the upper border of the pubic symphysis and the pubic crest as far as the pubic tubercle. The margin of the part of the aponeurosis between the anterior superior iliac spine and the pubic tubercle is a thick band, folded internally upon itself to present a grooved upper surface; this is the *inguinal ligament*. Expansions, continuous with the medial end of the inguinal ligament are attached to the pecten pubis and constitute the *lacunar ligament complex*. From this end of the inguinal ligament fibres also pass upwards and medially to join the rectus sheath and the linea alba; these constitute the *reflected part* of the inguinal ligament (**5**.50).

The muscular and aponeurotic parts of the external oblique are invested by external and internal layers of fascia of which the former is better developed. The upper and lower digitations may be absent; digitations or even the whole muscle may be reduplicated. Digitations may also be continuous with pectoralis major or serratus anterior.

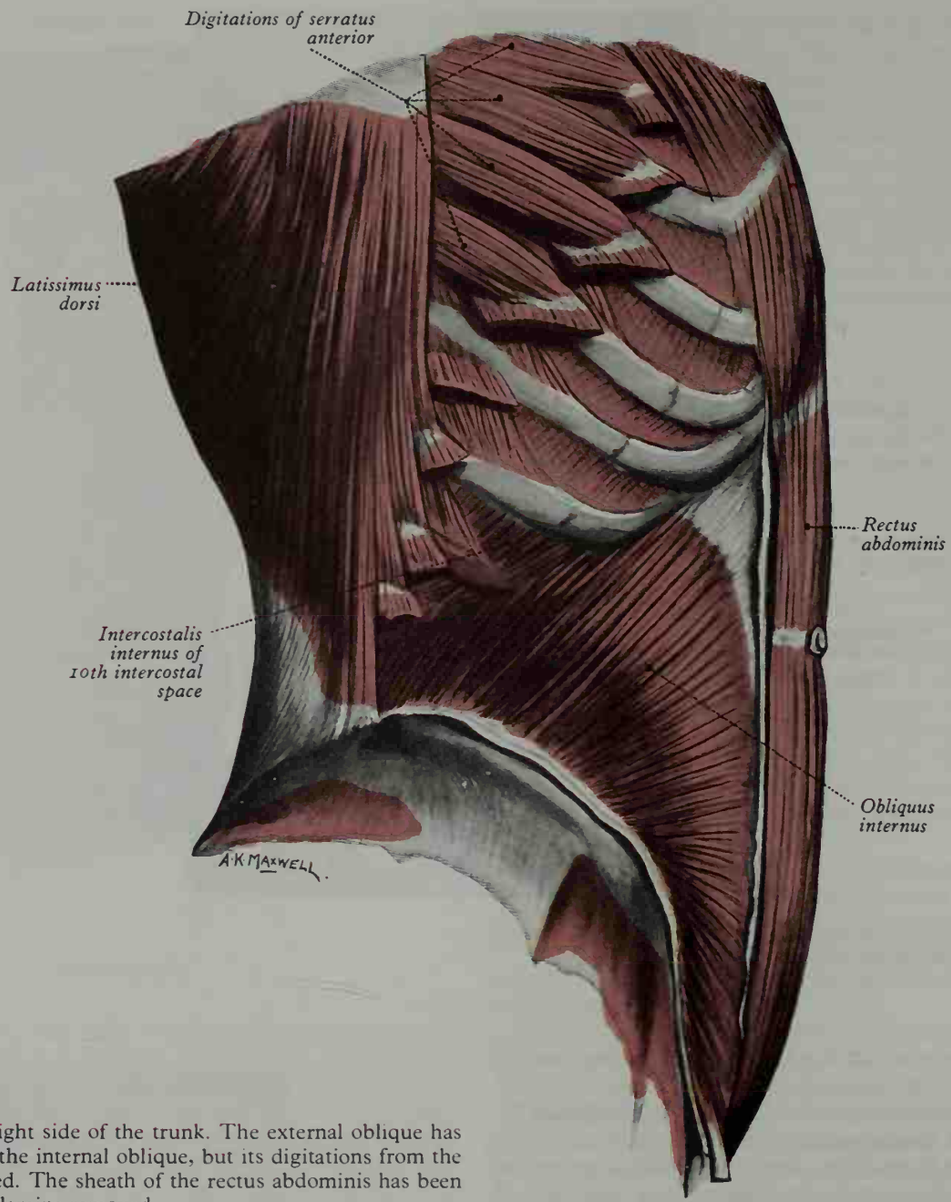
Nerve supply. The ventral rami of the lower six thoracic spinal nerves.

The inguinal ligament (**5**.46), as noted above, is the thick folded lower border of the aponeurosis of the external oblique, presenting a grooved, superior, abdominal surface (the 'floor' of the inguinal canal), and which stretches from the anterior superior iliac spine to the pubic tubercle. (It has variously been called the *crural arch*, the *superficial crural arch*, and *Poupart's ligament*.) The inguinal ligament is convex downwards towards the thigh and continuous with the fascia lata. In the adult it is some 12–14 cm in length and is inclined 40 to 35° to the horizontal. Its lateral half is rounded and more oblique; its medial half gradually widens towards its attachment to the pubis, is more horizontal and supports the spermatic cord. The fibres of the external oblique aponeurosis are *not* initially parallel to the long axis of the inquinal ligament: they approach the latter obliquely at an angle of 10–20°, and then, on reaching the ligament, each fibre turns *medially*, the majority now running in the long axis of the ligament to reach the pubic tubercle. The deeper fibres, however, splay out posteromedially to reach the pecten pubis (*see* Lytle 1974).

The lacunar ligament (*pectineal part of the inguinal ligament*) (**4**.58) has been described as composite in nature (Lytle 1974). Its abdominal, 'deep' part (i.e. the lacunar ligament of classical anatomy) consists of the extension of the aponeurosis of the external oblique, which continues backwards and laterally from the medial part of the inguinal ligament to the medial end of the pecten pubis. It is triangular, and almost horizontal when the body is upright; it is a little larger in the male, and measures about 2 cm from base to apex. Its base, directed laterally, is concave and thin, and forms the medial boundary of the femoral ring; its apex is attached to the pubic tubercle. Its posterior margin is attached to the pecten pubis, and is continuous with the *pectineal fascia*; its anterior margin is continued into the inguinal ligament. It has superior and inferior surfaces. A strong fibrous band, the *pectineal ligament* (of *Astley Cooper*) extends laterally from its base (**4**.58)



5.45 Superficial structures of the inguinal region and the lower part of the anterior abdominal wall. Right side.



along the pecten pubis to which it is attached. It is augmented by the pectineal fascia and by a lateral expansion from the lower end of the linea alba (*adminiculum lineae albae*, p. 559) It should be noted that the lacunar formation just described is best examined during dissection, and at operation, from its abdominal aspect (in the recent account by Lytle, this part is named as a subregion of the inguinal ligament). When approached from the thigh, however, in the living, a second, distinct lacunar fibrous sheet is distinguishable. This is derived from an inflexion of the *fascia lata* which, becoming confluent with the posterior border of the inguinal ligament, and receiving a reinforcement from the transversalis fascia, then fuses with pectineal fascia for a distance of about 1 cm, before proceeding upwards to reach and fuse with the thickened periosteum of the pecten pubis. This *fascial lacunar ligament* also presents a thickened curved lateral border which fits closely around the medial wall of the femoral sheath, and because of its pectineal fascial attachment is sited about 1 cm *below* and *anterior* to the pecten pubis, and some 3 cm lateral to the pubic tubercle. It should be noted that the traditional account of the boundaries of a femoral hernia, may need considerable revision. Further details will not be pursued here, expansion and confirmation of these new findings being awaited. (The interested reader should consult McVay and Anson 1940; Madden *et al.* 1971; Lytle 1957, 1974.)

The reflected ligament (part of the inguinal ligament) (**5**.46, 50) is an expansion from the lateral crus of the superficial inguinal ring. It passes upwards and medially behind the medial end of the superficial inguinal ring behind the external oblique and in front of the falx inguinalis; the fibres of the right and left ligaments interlace at the linea alba.

The superficial inguinal ring (**5**.45, 46) is a hiatus in the aponeurosis, just above and lateral to the crest of the pubis. The aperture is somewhat triangular, its long axis corresponding with the oblique course of the fibres of the aponeurosis. Its size is variable but usually it does not extend laterally beyond the medial third of the inguinal ligament. It is smaller in the female, the

5.46 Superficial structures of the inguinal region and the lower part of the anterior abdominal wall. Left side.

5.47 Muscles of the right side of the trunk. The external oblique has been removed to show the internal oblique, but its digitations from the ribs have been preserved. The sheath of the rectus abdominis has been opened and its anterior lamina removed.

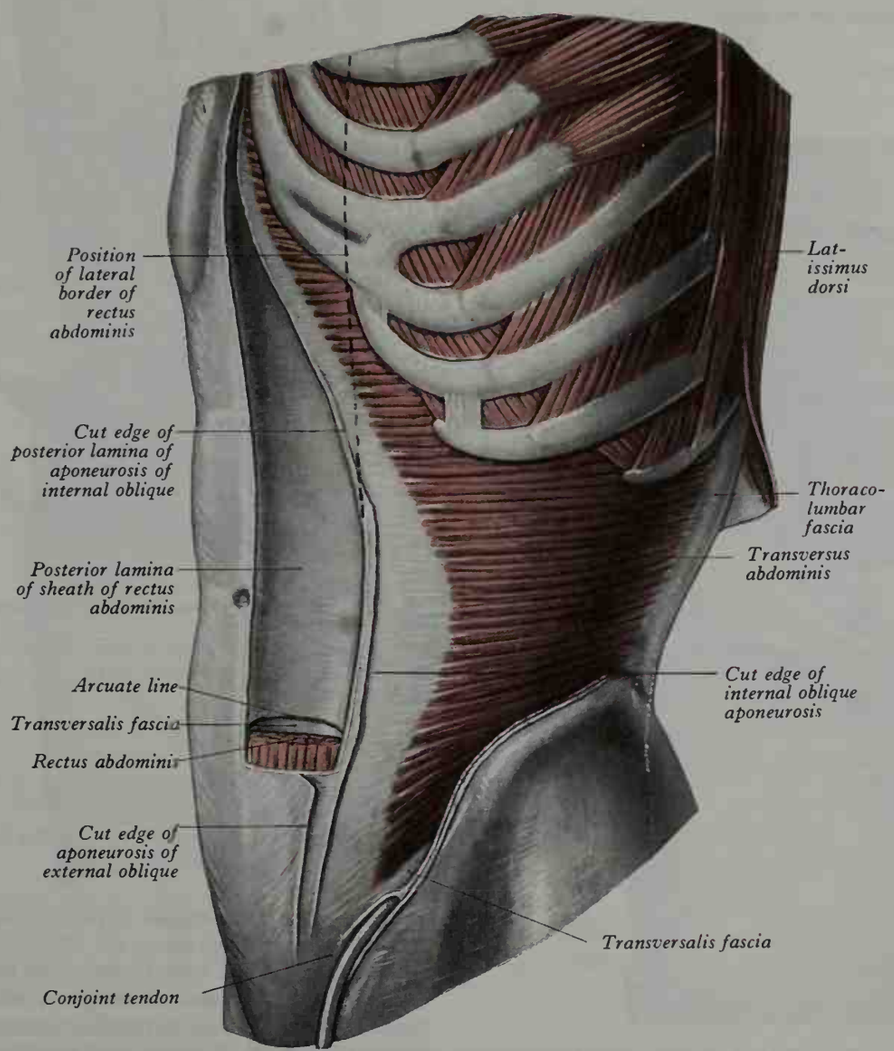
spermatic cord being absent. Its base is the crest of the pubis, and its sides are the margins of the opening in the aponeurosis, the *crura* of the ring. The lateral crus is the stronger, and is formed by fibres of the inguinal ligament inserted into the pubic tubercle; it is curved so as to form a kind of groove, in which the spermatic cord rests. The medial crus is a thin, flat band, attached to the front of the symphysis pubis, interlacing with the opposite crus. In the external layer of the investing fascia of the external oblique are bands of fibres of variable development and distribution which course at right angles to the fibres of the aponeurosis of the muscle. Some of these bands may arch above the apex of the superficial inguinal ring as *intercrural fibres*.

The superficial inguinal ring contains the spermatic cord in the male, the round ligament of the uterus in the female and the ilio-inguinal nerve in both. If the skin of the scrotum is invaginated upwards and laterally the spermatic cord can be followed up to the superficial inguinal ring. If the examining finger is then directed *backwards*, the crura of the ring can be recognized and the size of the ring appreciated.

At the margins of the ring the external oblique aponeurosis and overlying fascia are continued downwards as a delicate tubular prolongation of fibrous tissue around the spermatic cord and testis, as the outermost of their coverings, the *external spermatic fascia*. The superficial inguinal ring is only a distinct aperture after the continuity of this fascia and the aponeurosis has been severed (Anson *et al.* 1960).

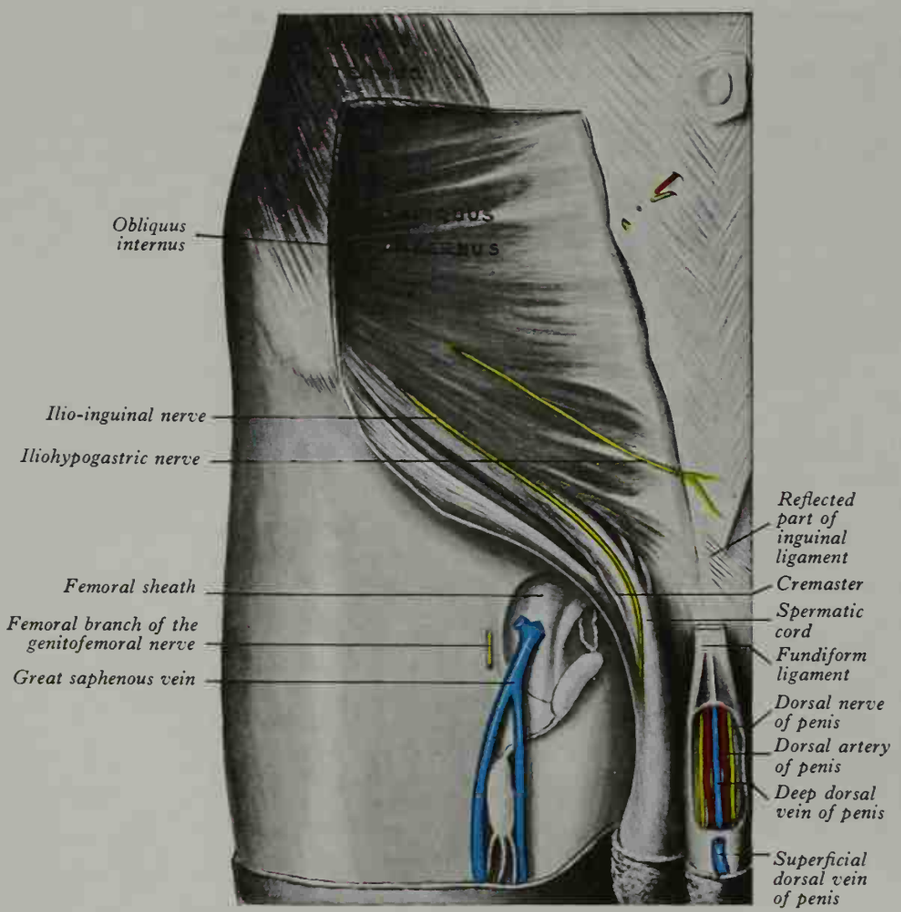
The obliquus internus abdominis (**5**.47), internal to the external oblique, is thinner and less bulky. It arises, by muscular fibres, from the lateral two-thirds of the grooved upper surface of the inguinal ligament, from the anterior two-thirds of the intermediate line of the ventral segment of the iliac crest, and from the thoracolumbar fascia (**5**.38). It has been described as attached to the iliac fascia and not directly to the inguinal ligament (McVay and Anson 1940); fascia and ligament are adherent at this point (p. 564). The posterior fibres pass upwards and laterally to the inferior borders of the lower three or four ribs, and are there continuous with the internal intercostals. The uppermost fibres form a short, free superomedial border. The fibres from the inguinal ligament, paler in colour, arch downwards and medially across the spermatic cord in the male and the round ligament of the uterus in the female. Becoming tendinous, they are attached with the corresponding part of the aponeurosis of the transversus abdominis to the crest and the medial part of the pecten pubis, forming the *falx inguinalis* (*conjoint tendon*). The rest of the fibres of the internal oblique diverge and end in an aponeurosis which gradually broadens from below upwards. In its upper two-thirds this aponeurosis splits at the lateral border of the rectus abdominis into two laminae which pass around it and reunite in the linea alba, which they help to form. The anterior layer blends with the aponeurosis of the external oblique, the posterior with the aponeurosis of the transversus abdominis, and its upper part is attached to the cartilages of the seventh, eighth and ninth ribs. In

the lower part of the abdominal wall the whole aponeurosis passes with that of the transversus in front of the rectus to the linea alba (p. 558).



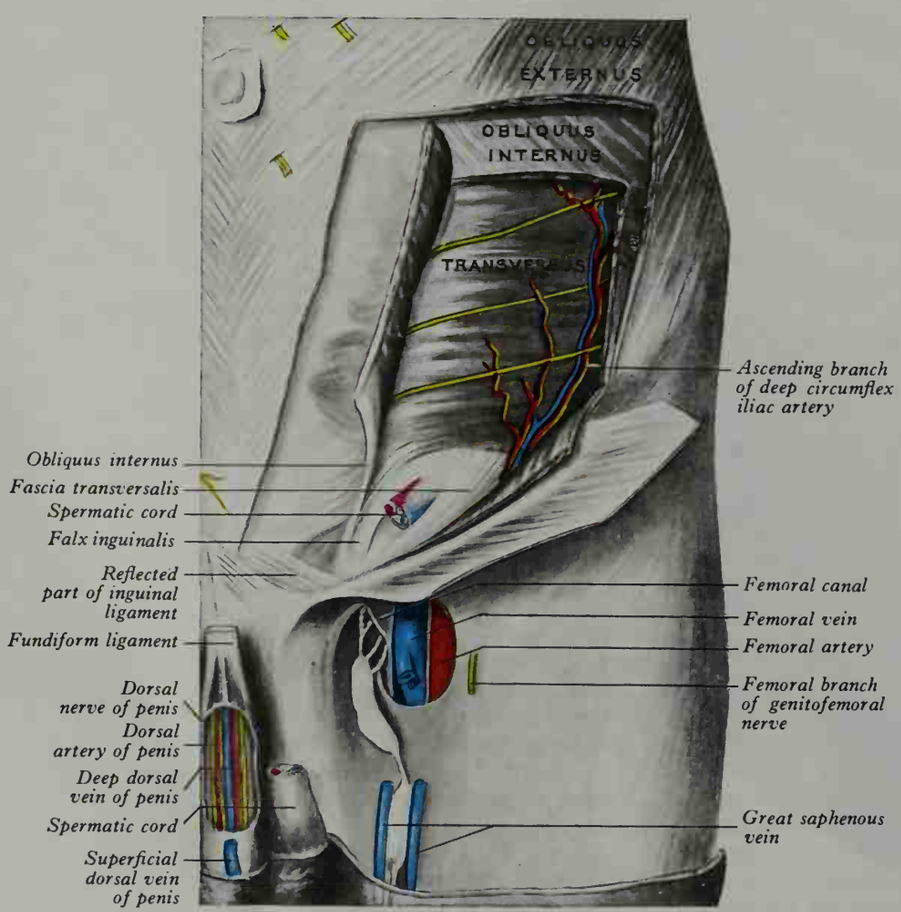
Nerve supply. The internal oblique is supplied by the ventral rami of the lower six thoracic and the first lumbar spinal nerves.

The cremaster (5.49) consists of a number of loosely arranged muscle fasciculi lying along the spermatic cord. They are united by areolar tissue to form the sac-like *cremasteric fascia* around the cord and testis within the external spermatic fascia. The lateral part of the muscle, arising from the inguinal ligament, has been variously described as in continuity with the medial edge of the internal oblique, deep to the internal oblique, extending as far as the anterior superior iliac spine and in continuity with either the internal oblique or transversus, or as a pointed tendon from the middle of the inguinal ligament, piercing the internal oblique near its medial margin. Of these possibilities one extensive study revealed that in sixty subjects, all exhibited both a tendinous attachment and cremasteric fibres derived from the obliquus internus and transversus (Blunt 1951). The fibres pass along the lateral aspect of the spermatic cord through the superficial inguinal ring and then spread out into fasciculi in loops of increasing length along its anterolateral aspect. The shortest and most superior fasciculi turn inwards in front of the cord to join the medial part, while the longer fasciculi gain attachment to the fascia over the cord and upper part of the tunica vaginalis. The medial part of the muscle is variably developed and may be absent. It arises from the pubic tubercle and possibly from the pubic crest, falx inguinalis and lower border of transversus. Its fasciculi loop on the posteromedial aspect of the cord, interlacing with those of the lateral part. The whole muscle may be described as forming continuous loops from the middle of the inguinal ligament as far as the tunica vaginalis and then returning to be attached to the pubic tubercle. In the female a few fibres descending on the round ligament of the uterus represent the lateral part of cremaster.



Nerve supply. the genital branch of the genitofemoral nerve, derived from the first and second lumbar spinal nerves.

Action. The cremaster pulls up the testis towards the superficial inguinal ring. Although its fibres are striated, it is not usually under voluntary control. Stroking of the medial side of the thigh evokes a reflex contraction of the muscle and this *cremasteric reflex* is much more active in children. Doubtless this may be a protective response, but the cremaster also appears to play an essential role in testicular thermoregulation. Shafik (1977) considers that the position of the testis is adjusted by conjoint action of the cremaster (which he divides into two distinct parts—*cremaster internus* and *externus*, separated by the internal spermatic fascia) and the dartos, the latter being attached to the testis by a '*scrotal ligament*' (p. 1416).



The transversus abdominis (5.48), so-called from the direction of its fibres, is the innermost of the flat muscles of the abdominal wall, being internal to the internal oblique. Its muscle fibres arise from the lateral third of the inguinal ligament, the anterior two-thirds of the inner lip of the ventral segment of the iliac crest, the thoracolumbar fascia between the iliac crest and the twelfth rib, and the internal aspects of the lower costal cartilages (usually six), where it interdigitates with the diaphragm (5.41). The precise origin of the fibres, whether from the inguinal ligament direct, or from adjacent iliac fascia has been the subject of dispute (McVay and Anson 1940). The muscle ends in an aponeurosis of variable extent, the lower fibres of which curve downwards and medially together with those of the aponeurosis

5.48 The left transversus abdominis.

5.49 A dissection of the regions shown in 5.45, with part of the obliquus externus removed.

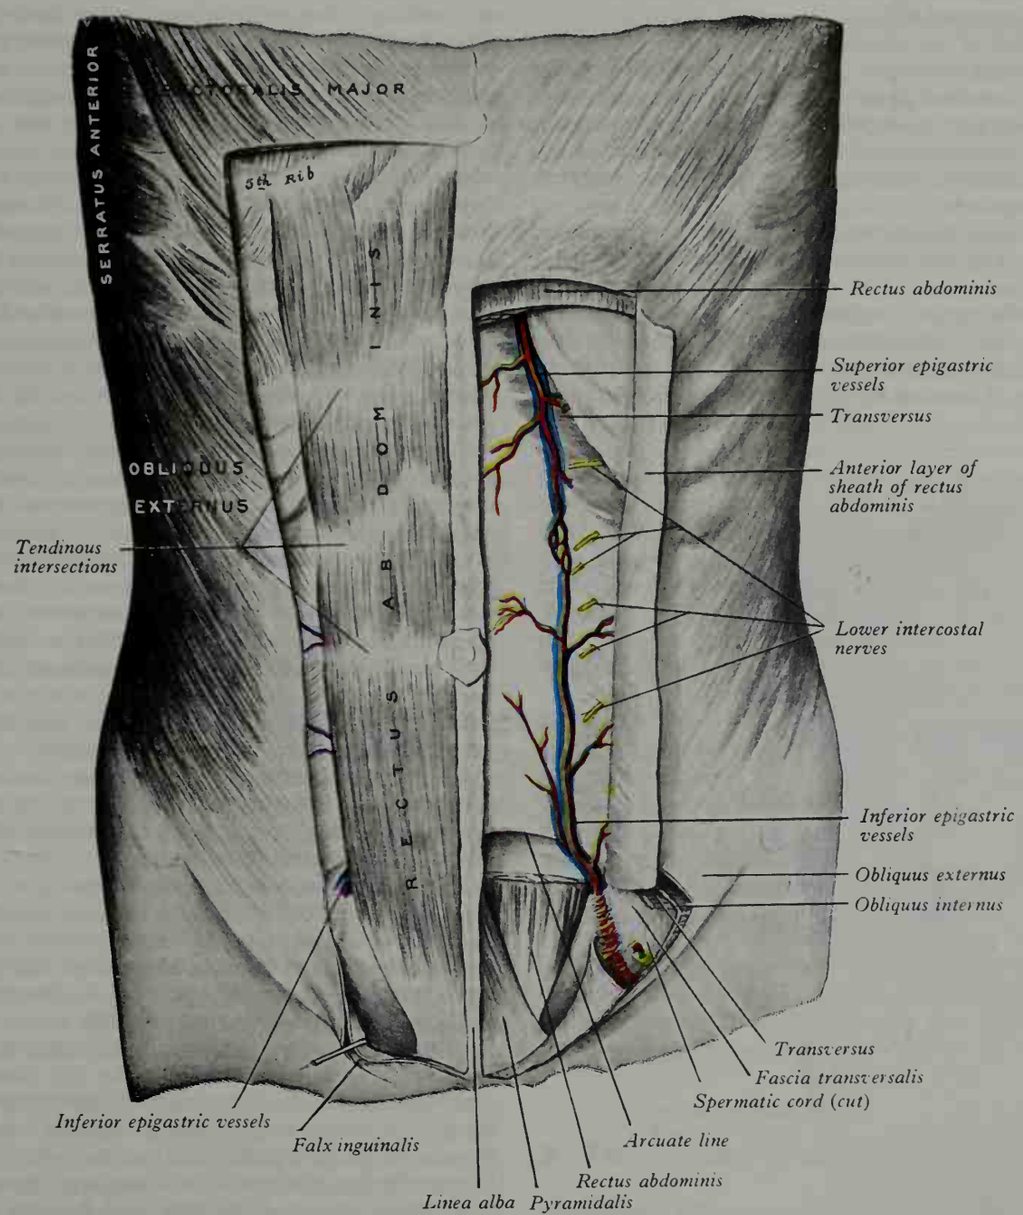
of the internal oblique to the crest and pecten of the pubis, forming the *falx inguinalis*. The rest of the aponeurosis passes horizontally to the median plane, and blends with the linea alba; its upper three-fourths lie behind the rectus abdominis and blend with the posterior lamina of the aponeurosis of the internal oblique; its lower fourth is in front of the rectus. The upper muscular fibres of the transversus abdominis are continued medially behind the rectus (**5**.48) and the posterior lamina of the aponeurosis of the internal oblique, sometimes being continuous across the midline with the opposite transversus. Near the xiphoid process they reach to within 2 or 3 cm of the linea alba. The muscular fibres of the transversus run into the aponeurosis along a line which is concave medially (**5**.48), the aponeurosis being widest opposite the origin of the muscle from the thoracolumbar fascia.

Fusiform defects filled with fascia occur in the lower muscular and the aponeurotic parts of both the internal oblique and the transversus abdominis. The two muscles are sometimes fused, or the transversus may be absent.

The falx inguinalis (conjoint tendon) of the internal oblique and transversus (**5**.50, 51) is mainly formed by the lower part of the aponeurosis of the transversus, and is inserted into the crest and pecten of the pubis; it descends behind the superficial inguinal ring, thus serving to protect from behind what would otherwise be a weak point in the abdominal wall. The attachment to the pecten pubis is frequently absent. Medially the falx inguinalis is directly continuous with the anterior wall of the sheath of the rectus abdominis. Laterally, it may be continuous with an inconstant ligamentous band, named the *interfoveolar ligament* (**5**.51), which sometimes connects the lower margin of the transversus to the superior ramus of the pubis; it occasionally contains a few muscular fibres. Muscular fasciculi, attached to the pecten pubis behind the falx inguinalis, may reach the

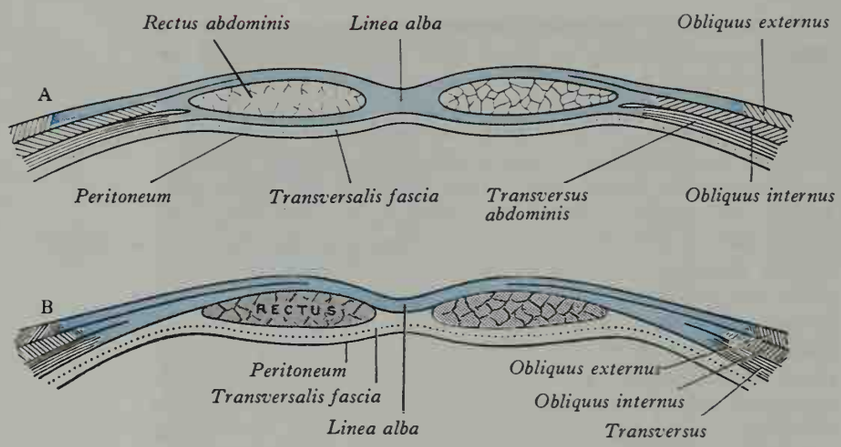
5.51 The lower part of the anterior abdominal wall (left side) showing the relations of the spermatic cord at the deep inguinal ring. (Modified from Braune.)

transversalis fascia, the aponeurosis of the muscle, or even the lateral end of the arcuate line.



Nerve supply. The ventral rami of the lower six thoracic and the first lumbar spinal nerves.

The rectus abdominis (**5**.52) is a long strap muscle, broader above, which extends along the whole length of the front of the abdomen, separated from its fellow by the linea alba. It arises by two tendons; the lateral and larger is attached to the crest of the pubis and may extend beyond the pubic tubercle to the pecten pubis; the medial interlaces with its fellow and is connected with the ligamentous fibres covering the front of the symphysis pubis.



Some fibres may spring from the lower part of the linea alba. The muscle is attached by three slips of unequal size into the fifth, sixth and seventh costal cartilages; the most lateral fibres are usually attached to the anterior end of the fifth rib but this slip may be absent, although conversely, the muscle may even reach the fourth and third; the most medial fibres are occasionally connected with the costoxiphoid ligaments and the side of the xiphoid process.

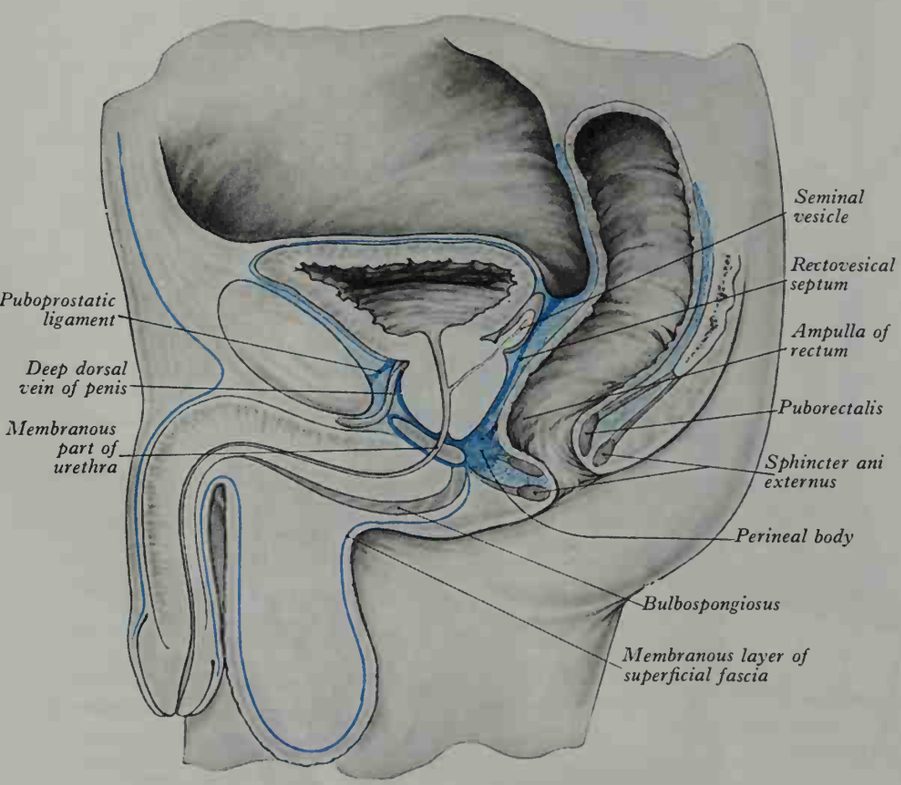
The muscle fibres of the rectus are interrupted by three fibrous bands, named *tendinous intersections*; one is usually situated opposite the umbilicus, another opposite the free end of the xiphoid process, and a third about midway between the xiphoid process and the umbilicus. These intersections pass transversely or obliquely across the muscle in a zigzag course; they rarely extend completely through its substance and may pass only halfway across it; they are intimately adherent to the anterior lamina of the sheath of the muscle. Sometimes one or two incomplete intersections are present below the umbilicus. The intersections may be secondary occurrences and opinions vary as to whether they represent the myosepta delineating the myotomes forming the muscle.

The rectus abdominis is enclosed between the aponeuroses of the obliqui and transversus, forming the so-called *rectus sheath* (5.44, 48, 53A). At the lateral margin of the rectus, the aponeurosis of the internal oblique divides into two, one lamina passing anterior to the rectus, to blend with the aponeurosis of the external oblique, the other behind it to blend with the aponeurosis of the transversus. These join again at the medial border of the rectus, to reach and help to form the linea alba. (It should be noted, however, that some authors do not regard the foregoing account as the common disposition—see e.g. Walmsley 1937; McVay and Anson 1940). This arrangement is, nevertheless, widely held to exist from the costal margin to a variable level, usually midway between the umbilicus and symphysis pubis, where the posterior wall of the sheath ends in a curved margin, named the *arcuate line*, its concavity directed downwards or downwards and laterally. As already stated (p. 566) the muscular fibres of the upper part of the transversus abdominis are continued behind the corresponding part of the rectus abdominis to within 2 or 3 cm of the linea alba (5.48, 53A), so that the posterior layer of the sheath is here muscular to a varying degree. Below the level of the arcuate line the aponeuroses of all three muscles pass in front of the rectus; those of the transversus and internal oblique are intimately fused together, but the aponeurosis of the external oblique is bound to them merely by loose connective tissue except in and near the median plane; this part of the rectus is separated from the peritoneum by the transversalis fascia (5.53B). Since the aponeuroses of the internal oblique and

5.52 The right rectus abdominis and the left pyramidalis. The greater part of the left rectus abdominis has been removed to show the superior and inferior epigastric vessels.

5.53A and B Transverse sections through the anterior abdominal wall. A Immediately above the umbilicus. B Below the arcuate line. Note the extent to which the external oblique aponeurosis remains as a separate entity, passing medially, ventral to rectus, before blending with the other aponeuroses: these have already fused, lateral to rectus.

transversus reach only as high as the costal margin it follows that above that level the muscle rests directly on the cartilages of the ribs; the front of this part of the rectus is overlapped merely by the aponeurosis of the external oblique.



The medial border of the muscle is closely related to the linea alba: its lateral border is marked on the surface of the anterior abdominal wall by a curved groove, termed the *linea semilunaris*, which extends from the tip of the ninth costal cartilage to the pubic tubercle. It is readily seen in a muscular subject even when the muscle is not actively contracting, but may be completely obscured in the corpulent.

Nerve supply. The rectus abdominis is supplied by the ventral rami of the lower six or seven thoracic spinal nerves.

The pyramidalis (**5**.52) is a triangular muscle in front of the lower part of the rectus abdominis and within its sheath. It is attached by tendinous fibres to the front of the pubis and the ligamentous fibres in front of the symphysis; the muscle passes upwards, diminishing in size as it ascends, and ends in a pointed extremity which is attached to the linea alba midway between the umbilicus and pubis, but may extend to a higher level. The muscle varies much in size and may be larger on one side than on the other, or may be absent on one or both sides. It is occasionally double. Anson *et al.* (1938) found the muscle absent in 76 of 430 cadavers (17.7 per cent).

Besides the rectus and pyramidalis, the sheath of the rectus contains the superior and inferior epigastric vessels, and the terminal portions of the lower intercostal nerves.

Nerve supply. The pyramidalis is supplied by the subcostal nerve, which is the ventral ramus of the twelfth thoracic spinal nerve.

5.54 Median sagittal section through the pelvis, showing the arrangement of the fasciae (*blue*).

Actions. The anterolateral group of abdominal muscles provide a firm but elastic wall to retain the abdominal viscera in position and to oppose the action of gravity on them in the erect and sitting postures. This function is principally dependent on the normal contraction of the oblique muscles, especially the internal oblique. However, their most frequent involvement is in respiratory movements.

When the thorax and pelvis are fixed, the active contraction of these muscles exercises a compressing force on the abdominal viscera. In this way they play an important part in expiration, and they assist in expelling faeces from the rectum, the fetus from the uterus, the urine from the bladder and the contents of the stomach in vomiting. This action is mainly due to the oblique muscles. They tense the rectus sheath, whilst the rectus abdominis itself plays a minor role. If the pelvis and vertebral column are fixed, the external oblique muscles aid further in expiration by depressing and compressing the lower part of the thorax.

When the pelvis is fixed, the recti and to a lesser extent the obliqui of the two sides, acting together, bend the trunk forwards and flex the lumbar part of the vertebral column; when the thorax is fixed, they draw the front of the pelvis upwards and have the same effect as before on the vertebral column (Floyd and Silver 1950). If the muscles of only one side act, the trunk is bent towards that side. In addition, the external oblique tends to turn the front of the abdomen towards the opposite side, and the internal oblique turns it to the same side. Electromyographic studies suggest that in most movements of the trunk, whether in the sitting or the standing position, the abdominal musculature is little involved, unless considerable resistance is applied. Extension of the trunk raises activity in these muscles, flexion does not. All activity ceases in the supine position, but the recti in particular at once spring into action even when merely the head is raised. Further flexion brings the obliques into action, but less forcibly. In general the obliques appear to be largely concerned in compressive and forcible twisting movements, the recti in flexion when resistance has to be overcome. In normal standing there is little postural activity in the entire musculature, except for the lower part of the internal oblique, where it is accessible to electromyographic recording through the aponeurosis of the external oblique (*see* inguinal canal, p. 559).

The transversus probably acts only on the abdominal contents and has no appreciable effect on the vertebral column. It has not proved possible to carry out effective electromyographic investigations on this muscle.

The pyramidalis is a tensor of the linea alba, but the advantage of, or the necessity for this action is by no means clear.

The linea alba (**5**.44, 53) is a tendinous raphe between the xiphoid process and the symphysis pubis. It is between the recti, and is formed by the interlacement of the fibres of the aponeuroses of the obliqui and transversi. A little below its midpoint is a fibrous cicatrix, covered by a puckered adherent area of skin—the *umbilicus*. In its infra-umbilical part the linea alba is narrow, corresponding to the linear interval between the recti; in life its position is visible only in the young and muscular as a slight groove. In its supra-umbilical portion where the recti diverge from each other it is broader, and can be recognized on the surface as a shallow groove. At its lower end the linea alba has a double attachment—its superficial fibres passing in front of the medial heads of the recti to the front of the symphysis pubis, while its deeper fibres form a triangular lamella, attached behind the recti

to the posterior surface of the crest of the pubis, and named the *adminiculum lineae albae*. The linea alba is traversed by a few minute vessels; in the fetus the umbilicus transmits the umbilical vessels, urachus and, up to the third month, the vitelline or yolk stalk. The umbilicus is closed a few days after birth, but the vestiges of the vessels and urachus remain attached to its deep surface (i.e. the *ligamentum teres of the liver*—remnant of the fetal left umbilical vein; the *medial umbilical ligaments*, enclosed in peritoneal folds bearing the same names, and being the obliterated umbilical arteries; and the *median umbilical ligament*—the partially obliterated remains of the urachus).

The transversalis fascia is a thin connective tissue stratum between the internal surface of transversus and the extraperitoneal fat. It is part of the general layer of fascia between the peritoneum and the abdominal walls, and is continuous with the iliac and pelvic fasciae. In the inguinal region it is thick and dense, and augmented by the aponeurosis of the transversus, but it becomes thin as it ascends to the diaphragm, and blends with the fascial covering of its inferior surface. Behind, it fuses with the anterior lamina of the thoracolumbar fascia. Below, it has the following attachments: posteriorly, to the whole length of the iliac crest, between the origins of the transversus and iliacus; between the anterior superior iliac spine and the femoral vessels it is connected to the posterior margin of the inguinal ligament, and is there continuous with the iliac fascia. Medial to the femoral vessels it is thin and is fixed to the pecten pubis, behind the falx inguinalis, with which it is united; it descends in front of the femoral vessels to form the anterior part of the femoral sheath (p. 725). In front of the femoral vessels the transversalis fascia is strengthened by transversely arched fibres which spread laterally towards the anterior superior iliac spine and medially diverge behind the rectus abdominis, while some descend to the pecten pubis behind the falx inguinalis. These arched fibres constitute the *deep crural arch*. The spermatic cord or the round ligament of the uterus pass through the transversalis fascia at the *deep inguinal ring*. This opening is not visible externally since the transversalis fascia is prolonged on these structures as the *internal spermatic fascia*. Around the testis this blends with the areolar tissue on the parietal layer of the tunica vaginalis (p. 1418) and may contain smooth muscle fibres (Barrett 1951). The curved fibres of the deep crural arch thicken the inferomedial part of the rim of the deep inguinal ring.

The deep inguinal ring is situated in the transversalis fascia, midway between the anterior superior iliac spine and the symphysis pubis, and about 1·25 cm above the inguinal ligament. It is oval, the long axis being vertical; it varies in size, and is much larger in the male. It is related above to the arched lower margin of transversus abdominis, and medially to the inferior epigastric vessels and the interfoveolar ligament, when present. The drag on the fascial ring exerted by the internal oblique muscle constitutes a valve-like safety mechanism when intra-abdominal pressure is raised (Lytle 1970).

The inguinal canal contains the spermatic cord or the round ligament of the uterus, and in both sexes the ilio-inguinal nerve. It is oblique and about 4 cm long, slanting downwards and medially, parallel with, and a little above, the inguinal ligament; it extends from the deep to the superficial inguinal ring. It is bounded *in front* throughout by the skin, superficial fascia, and aponeurosis of external oblique, and in its lateral one-third by the muscular fibres of the internal oblique; *behind*, by the reflected inguinal ligament, the falx inguinalis, and the transversalis fascia, which separate it from extraperitoneal connective tissue and peritoneum; *above*, by the arched fibres of the internal oblique and transversus abdominis; *below*, by the union of the transversalis fascia with the inguinal ligament, and at its medial end by the lacunar ligament.

The presence of the canal would appear to weaken the lower part of the anterior abdominal wall, but this is compensated partly by the obliquity of the canal and partly by the arrangement of the structures in its walls. Owing to the oblique direction of the canal the two inguinal rings do not coincide and increases in intra-abdominal pressure exercise their effect not only at the deep inguinal ring but also on the posterior wall of the canal thus approximating it to the anterior. The posterior wall is strengthened by the falx inguinalis and the reflected inguinal ligament posterior to the superficial inguinal ring, and the internal oblique takes part in the formation of the anterior wall, where it lies opposite to the deep inguinal ring (*see* p. 554). This part of the internal oblique, and that of the transversus which also arises from the inguinal ligament (i.e. the parts of those muscles which 'arch' over the oblique canal), are constantly active in standing; any increase in intra-abdominal pressure (as in coughing or straining) accentuates contraction in the internal oblique (and probably the transversus).

The extraperitoneal connective tissue. Between the peritoneum and the inner surface of the general layer of the fascia which lines the interior of the abdominal and pelvic cavities, there is a considerable amount of areolar connective tissue. This extraperitoneal tissue varies in quantity in different situations. It is especially abundant on the posterior wall of the abdomen, and particularly around the kidneys, where it contains much fat. It is scanty on the anterolateral wall, except in the pubic region and above the iliac crest; there is a considerable amount in the pelvis.

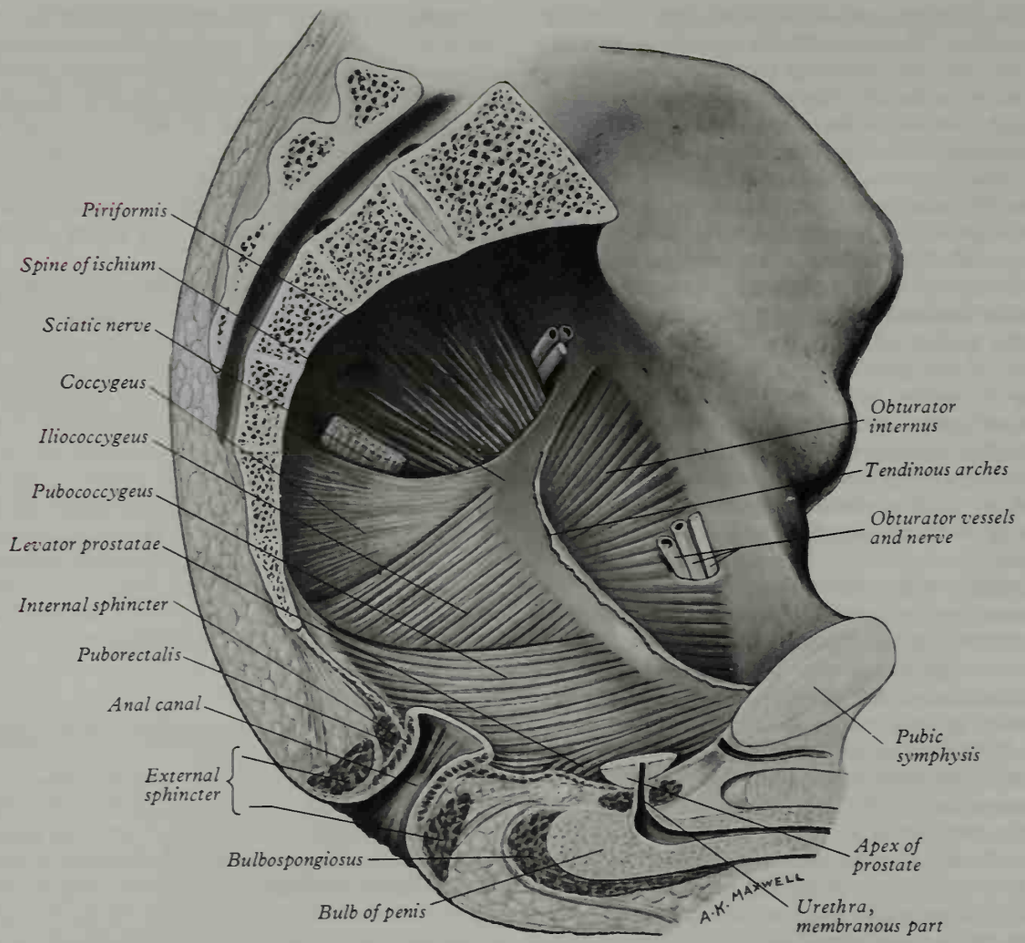
It is perhaps worthy of note that such fasciae are no more than the connective tissue usually present between differentiated structures. The extraperitoneal tissue is, of course, in continuity with the epimysium of the muscles of the abdominal wall and through this with the internal connective tissue of these structures.

THE POSTERIOR MUSCLES OF THE ABDOMEN

The psoas major and minor, and the iliacus, with the fasciae covering them, though forming part of the abdominal parietes, are muscles of the lower limb and are described with them. Only the quadratus lumborum will be considered here.

The *fascia* covering the quadratus lumborum is the *anterior layer of the thoracolumbar fascia* (p. 542). It is attached, medially, to the anterior surfaces of the transverse processes of the lumbar vertebrae; below, to the iliolumbar ligament; above, to the apex and lower border of the last rib. Its upper margin, which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib, is the lateral arcuate ligament (p. 543). Laterally, the fascia blends with the fused posterior and middle layers of the thoracolumbar fascia (**5**.38).

The quadratus lumborum (**5**.37, 43) is irregularly quadrilateral, being broader inferiorly. It is attached below by aponeurotic fibres to the iliolumbar ligament and the adjacent portion of the iliac crest for about 5 cm, and above to the medial half of the lower border of the last rib, and by four small tendons to the apices of the transverse processes of the upper four lumbar vertebrae, and sometimes to the transverse process or body of the twelfth thoracic. Occasionally a second layer of this muscle is found in front of the preceding; it passes from the upper borders of the lumbar transverse processes of the lower three or four lumbar vertebrae to the lower margin and the lower part of the anterior surface of the last rib.



Anterior to the quadratus lumborum are the colon, kidney, psoas major et minor, and diaphragm; the subcostal, iliohypogastric, and ilio-inguinal nerves are anterior to the fascia over the muscle, but are bound down to it by the medial continuation of the transversalis fascia.

Nerve supply. The ventral rami of the twelfth thoracic and upper three or four lumbar spinal nerves.

Actions. The quadratus lumborum fixes the last rib, and acts as a muscle of inspiration by helping to steady the origin of the diaphragm. If the pelvis is fixed, it may act upon the vertebral column, flexing it to the same side; and when both muscles act together they probably help to extend the lumbar part of the vertebral column.

V. The Pelvic Muscles and Fasciae

The muscles within the pelvis may be divided into two groups: (1) the piriformis and obturator internus, which are described with the muscles of the lower limb (pp. 601, 602); (2) the levator ani and coccygeus, which, with the corresponding muscles of the

5.55 Pelvic aspect of the left levator ani and coccygeus. The superior gluteal vessels and nerve have been cut close to the upper border of the piriformis; the anal canal has been divided below the anorectal flexure and the greater part of the prostate has been removed. The constituent parts of the levator ani are shown.

opposite side, form the **pelvic diaphragm**. The fasciae investing the muscles form a connective tissue continuum (**5**.54), which connects with the fascial coverings of the pelvic viscera above and with the fasciae of the perineum below. (For the muscles and fasciae of the **urogenital diaphragm** *see* pp. 562–564.)

The pelvic fascia. The fascia of the pelvis may be resolved for description into: (1) The *parietal pelvic fascia*, the fascial sheaths of the pelvic muscles; (2) the *visceral pelvic fascia*, the fascial sheaths of the pelvic viscera and of their blood vessels and nerves (*see* individual organs).

The parietal pelvic fascia covering the pelvic surface of obturator internus is well differentiated as the *obturator fascia*. Above, it is connected to the posterior part of the arcuate line of the hip bone, and is there continuous with the iliac fascia. In front of this, as it follows the line of origin of the obturator internus, it gradually separates from the iliac fascia, and the continuity between the two is retained only through the periosteum. It arches below the obturator vessels and nerve, completing the obturator canal, and at the front of the pelvis is attached to the back of the body of the pubis. Above the *tendinous arch of the levator ani* (*vide infra*) the obturator fascia is markedly aponeurotic and is concerned in the attachment of levator ani (p. 561); below that level it is thin and membranous and forms the lateral wall of the ischiorectal fossa (p. 561). Here it blends with the fascial sheath of the internal pudendal vessels. Behind, it is indirectly continuous with the fascia on piriformis.

The *fascia of the piriformis* is very thin and fuses with periosteum on the front of the sacrum around the margins of the anterior sacral foramina. At its sacral attachment it ensheathes the nerves emerging from these foramina; hence the sacral anterior primary rami are frequently described as lying behind the fascia. The internal iliac vessels and their branches, on the other hand, are in the extraperitoneal tissue in front of the fascia, and branches of these vessels carry sheaths of this tissue into the gluteal region, above and below piriformis.

The *fascia of the pelvic diaphragm* extends over both surfaces of the levator ani. On the inferior surface of the muscle it is thin, and is the so-called, *inferior fascia of the pelvic diaphragm* (anal fascia); it covers the medial wall of the ischiorectal fossa, and above is continuous with the fascia of the pudendal canal and with the obturator fascia along the line of attachment of levator ani; it is continuous below with the fasciae on the sphincter urethrae and the sphincter ani externus. The fascia on the muscle's superior surface is often named the *superior fascia of the pelvic diaphragm*. Laterally it follows the line of attachment of the muscle, and is therefore somewhat variable. In front it is attached to the back of the symphysis pubis about 2 cm above its lower border, and can be traced laterally across the back of the superior ramus of the pubis for a short distance to the obturator fascia. It blends with this along a somewhat irregular line to the spine of the ischium. This irregularity is explained by the fact that while in lower mammals the levator ani arises posteriorly from the pelvic brim, in man its attachment is at a lower level, leaving its aponeurosis as the thickened upperpart of the obturator fascia. In some cases tendinous fibres of attachment extend up towards, and may reach, the pelvic brim. Medially, the superior fascia of the pelvic diaphragm blends with the visceral pelvic fascia. The fascia covering the part of obturator internus above the attachment of levator ani is therefore a composite structure and includes, (*a*) the obturator fascia, (*b*) the fascia of levator ani, and (*c*) the degenerated aponeurosis of the levator. A thickening in the obturator fascia along the line of fusion of these structures is the *tendinous arch of the levator ani*.

To be distinguished from the latter is the *tendinous arch of the*

pelvic fascia which is a thickened whitish band in the superior fascia of the pelvic diaphragm along a line from the lower part of the symphysis pubis to the spine of the ischium. It marks the line of attachment of the lateral 'true' ligament of the urinary bladder. Anteriorly the fascia forms two thickened bands, the *puboprostatic (pubovesical) ligaments*, one on each side of the median plane. Both tendinous arches may be more or less well defined.

The levator ani (**5**.55), a broad, thin muscle, is attached to the inner surface of the side of the true pelvis, and unites with the opposite muscle to form the greater part of the floor of the pelvic cavity. It is attached, in front, to the pelvic surface of the body of the pubis lateral to the symphysis, behind, to the medial surface of the spine of the ischium, and between these two points, to the obturator fascia. Posteriorly this attachment to the obturator fascia corresponds, more or less closely, with the tendinous arch of the levator ani, but in front, the muscle arises from the fascia at a varying distance above the arch, in some cases reaching nearly as high as the canal for the obturator vessels and nerve. The muscle's fibres pass towards the median plane with varying degrees of obliquity. The most anterior sweep backwards and downwards across the side of the prostate to end in the perineal body (p. 562). They constitute the *levator prostatae*, but in the female they cross the sides of the vagina to reach their attachment, and so constitute an additional and important sphincter for it, the *pubovaginalis*. Intermediate fibres pass backwards and downwards across the side of the prostate and then turn medially to become continuous with those of the opposite side and form a muscular sling around the anorectal flexure. This relatively thick part of the muscle is termed the *puborectalis*. Posteriorly its fibres are inextricably mingled with those of the deep part of the external anal sphincter. Other intermediate fibres blend with the longitudinal muscle coat of the rectum and descend within the puborectal sling as the conjoined longitudinal coat of the anal canal (p. 1359). More posterior fibres are attached to the last two coccygeal segments and to the anococcygeal ligament or raphe (p. 1359).

Morphologically, the levator ani may be divided into *pubococcygeus* and *iliococcygeus*. Although this is a useful approximation for convenience of description, it must be added that the homologies of these muscles with arrangements in other mammals are still matters of controversy (Wendell-Smith 1967).

The *pubococcygeus* arises from the back of the pubis and from the anterior part of the obturator fascia, and is directed backwards almost horizontally along the side of the anal canal. It is attached to the front of the coccyx by a tendinous plate which is continuous with the ventral sacrococcygeal ligament. The *iliococcygeus* arises from the ischial spine and from the posterior part of the tendinous arch of the levator ani. Its fibres attach to the sides of the coccyx and to those of the opposite side in a median raphe on the undersurface of the tendinous plate of pubococcygeus, contributing to the anococcygeal ligament. Iliococcygeus is usually thin and may be mostly aponeurotic. An accessory slip at its posterior part is sometimes named *iliosacralis*. In lower mammals both muscles are inserted only into the caudal vertebrae. The iliococcygeus is then responsible for side to side movements of the tail, and the pubococcygeus draws it downwards and forwards between the hind limbs. The gradual disappearance of the tail sets free these muscles to meet the demands for a more complete pelvic floor, partially necessary to adoption of the erect attitude.

The levator and depressor caudae of tailed mammals are represented by rudimentary *ventral* and *dorsal sacrococcygeal* muscles in man. These run from the sacrum to the coccyx anterior and posterior to the sacrococcygeal joint.

Relations. The *superior* or *pelvic surface* of the levator ani is separated by its covering fascia from the bladder, prostate, rectum and peritoneum. Its *inferior* or *perineal surface* forms the medial boundary of the ischiorectal fossa, and is covered by the inferior fascia of the pelvic diaphragm. Its *posterior border* is free and separated from the coccygeus by areolar tissue. The *medial borders* of the two muscles are separated by the *visceral outlet*, an interval through which the urethra, vagina, and the ano-rectum pass from the pelvis.

Nerve supply. The levator ani is supplied by a branch from the fourth sacral spinal nerve and by a branch which arises either from the inferior rectal nerve (p. 1116) or from the perineal division of the pudendal nerve.

Actions. The levatores ani constrict the lower end of the rectum and vagina and probably fix the perineal body. Together with the coccygei they form a muscular diaphragm which supports the pelvic viscera and opposes itself to the downward thrust produced by any increase in the intra-abdominal pressure. (These muscles are, however, not accessible for direct or electromyographic examination, and dogmatic views are to be avoided.)

The coccygeus (**5**.55) is posterosuperior to, but in the same tissue plane, as the levator ani. It is a triangular sheet of muscular and tendinous fibres, arising by its apex from the pelvic surface of the spine of the ischium and the sacrospinous ligament, and attached at its base to the margin of the coccyx and the side of the fifth segment of the sacrum. The coccygeus is occasionally absent, but more often varies in the proportions of muscle and fibrous tissue in it. It lies on the pelvic aspect of the sacrospinous ligament, and the latter is commonly regarded as a degenerate part of the muscle, or as an aponeurosis of it. The muscle is well developed, and the ligament often absent, in mammals with a mobile tail. Morphologically, the coccygeus (*ischiococcygeus*) is probably to be associated with the iliococcygeal moiety of the levator ani.

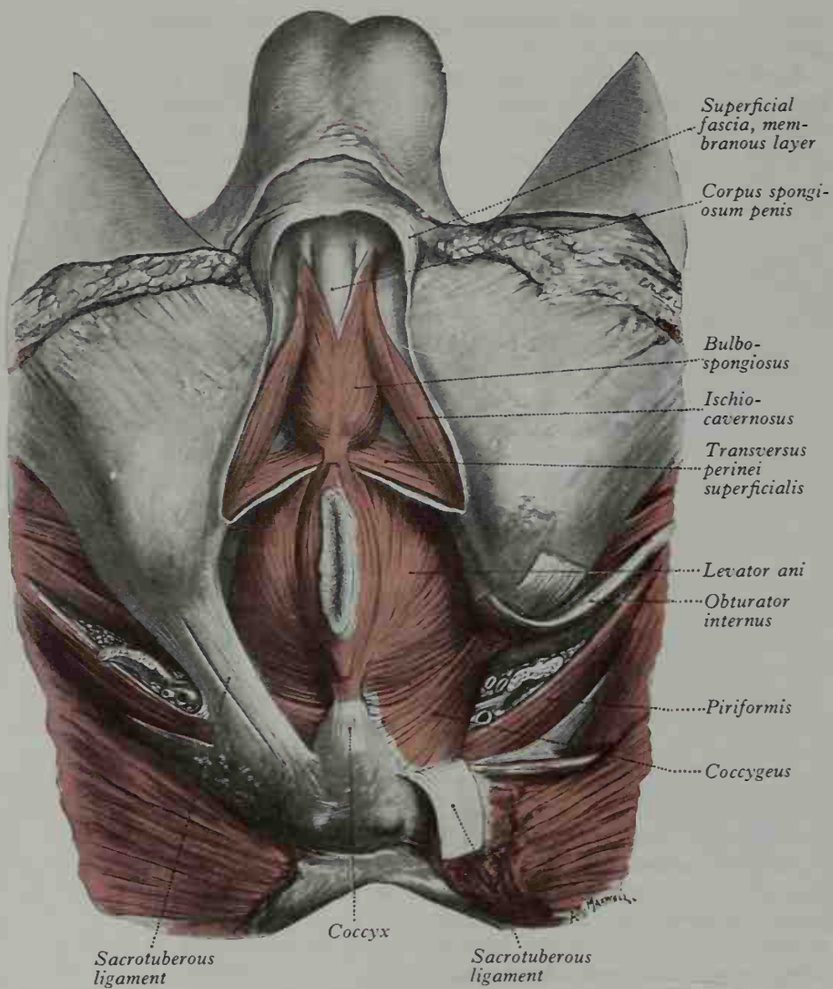
Nerve supply. A branch from the fourth and fifth sacral spinal nerves.

Actions. The coccygei may pull forward and support the coccyx, after it has been pressed backwards during defecation or parturition. With the levatores ani and piriformes, they close the posterior part of the pelvic outlet.

Applied Anatomy. Injury to the muscles forming the pelvic floor occurs not infrequently during parturition. Rupture of the perineal body (p. 562), which includes fibres of the pubovaginalis, permits divarication of the levatores and may contribute to uterovaginal prolapse at a later date.

VI. The Perineal Muscles and Fasciae

The perineum overlies the **inferior pelvic aperture** (pelvic outlet). Its deep boundaries are—in front, the pubic arch and the arcuate pubic ligament; behind, the tip of the coccyx; on each side, the inferior ramus of the pubis and the ramus of the ischium, the ischial tuberosity and the sacrotuberous ligament. The space within these boundaries is somewhat trapezoid. On the surface of the body the perineum in the male is limited by the scrotum in front, the buttocks behind, and the medial sides of the thighs laterally. For descriptive purposes a line drawn transversely in front of the ischial tuberosities divides the region into two triangular parts. The posterior contains the termination of the anal canal, and is known as the **anal region** (*anal triangle*); the anterior contains the external urogenital organs, and is termed the **urogenital region** (*urogenital triangle*).



The muscles and fasciae of the perineum may therefore be divided into two groups—anal, and urogenital (male and female), but it should be remembered that the two groups meet in the perineal body and constitute a single morphological unit derived from the *sphincter cloacae*.

THE MUSCULATURE AND FASCIAE OF THE ANAL REGION

The superficial fascia of the region is very thick, areolar in texture, and contains many fat cells in its meshes. On each side a pad of fatty tissue extends deeply into the vertical, cuneiform cleft between the levator ani and obturator internus called the *ischiorectal fossa*.

The deep fascia lines the ischiorectal fossa; it comprises the inferior fascia of the pelvic diaphragm and the part of the obturator fascia below the attachment of levator ani.

The ischiorectal fossa, as noted above, is somewhat wedge-shaped, with its base directed to the surface of the perineum and its thin edge at the line of meeting of the obturator internus and

5.56 The muscles of the male perineum. (From Quain's *Anatomy*, 11th edition.)

levator ani, covered by the obturator fascia and inferior fascia of the pelvic diaphragm. It is bounded medially by the sphincter ani externus and the inferior fascia of the pelvic diaphragm and laterally, by the tuberosity of the ischium and the obturator fascia. Posteriorly, the fossa is partly limited by the lower border of the gluteus maximus but extends deep to it as far as the sacrotuberous ligament. Anteriorly, the fossa is partly limited by the posterior region of the urogenital diaphragm, but it is prolonged as a narrow recess above it, reaching almost to the posterior surface of the pubis. This *anterior recess* has the same relations to the obturator internus and levator, but inferiorly it is separated from the surface of the perineum by the muscles and fascia of the urogenital diaphragm. The anterior extent of the recess is variable and limited by fusion between the inferior fascia of the pelvic diaphragm with the superior fascia of the urogenital diaphragm. It may, however, reach the retropubic space (p. 1405).

The internal pudendal vessels and their accompanying nerves are in the lateral wall of the ischiorectal fossa, and are enclosed in a special sheath of fascia forming the *pudendal canal*. This sheath is fused with the lower part of the obturator fascia, extending upwards to blend with the inferior fascia of the pelvic diaphragm and downwards to become continuous with the falciform process of the sacrotuberous ligament (p. 474). It is sometimes termed the *lunate fascia* (**8.**124B), and regarded as forming the roof and lateral wall of the fossa. In front it passes above the urogenital diaphragm, blending with its lateral margin at its attachment to the inner surface of the inferior ramus of the pubis.

The sphincter ani externus (**5.**56, **8.**124, p. 1359) surrounds the lowest part of the anal canal. Below, it is intimately adherent to the skin; above, it overlaps the sphincter ani internus. Details of its attachments, subdivisions, nerve supply and actions are given on p. 1359. Suffice it here to say that it has deep, superficial, and subcutaneous parts which relate to other muscles of the visceral outlet. The deep part exchanges fibres not only with the puborectal sling above it (p. 561) but also via the perineal body with the muscles of the deep perineal pouch which lie anterior to it in the same curved plane. Similarly, the superficial part exchanges fibres with the superficial urogenital muscles, with which they are coplanar. The superficial part, and to a lesser extent the other parts, gains a substantial attachment to the coccyx and contributes to the anococcygeal ligament. Above this attachment there is a *retrosphinteric space* connecting the ischiorectal fossae of the two sides (Courtney 1949).

The anococcygeal ligament is a layered musculotendinous structure occupying the midline between the anorectum and the coccyx. With the overlying presacral fascia it has been termed the *postanal plate* (Wendell-Smith and Wilson 1977). From above downwards it comprises the tendinous plate of pubococcygeus, the muscular raphe of iliococcygeus and the posterior attachments of the external anal sphincter.

Nerve supply. The perineal branch of the fourth sacral spinal nerve and by twigs from the inferior rectal branch of the pudendal nerve (second and third sacral spinal nerves).

MUSCLES AND FASCIAE OF THE MALE UROGENITAL REGION

The musculature of the urogenital region consists in both sexes (**5.**56, 57) of the bulbospongiosus, ischiocavernosus, transversi perinei superficialis et profundus, and sphincter urethrae, concerned in the functions of urination, copulation, and general support of the pelvic contents. The muscles may be grouped into superficial and deep strata: (1) the *superficial urogenital muscles*, namely, the median bulbospongiosus, and the right and left ischiocavernosus and transversus perinei superficialis; these occupy the *superficial perineal space* which is detailed below. (2) Occupying the *deep perineal space* (also detailed below) are the sphincter urethrae and the right and left transversus perinei profundus; collectively this deep muscular stratum is called **the urogenital diaphragm** (and this accords with the modern terminology applied to the deep fasciae of the region).

The superficial fascia of this region consists of a superficial, fatty, and a deeper, membranous or fibrous layer.

The *fatty layer* is thick, loose, areolar in texture, and contains a variable accumulation of fat cells in its meshes. In front, it is continuous with the dartos muscle of the scrotum, behind, with the subcutaneous areolar tissue surrounding the anus, and, on each side, with the same fascia on the medial sides of the thighs. In the median plane, it is adherent to the skin and to the membranous layer of the superficial fascia.

The *membranous layer* (**5.**54) is thin, aponeurotic in structure, and of considerable strength, perhaps serving to bind down the muscles of the root of the penis. It is continuous, in front, with the dartos muscle, the fascia penis, and the membranous layer of the superficial fascia upon the anterior wall of the abdomen; on each side it is attached to the margins of the rami of the pubis and ischium, lateral to the crus penis and as far back as the tuberosity of the ischium; posteriorly it curves round the transversi perinei superficiales to join the posterior margins of the fasciae of the urogenital diaphragm and the perineal body. Between the membranous layer of superficial fascia and the inferior fascia of the urogenital diaphragm is the **superficial perineal space** or *pouch*.

The perineal body (the official term, centrum tendineum, is unsuitable; the body is not an insubstantial centre, nor is it tendinous) is a pyramidal fibromuscular node in the median plane occupying the angle between the anal canal and the urogenital apparatus with the *rectovesical (rectovaginal) septum* at its apex. Below this, muscles and their fasciae converge and interlace. From above downwards these are the two levatores prostatae (pubovaginales), the deep and some of the superficial perineal muscles. The deep muscles comprise the sphincter urethrae, the two deep transversi perinei, and the deep part of the sphincter ani externus. The superficial muscles comprise the bulbospongiosus,

the two superficial transversi perinei, and the superficial part of the sphincter ani externus. The attachments of these muscles to the pubes, ischia, and coccyx, determine the position of the perineal body and thus of the visceral canals in all three dimensions.

The transversus perinei superficialis is a narrow muscular strip which passes more or less transversely across the superficial space in front of the anus. It is very variable and often feebly developed, sometimes being absent. It arises by tendinous fibres from the medial and anterior part of the tuberosity of the ischium, and, running medially, it ends in the perineal body, joining in this situation with the muscle of the opposite side, the superficial part of the sphincter ani externus behind, and bulbospongiosus in front. In some cases, the fibres of the deeper layer of the sphincter ani externus decussate in front of the anus, become more superficial, and are continued into this muscle. Occasionally it gives off fibres which join the bulbospongious of the same side or the sphincter ani externus.

Action. The simultaneous contraction of the two transversi perinei superficiales probably helps to fix the perineal body, but the precise value of this is not entirely clear.

The bulbospongiosus (bulbocavernosus) is in the median line of the perineum, in front of the anus, and consists of two symmetrical parts, united by a median tendinous raphe. It arises from this median raphe and from the perineal body. Its fibres diverge like two halves of a feather; the most posterior form a thin layer, which peters out on the inferior fascia of the urogenital diaphragm; the middle fibres encircle the bulb and the adjacent part of the corpus spongiosum penis, and are attached to a strong aponeurosis on their upper surfaces; the anterior fibres spread out over the side of the corpus cavernosum penis, ending partly in the corpus, anterior to the ischiocavernosus, and partly in a tendinous expansion which covers the dorsal vessels of the penis.

Actions. The bulbospongiosus aids emptying of the urethra, after the bladder has expelled its contents; during the greater part of the act of micturition its fibres are relaxed, and they only come into action at the end of the process, and can be used to arrest it. The middle fibres assist in the erection of the corpus spongiosum penis, probably by compressing the erectile tissue of the bulb. The anterior fibres also contribute to the erection of the penis by compressing the deep dorsal vein of the penis, as their tendinous expansion is inserted into, and is continuous with, the deep fascia covering the deep dorsal vessels of the penis (see also p. 1419). This, and the other perineal muscles have been little investigated by electromyography, but this technique suggests that the bulbospongious (and the sphincter urethrae) contract repeatedly in ejaculation, as simple palpation in part reveals.

The ischiocavernosus covers the crus penis. It is attached by tendinous and fleshy fibres to the inner surface the ischial tuberosity behind the crus penis and to the ramus of the ischium on both sides of the crus. The muscular fibres end in an aponeurosis attached to the sides and under surface of the crus penis.

Action. The ischiocavernosus compresses the crus penis, and so may play a part in maintaining erection of the penis.

Between the above muscles a triangular space exists, bounded medially by bulbospongiosus, laterally by ischiocavernosus, and behind by transversus perinei superficialis; its floor is the inferior fascia of the urogenital diaphragm. The posterior scrotal vessels and nerves, and the perineal branch of the posterior femoral cutaneous nerve traverse the space from behind forwards; the transverse perineal artery courses along its posterior boundary on the transversus perinei superficialis.

The deep stratum of urogenital muscles, together with their fasciae, i.e. transversus perinei profundus and sphincter urethrae, as noted above, constitute the **urogenital diaphragm**. Superficial to the transversus perinei profundus and the sphincter urethrae is the *inferior fascia of the urogenital diaphragm* (also widely termed the *perineal membrane*). This strong layer stretches almost horizontally across the pubic arch. Its base, directed backwards, is connected to the perineal body and continuous with the superior fascia of the urogenital diaphragm, behind the transversus perinei superficialis, and with the membranous layer of the superficial fascia. Its lateral margins are attached to the inferior ramus of the pubis and the ramus of the ischium, above the crus penis. Its apex, directed forwards, is thickened to form the *transverse perineal ligament*; between this ligament and the arcuate pubic ligament the deep dorsal vein of the penis (or clitoris) enters the pelvis and the dorsal nerve of the penis passes forwards. The diaphragm is perforated by the following: from 2 to 3 cm behind the inferior edge of the symphysis the urethra, the aperture for which is circular and about 6 mm in diameter; the arteries and nerves to the bulb and, close to the urethra, the ducts of the bulbo-urethral glands; the deep arteries of the penis, one on each side close to the pubic arch and about halfway along its attached margin; the dorsal arteries of the penis near its apex. Its base is also perforated by the posterior scrotal vessels and nerves.

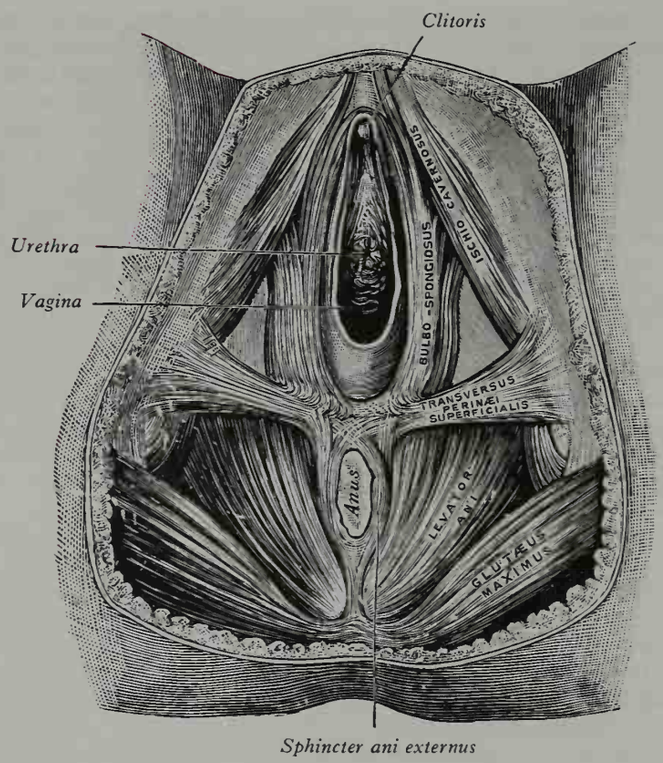
Superior (deep) to the transversus perinei profundus and the sphincter urethrae is a less definite layer of fascia, the *superior fascia of the urogenital diaphragm*. It stretches across the pubic arch and is continuous laterally with the obturator fascia. Behind, it blends with the inferior fascia of the diaphragm, the perineal body and the membranous layer of the superficial fascia; above, it is pierced by the urethra and is continuous at this point with the prostatic fascia.

Between the superior and inferior fasciae of the urogenital diaphragm is the **deep perineal space** or *pouch*. In it are the membranous section of the urethra, the two transversi perinei profundi and the sphincter urethrae, the bulbo-urethral glands and the proximal parts of their ducts, the pudendal vessels and dorsal nerves of the penis in the forward continuation of the pudendal canal, the arteries and nerves of the bulb of the penis, and a plexus of veins.

The transversus perinei profundus starts from the inner surface of the ramus of the ischium and runs to the median plane, where it ends in the perineal body, joining in this situation with its fellow of the opposite side, the deep part of the sphincter ani externus behind and sphincter urethrae in front, with any of which it may exchange fibres.

Action. The transversus perinei profundus can be said to help to steady the perineal body. In this way it is likely to contribute to the general supportive function of the region, but clear functional observations are lacking.

The sphincter urethrae surrounds the membranous part of the urethra, as far as the inferior fascia of the urogenital diaphragm. Its *superficial* or *inferior fibres* arise in front from the transverse perineal ligament and from the neighbouring fasciae. They pass backwards on each side of the urethra and converge on the perineal body. Its *deep fibres*, some of which arise from the inner surface of the ramus of the pubis and pass medially, form a continuous circular investment for the membranous urethra.



Actions. The muscles of both sides act together as a sphincter, compressing the membranous region of the urethra, particularly if the bladder contains fluid (Basmajian and Spring 1955). During micturition, like the bulbospongiosus, they are relaxed, and only come into action at the end of the process to eject the last drops of urine; they are also concerned in ejaculation.

Nerve supply. All the muscles of the urogenital region are supplied by the perineal branch of the pudendal nerve (second, third and fourth sacral spinal nerves).

MUSCLES AND FASCIAE OF THE FEMALE UROGENITAL REGION

This group, in the female, includes the same five paired muscles as in the male, with some differences in size and disposition due to the presence of the vagina and female external genitalia (**5**.57). They are similarly grouped into superficial and deep strata, the latter constituting the *urogenital diaphragm*.

The transversus perinei superficialis in the female is a narrow muscular slip, which differs little from the corresponding muscle in the male (*vide supra*).

5.57 The muscles of the female perineum.

The bulbospongiosus surrounds the orifice of the vagina. It covers the lateral parts of the vestibular bulbs, and is continuous posteriorly with the perineal body, where it blends with the sphincter ani externus. Its fibres pass forwards on each side of the vagina, to be attached to the corpora cavernosa clitoridis; a fasciculus crosses over the body of the clitoris as if to compress the deep dorsal vein.

Actions. The bulbospongiosus diminishes the orifice of the vagina. The anterior fibres probably contribute to the erection of the clitoris by the compression of its deep dorsal vein.

The ischiocavernosus, smaller than it is in the male, covers the unattached surface of the crus clitoridis. It arises by the tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus clitoridis and from the adjacent surface of the ramus of the ischium. The muscular fibres end in an aponeurosis which is attached to the sides and under surface of the crus clitoridis.

Actions. The ischiocavernosus may compress the crus clitoridis and thus retard the return of blood through the veins, thus serving to erect the clitoris.

The *inferior fascia of the urogenital diaphragm* in the female is less extensive than it is in the male, and is pierced by the aperture of the vagina, with the external coat of which it blends, as well as by the urethra and vessels and nerves corresponding to those already enumerated for the male (p. 562). It covers the following structures: parts of the urethra and the vagina, the transversus perinei profundus and sphincter urethrae muscles, the internal pudendal vessels, the dorsal nerves of the clitoris, the arteries and nerves of the vestibular bulbs, and a plexus of veins.

The transversus perinei profundus extends from the inner surface of the ramus of the ischium and runs across behind the vagina to meet the muscle of the opposite side and other structures in the perineal body. The more anterior fibres sink into the vaginal wall.

Action. The transversus perinei profundus probably aids in fixing the perineal body.

The sphincter urethrae, like the corresponding muscle in the male, consists of inferior and superior fibres.

The *inferior fibres* arise on each side from the transverse perineal ligament and sweep backwards on each side of the urethra. Some of the fibres interlace with those of the opposite side between the urethra and the vagina, while others can be traced into the vaginal wall. The *superior fibres* encircle the lower end of the urethra.

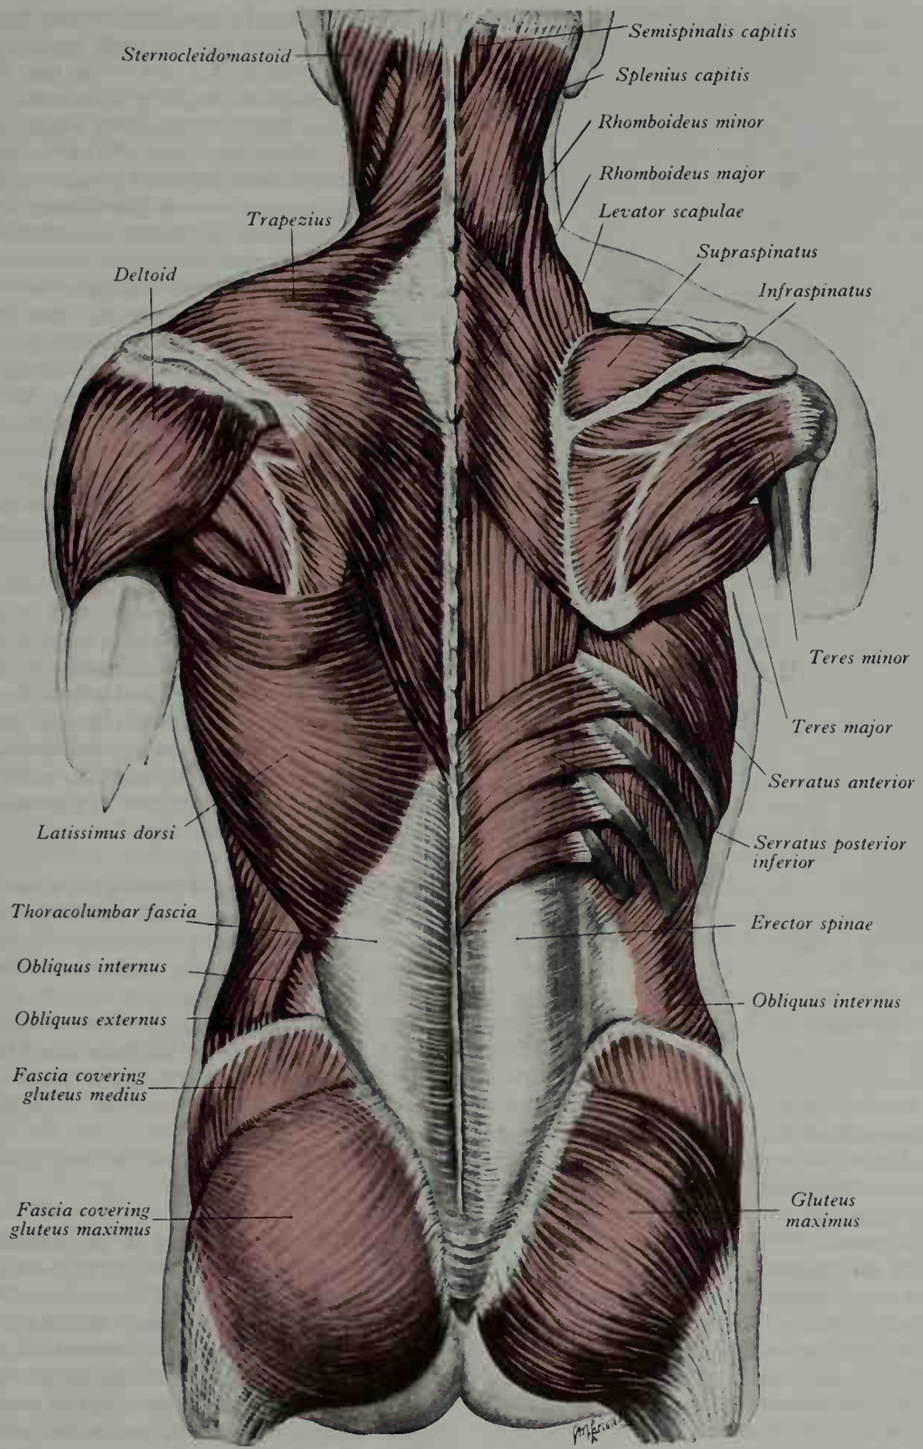
Actions. The muscles of the two sides act as a constrictor of the urethra.

THE FASCIAE AND MUSCLES OF THE UPPER LIMB

The muscles of the upper limb may be considered in the following groups:

I. Muscles connecting the upper limb with the vertebral column.
II. Muscles connecting the upper limb with the thoracic wall.
III. Muscles of the scapula.
IV. Muscles of the upper arm.
V. Muscles of the forearm.
VI. Muscles of the hand.

In the remainder of this section the use of brackets around numerals indicates that it is doubtful whether the spinal nerve in question actually contributes to the motor innervation of a muscle. On the other hand, the use of heavy type indicates that the nerve or nerves indicated are the predominant source of motor supply. (See also p. 1120.)



I. The Muscles connecting the Upper Limb and Vertebral Column

The trapezius, rhomboid major and minor, and levator scapulae, all extend from the cervico-dorsal part of the vertebral column to the pectoral girdle; the latissimus dorsi reaches beyond this to the humerus.

The superficial fascia of the cervico-dorsal region is of considerable thickness and strength, and contains much fat. It is continuous with the general superficial fascia. In the upper part of the neck it forms a thick, tough layer, characterized by the presence of numerous white connective tissue fibres, by which it is firmly attached to the overlying skin.

The deep fascia of the region is a dense fibrous layer where it is attached above to the superior nuchal line of the occipital bone, and in the median plane to the ligamentum nuchae and supraspinous ligament, and to the spines of all the vertebrae below the seventh cervical. Elsewhere it is, for the most part, a thin fibrous membrane. Laterally, in the neck, it is attached to the spine and acromion of the scapula, and is continued downwards over the deltoid to the arm; on the thorax it is continuous with the deep fascia of the axilla and chest, and on the abdomen with the fascia covering the abdominal muscles; below, it is attached to the crest of the ilium.

The trapezius (5.58) is a flat, triangular muscle, extending over the back of the neck and upper thorax. It is attached to the medial one-third of the superior nuchal line of the occipital bone, the external occipital protuberance, the ligamentum nuchae, the seventh cervical and all the thoracic vertebral spinous processes, and the corresponding supraspinous ligaments. The superior fibres proceed downwards, the inferior upwards, and the middle horizontally, all converging laterally upon the shoulder; the superior fibres are there attached to the posterior border of the

5·58 Superficial muscles of the back of the neck and trunk. On the left only the skin, superficial and deep fasciae have been removed; on the right, the sternocleidomastoid, trapezius, latissimus dorsi, deltoid and obliquus externus abdominis have been dissected away.

lateral third of the clavicle; the middle fibres to the medial margin of the acromion and superior lip of the crest of the spine of the scapula; the inferior fibres pass into an aponeurosis, which glides over the smooth triangular surface at the medial end of the spine of the scapula and is attached to a tubercle at the apex of this surface. The upper part of the midline attachment of the muscle is connected to the occipital bone by a thin fibrous lamina, firmly adherent to the skin; the middle part consists of a broad triangular aponeurosis, which reaches from the sixth cervical to the third thoracic vertebra; the lower part contains short tendinous fibres. the two muscles together resemble a trapezoid; the lateral angles correspond to the shoulders, the superior to the occipital protuberance and the inferior to the spine of the twelfth thoracic vertebra.

The clavicular attachment of this muscle varies in extent; it sometimes reaches as far as the middle of the clavicle, and occasionally blends with the posterior edge of the sternocleidomastoid. The vertebral attachment is also variable and may not descend beyond the eighth thoracic spine. The occipital attachment may be absent. The cervical and dorsal parts of the muscle are occasionally separate.

Nerve supply. The trapezius is supplied by the accessory nerve and by branches, generally believed to be entirely sensory (proprioceptive), from the ventral rami of the third and fourth cervical spinal nerves.

Actions. Acting with other muscles attached to the scapula, the trapezius steadies that bone and controls its position and movements during active use of the upper limb. In this way it *is*

concerned in maintaining the level and poise of the shoulder; but it should be noted that in the 'unloaded' arm electromyographic activity is often low or even absent. Moreover, many people can suspend considerable loads with the arm, with little contribution from the upper part of trapezius (Bearn 1960). Acting with the levator scapulae, its upper fibres elevate the scapula and with it the point of the shoulder; acting with the serratus anterior, it rotates the scapula in a forward direction so that the arm can be raised above the head; acting with the rhomboids, it retracts the scapula and so braces back the shoulder. When the shoulder is fixed, the trapezius may draw the head backwards and laterally. The trapezius, levator scapulae, rhomboids and serratus anterior are a concerted group in producing varieties of scapular rotation (*see* p. 456).

The latissimus dorsi (**5**.58) is a large, triangular, flat muscle, extended over the lumbar region and the lower half of the thorax, from which its fibres converge to a narrow tendon. It arises by tendinous fibres from the spines of the lower six thoracic vertebrae anterior to trapezius, and from the posterior layer of the thoracolumbar fascia (p. 542), by which it is attached to the spines of the lumbar and sacral vertebrae, to the supraspinous ligaments, and to the posterior part of the crest of the ilium. In addition, it arises by muscular fibres from the posterior part of the outer lip of the crest of the ilium, lateral to the margin of the erector spinae, and by fleshy slips from the three or four lower ribs; the latter interdigitate with the lower slips of the obliquus abdominis externus (**5**.44). From this extensive attachment the fibres pass laterally with varying degrees of obliquity, the upper ones horizontally, the middle obliquely upwards, and the lower almost vertically upwards, to converge into a thick fasciculus, the upper part of which crosses, and usually receives a few fibres from, the inferior angle of the scapula. The muscle is wrapped round the lower border of the teres major, curving round to its anterior surface. Here it ends in a quadrilateral tendon, about 7 cm long, which passes in front of the tendon of the teres major, and is attached to the bottom of the intertubercular sulcus of the humerus, giving an expansion which blends with the deep fascia of the upper arm; it extends higher on the humerus than the teres major. The lower border of the tendon is united with the tendon of teres major, the surfaces of the two being separated near their attachment by a bursa; another bursa sometimes occurs between the muscle and the inferior angle of the scapula. On account of the way in which the muscle curves round the lower border of the teres major, its constituent fibres are spiralized, consequently the fibres which were *lowest* at the midline attachment are attached highest on the humerus, while the *highest* midline fibres pass into the lower part of its tendon.

The latissimus dorsi, and intimately related teres major, together produce the posterior fold of the axilla. When attempts are made to adduct the arm against resistance, this fold is accentuated and the inferolateral border of the latissimus dorsi can be traced downwards to its attachment to the iliac crest.

A muscular slip, the *axillary arch*, varying from 7 to 10 cm in length, and from 5 to 15 mm in breadth, occasionally springs from the edge of the latissimus dorsi about the middle of the posterior fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the pectoralis major, the coracobrachialis, or the fascia over the biceps. It is present in about 7 per cent of subjects and may be multiple. (For a bibliography and views on the nerve supply of such arches consult Kasai and Chiba 1977.) The vertebral and costal attachments of the latissimus dorsi may be reduced or, more rarely, increased.

A fibrous slip usually passes from the lower border of the tendon of the latissimus dorsi, near its insertion, to the long head of the triceps. This is occasionally muscular, and is the homologue of the *dorso-epitrochlearis brachii* of apes.

Nerve supply. The thoracodorsal nerve from the posterior cord of the brachial plexus, C. **6, 7** and 8.

Actions. The latissimus dorsi is active in the movements of adduction, extension and especially medial rotation of the humerus. Further, it acts with the sternocostal part of the pectoralis major and teres major to depress the raised arm against resistance. It is active also in backward swinging of the arm. When the arms are raised above the head and fixed, as in climbing, the same muscles act to pull the trunk upwards and forwards.

The latissimus dorsi is said to take part in all violent expiratory movements, such as coughing or sneezing, and palpation largely confirms this. Electromyography suggests that it aids in deep inspiration. When the fibres of the muscle are stretched, as in elevation of the arm, sufficient pressure is exerted on the inferior angle of the scapula to keep it in contact with the chest wall.

The lower part of the lateral margin of the latissimus dorsi is commonly separated from the posterior free border of the external oblique by a small triangular interval, named the *lumbar triangle*, the base of which is the iliac crest, and the floor the internal oblique (**5**.58). Another triangle, sometimes termed the *triangle of auscultation*, is situated medial to the scapula. It is bounded above by trapezius, below by latissimus dorsi, and laterally by the medial border of the scapula; part of rhomboideus major is exposed in the triangle. If the scapula is drawn forwards by folding the arms across the chest, and the trunk bent forwards, parts of the sixth and seventh ribs and the interspace between them become subcutaneous in this situation.

The rhomboideus major (**5**.58) arises by tendinous fibres from the spines of the second, third, fourth and fifth thoracic vertebrae and the supraspinous ligaments. The muscle passes downwards and laterally to be attached to the medial border of the scapula between the triangular surface of the root of the spine and the inferior angle. Usually the muscular fibres end in a tendinous band which is fixed at its ends to the two points mentioned and is joined to the medial border by a thin membrane; occasionally the arch is incomplete, and some of the muscular fibres are then inserted directly into the scapula.

The rhomboideus minor (**5**.58) arises from the lower part of the ligamentum nuchae and from the spines of the seventh cervical and first thoracic vertebrae; it is attached to the base of the triangular smooth surface at the medial end of the spine of the scapula. It is usually separated from the rhomboideus major by a slight interval, but the edges of the two muscles are occasionally united. The vertebral and scapular attachments of the rhomboids may vary in extent. Along the upper border of the minor a slender strip of muscle may reach the occipital bone (*rhomboideus occipitalis*).

Nerve supply. The nerve to the rhomboids is the dorsal scapular, C. 4, **5**.

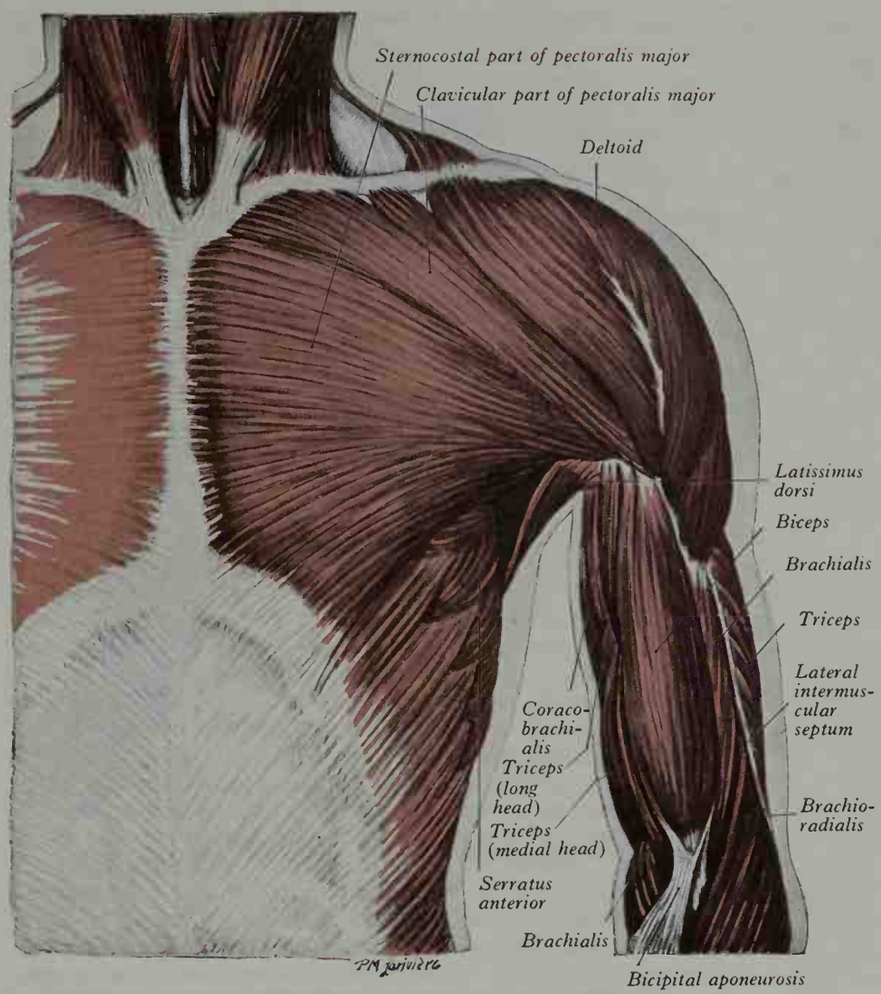
The levator scapulae (**5**.36, 58) is attached by tendinous slips to the transverse processes of the atlas and axis and the posterior tubercles of the transverse processes of the third and fourth cervical vertebrae. It descends diagonally to be attached to the medial border of the scapula between the superior angle and the triangular smooth surface at the medial end of the spine. This muscle is very variable in its vertebral attachments, its degree of separation into slips, and the occurrence of accessory attachments to the mastoid process, occipital bone, first or second rib, scalene, trapezius and serrate muscles.

Nerve supply. The levator scapulae is supplied directly by the third and fourth cervical nerves, and from the fifth cervical through the dorsal scapular nerve.

The blood supply of this muscle is chiefly from the transverse cervical and ascending cervical arteries; its vertebral extremity is, however, supplied by rami of the vertebral artery, an important consideration in transposition of the muscle (Smith *et al.* 1974).

Actions. In association with the other muscles inserted into the scapula, the rhomboids and levator scapulae help to control its position and movements during active use of the upper limb.

Acting with the trapezius, the rhomboids retract the scapula and brace back the shoulder; acting with the levator scapulae and pectoralis minor, they rotate the scapula so as to depress the point of the shoulder.



When the cervical part of the vertebral column is fixed, the levator scapulae acts with the trapezius to elevate the scapula, or to sustain a weight carried on the shoulder. If the shoulder is fixed, the muscle inclines the neck to the same side.

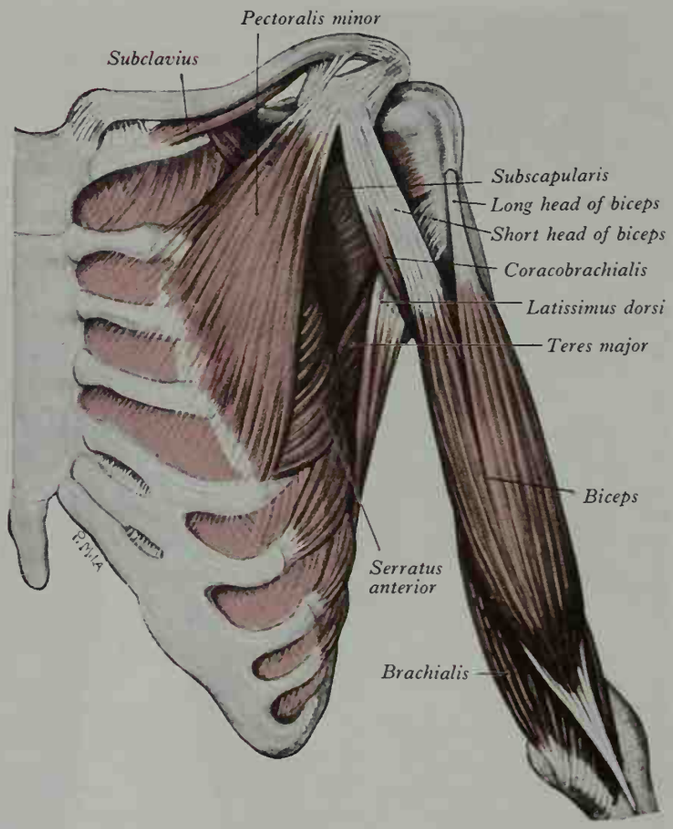
II. The Muscles connecting the Upper Limb and Thoracic Wall

The group includes the serratus anterior and pectoralis minor, which extend from costal attachments to the scapula, the pectoralis major, which acts from the upper thorax to move the humerus, and the subclavius, a much smaller muscle, which is connected only to the first rib and clavicle.

The superficial fascia of the anterior thoracic region is, of course, continuous with that of the neck and upper limb above, and of the abdomen below. It contains the mammary gland and gives off numerous septa which pass between its lobes. From the fascia superficial to the gland, fibrous processes, termed the *mammary suspensory ligaments*, extend to the skin and nipple.

The pectoral fascia is a thin lamina, covering the surface of pectoralis major and sending numerous prolongations between its fasciculi. It is attached in the median plane to the front of the sternum, above, to the clavicle; laterally and below, it is continuous with the fascia of the shoulder, axilla and thorax. It is very thin over the upper part of the pectoralis major, but thicker in the interval between it and latissimus dorsi, which it crosses as the *axillary fascia*; this divides at the lateral margin of the latissimus dorsi into two layers which ensheathe the muscle and are attached behind to the spines of the thoracic vertebrae. As the fascia leaves the lower edge of the pectoralis major to cross the concavity of the axilla, it sends a layer upwards under cover of the muscle; this lamina splits to envelop the pectoralis minor, and at the upper edge of this muscle is continuous with the clavipectoral fascia (p. 568). The hollow of the armpit, seen when the arm is abducted, is produced mainly by the tethering effect of this fascia between the skin and structures of the axillary floor, and hence the lamina is sometimes named the *suspensory ligament of the axilla*. The axillary fascia is pierced by the axillary tail of the mammary gland (p. 1435). At the lower part of the thoracic region the deep fascia is well developed, and is continuous with the fibrous sheath of the rectus abdominis.

5.59 Superficial muscles of the front of the chest and upper arm. Left side.



The pectoralis major (5.59) is a thick, triangular muscle arising from the anterior surface of the sternal half of the clavicle, from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or seventh rib, from the cartilages of all the true ribs, with the exception, frequently, of the first, or seventh, or both, from the ventral extremity of the sixth rib, and from the aponeurosis of the obliquus externus abdominis. The clavicular fibres are usually separated from the sternal fibres by a slight interval. The muscle is attached by a flat tendon, about 5 cm broad, into the lateral lip of the intertubercular sulcus of the humerus. This tendon has two laminae, anterior and posterior, usually blended together below. The *anterior lamina* is thicker and formed by fibres arising from the manubrium joined, superficially, by clavicular fibres, and, deeply, by the fibres from the margin of the sternum and from the second to the fifth costal cartilages. The clavicular fibres may be prolonged downwards into the tendon of the deltoid. The *posterior lamina* receives the fibres from the sixth and frequently the seventh costal cartilages and ribs, from the front of the sternum and from the aponeurosis of the obliquus abdominis externus. The costal fibres join the lamina directly without twisting. The fibres from the sternum and from the aponeurosis curve round the lower border of the rest of the muscle, the lower turning successively behind those cranial to them so that this part of the muscle is twisted on itself and the abdominal fibres rise highest upon the tendon (Ashley 1952). The posterior lamina of the tendon reaches higher on the humerus than the anterior, and gives off an expansion which covers the intertubercular sulcus and blends with the capsular ligament of the shoulder joint. From the deepest fibres of this lamina, at its insertion, an expansion is given off which lines the intertubercular sulcus, while from the lower border of the tendon a third expansion passes downwards to the fascia of the upper arm.

The number of costal attachments of the muscle varies, as does the degree of separation of its clavicular and costal parts. The muscles may decussate across the sternum. Superficial to the pectoralis a vertical slip, or slips, may pass from the lower costal cartilages and rectus sheath to blend above with the sternocleidomastoid, or to be attached to the upper sternum or costal cartilages. This constitutes the *sternalis* muscle (termed by some the *rectus sternalis*). For other variations, including agenesis, consult Čihák and Popelka (1961) and Kasai and Chiba (1977).

The rounded lower border of the muscle forms the anterior axillary fold and becomes conspicuous in the living subject when the abducted arm is adducted against resistance. When the arm is swung forwards to a right angle, the clavicular head is thrown into contraction, while the sternocostal head is relaxed; but when the flexed arm is swung backwards against resistance, the clavicular head becomes relaxed while the sternocostal head stands out in bold relief.

Relations. *In front*, the pectoralis major is related to skin, superficial fascia, platysma, anterior and middle supraclavicular nerves, mammary gland, and deep fascia; its *posterior surface* is in contact with the sternum, ribs and costal cartilages, clavipectoral fascia, subclavius, pectoralis minor, serratus anterior and intercostal muscles; it forms the superficial stratum of the anterior wall of the axilla, and is hence anterior to the axillary vessels and nerves and the upper parts of the biceps and coracobrachialis. Immediately below the clavicle its *upper border* is separated from the deltoid by the *infraclavicular fossa*, in which are the cephalic vein and deltoid branch of the thoraco-acromial artery. Its *lower border* forms the anterior fold of the axilla; it is separated from the latissimus dorsi by a considerable interval at the medial wall of the axilla, but the two muscles gradually converge towards the lateral wall of the axilla (the floor of the intertubercular sulcus of the humerus between the attachments of these muscles).

Nerve supply. The pectoralis major is supplied by the lateral and medial pectoral nerves; the fibres for the clavicular part of the muscle are derived from C. 5 and **6**, and those for the sternocostal part arise from C. **7**, **8**, and T. 1.

5.60 The deep muscles of the front of the chest and arm. Left side.

Actions. The two parts of the pectoralis major are capable of acting in combination or independently of each other. As a whole the muscle takes an active part in the movements of adduction and medial rotation of the humerus, but the activity is only marked if resistance is to be overcome; when the arm has been drawn backwards and laterally, i.e. extended, the pectoralis major draws it forwards and medially. When the arm is swung forwards and medially, the sternocostal fibres take no part in the movement, which is carried out by the clavicular fibres (*portio attollens*) acting with the anterior fibres of deltoid and coracobrachialis. When the opposite movement, usually carried out with the assistance of the force of gravitation, is resisted, the sternocostal part (*portio deprimens*) helps latissimus dorsi and teres major. When the raised arms are fixed, e.g. by gripping a branch of a tree, the same combination of muscles operates to draw the trunk upwards and forwards in climbing. Pectoralis major is also active when inspiration is deep and forcible. Electromyography (de Sousa *et al.* 1969) suggests that only the clavicular part of pectoralis major is active in medial rotation, with or without resistance.

The clavipectoral fascia is a strong fibrous sheet posterior to the clavicular part of pectoralis major. It occupies the interval between the pectoralis minor and subclavius, and covers the axillary vessels and nerves. Traced upwards, it splits to enclose subclavius, and is attached to the clavicle, anterior and posterior to the muscle: the posterior layer fuses with the deep cervical fascia connecting the omohyoid to the clavicle (*see* p. 541) and with the sheath of the axillary vessels. Medially, the clavipectoral fascia blends with that covering the first two intercostal spaces, and is attached also to the first rib medial to subclavius. Laterally, it is thick and dense and attached to the coracoid process, blending with the coracoclavicular ligament. The part between the first rib and coracoid process is often a thickened band, the *costocoracoid ligament*. Below this, the fascia is thin; it splits around pectoralis minor and from its lower border passes downwards to the axillary fascia and laterally to the fascia covering the short head of biceps. The clavipectoral fascia is pierced by the cephalic vein, thoraco-acromial artery and vein, and lateral pectoral nerve.

The pectoralis minor (5.60), thin and triangular, is posterior or deep to the pectoralis major. From the upper margins and outer surfaces of the third, fourth and fifth ribs (frequently the second, third and fourth ribs) near their cartilages, and from the fasciae covering the external intercostals its fibres pass up and laterally, converging into a flat tendon, attached to the medial border and upper surface of the coracoid process of the scapula. Sometimes part or the whole of the tendon passes over the coracoid process into and even through the coraco-acromial ligament; when the latter occurs the tendon blends with the coracohumeral ligament and is thus attached to the humerus. The slips of this muscle are sometimes fully separated, and they vary in number and level. A slip passes from the first rib to the coracoid (*pectoralis minimus*) on rare occasions. Anson *et al.* (1953, 1963) recorded the costal attachments of 1,000 muscles as follows: 2nd to 5th ribs—337, 3rd to 5th—344, 2nd to 4th—193, 3rd to 4th—67. In this series the muscle was never absent.

Relations. The muscle's *anterior surface* is contiguous with the pectoralis major, the lateral pectoral nerve and the pectoral branches of the thoraco-acromial artery, its *posterior surface*, with the ribs, external intercostals, serratus anterior, the axilla, the axillary vessels and brachial plexus of nerves. Its *upper border* is separated from the clavicle by a narrow triangular interval occupied by the clavipectoral fascia, posterior to which are the axillary vessels and nerves. Parallel with the *lower border* is the lateral thoracic artery; piercing and partly supplying the muscle is the medial pectoral nerve.

Nerve supply. Both the pectoral nerves, C. 6, 7 and 8.

Actions. The pectoralis minor assists the serratus anterior in drawing the scapula forwards round the chest wall. Acting with the levator scapulae and the rhomboids, it rotates the scapula so as to depress the point of the shoulder. Both pectoral muscles are electromyographically 'quiet' in inspiration, unless this is very forcible.

The subclavius (5.60) is a small, triangular muscle, between the clavicle and first rib. It arises from the junction of the first rib and its costal cartilage, in front of the costoclavicular ligament, by a thick tendon which is prolonged along the inferior margin of the muscle (Cave and Brown 1952). It proceeds obliquely upwards and laterally to the groove on the under surface of the middle third of the clavicle where it is attached by muscular fibres. Occasionally, the latter attachment may be to the coracoid process in addition to, or instead of, the clavicle. It may also reach the upper border of the scapula.

Relations. Its *posterior surface* is separated from the first rib by the subclavian vessels and brachial plexus of nerves, its *anterior surface* from the pectoralis major by the clavipectoral fascia.

Nerve supply. A branch of the brachial plexus which derives its fibres from C. 5 and 6 (p. 1095).

Action. The subclavius probably pulls the point of the shoulder downwards and forwards and steadies the clavicle, during movements of the shoulder, by bracing it against the articular disc of the sternoclavicular joint. It is, however, inaccessible to palpation and difficult to investigate by electromyography.

The serratus anterior (5.60) is a muscular sheet which passes backwards around the thorax from an extensive costal attachment to a more limited attachment on the scapula. Its muscular digitations arise from the outer surfaces and superior borders of the upper eight, nine or even ten ribs, and from the fasciae covering the intervening intercostals. The first springs from both the first and second ribs, and from the fascia covering the first intercostal space, the others from a single numerically corresponding rib. The lower four interdigitate with the upper five slips of obliquus externus abdominis. Closely applied to the chest wall, and ventral to the scapula, the muscle reaches its medial border in the following manner. The first digitation is attached to a triangular area on the costal surface of the superior angle; the next two or three spread out to form a thin, triangular sheet, the base of which is directed backwards to nearly the whole length of the costal surface of the medial border. The lower four or five digitations converge like a fan to be attached by muscular and

tendinous fibres to a triangular impression on the costal surface of the inferior angle. Digitations may be lacking, particularly the first and the eighth; the middle part of the muscle is also sometimes absent. The muscle may be partly fused with the levator scapulae, adjacent external intercostals, or the external oblique.

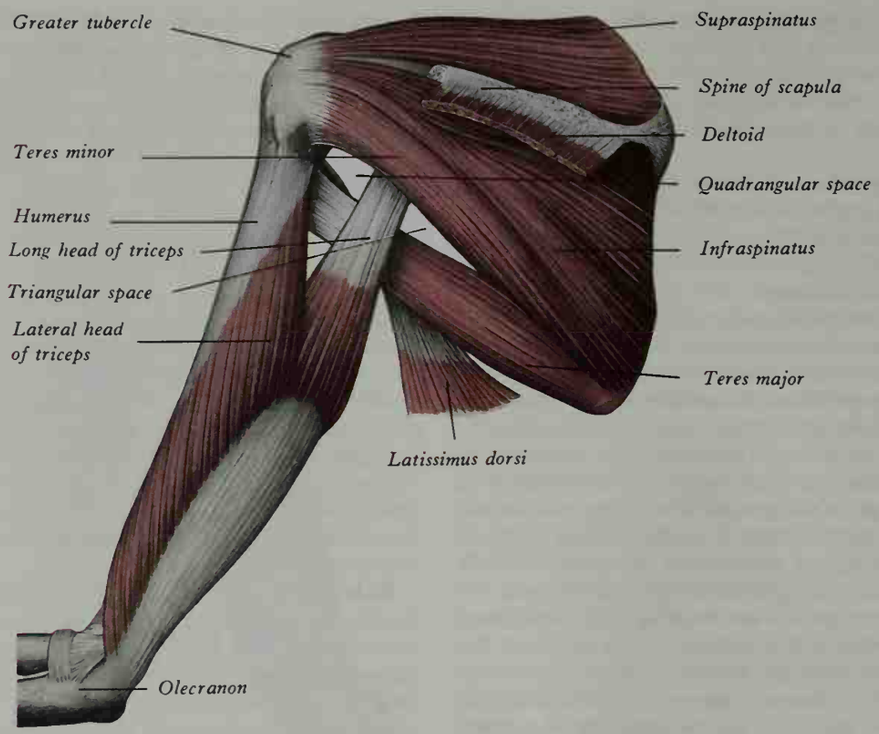
Nerve supply. The long thoracic nerve, C. 5, **6** and **7**, which descends on the external surface of the muscle.

Actions. The serratus anterior, with the pectoralis minor, draws the scapula forwards, and is the chief muscle concerned in all reaching and pushing movements. The upper part of serratus anterior, together with levator scapulae and the upper fibres of trapezius, provide a muscular suspension for the scapula, for which a mild grade of activity is sufficient to support the unloaded arm. The lower and stronger fibres of serratus anterior draw the lower angle of the scapula forwards round the chest wall and assist the trapezius in upward rotation of the bone. They thus play an important part in the movement of raising the arm above the head (p. 455). In the initial stages of abduction the serratus anterior acts with other scapular muscles to steady it so that deltoid is able to exert its action on the humerus and not on the scapula. While deltoid is raising the arm to a right angle with the scapula, the serratus anterior and the trapezius are rotating the scapula, and the arm can be raised even to the vertical as the result of this combination. During such an upward rotation of the scapula, the muscles cooperate in the following manner: the forward pull exerted on the inferior angle of the scapula by the lower digitations of serratus anterior is coupled with an upward and medially directed pull on the lateral end of the clavicle and acromion by the trapezius (upper fibres) and a downward and medial pull on the base of the scapular spine by the lower fibres of trapezius. Conversely, a slow downward rotation of the scapula, assisted by gravity, follows controlled lengthening of the foregoing muscles, whereas a more powerful downward rotation follows balanced contraction of the upper fibres of serratus anterior, the levator scapulae, the rhomboids, the pectoralis minor and the middle part of the trapezius. When weights are carried in front of the body, activity of the serratus anterior increases to prevent backward rotation of the scapula. It has been claimed that electromyography has finally disproved the popular view that the serratus anterior is an accessory inspiratory muscle; but of the references cited Jefferson *et al.* 1960 refer to work on dogs, whereas an electromyographic study on man (Catton and Gray 1951) ignores the effect of fixing the scapula by holding on to, say, a bedrail, railing, and so on as asthmatics and athletes may be seen to do! This problem is clearly not yet resolved.

Applied Anatomy. When the muscle is paralysed, the medial border and especially the lower angle of the scapula stand out prominently, giving a peculiar 'winged' appearance to the back. The patient is unable to raise the arm fully or to carry out pushing movements, and attempts to do so are followed by a further projection of the lower angle of the scapula from the back of the thorax.

III. The Scapular Muscles

The shoulder joint is surrounded by a group of six muscles (deltoid, supra- and infra-spinatus, subscapularis, and teres major and minor) which all extend from scapula to humerus. By their general proximity of attachment to the joint, which they can move in any direction, they also maintain safe contact of the articular surfaces, in both static and dynamic conditions, in a particularly shallow multiaxial joint (p. 430).



The deep fascia over the deltoid sends numerous septa between its fasciculi. In front, it is continuous with the pectoral fascia, behind, where it is thick and strong, with the infraspinous fascia; above, it is attached to the clavicle, acromion, and crest of the spine of the scapula; below, it is continuous with the brachial fascia.

The deltoid (**5**.59), a thick, triangular muscle, like the Greek letter delta inverted, is attached at its base above to the anterior border and superior surface of the lateral third of the clavicle, the lateral margin and superior surface of the acromion, and the lower edge of the crest of the spine of the scapula, as far as the smooth triangular surface at its medial end. The muscle converges into a short and substantial tendon attached to the deltoid tuberosity on the lateral aspect of the humeral shaft. The anterior and posterior fibres descend obliquely and without interruption into the tendon, whereas the intermediate part of the muscle is multipennate; four intramuscular tendinous septa descend from the acromion to interdigitate with three which ascend from the deltoid tuberosity, and short fibres pass between them, providing a short but powerful pull. The fasciculi of the muscle are comparatively large, giving it a coarsely striped appearance. The deltoid is wrapped around the humeral articulation on all sides except below and medially, and its bulk determines the rounded profile of the shoulder. When contracted its borders are easily seen and palpated. The tendon gives off an expansion into the brachial deep fascia, and it may on rare occasions reach the forearm. Commoner variations are partition into the three parts described above, union with the pectoralis major, or additional slips from trapezius, the infraspinous fascia, or from the axillary border of the scapula.

Relations. Superficially are skin, superficial and deep fasciae, platysma, lateral supraclavicular and upper lateral brachial cutaneous nerves. Deep to the muscle are the coracoid process, coraco-acromial ligament, subacromial bursa, the tendon of insertion of the pectoralis minor, the tendons of origin of the coracobrachialis and both heads of the biceps, the tendon of the pectoralis major, the insertions of the subscapularis, supra-spinatus, infraspinatus, and teres minor, the long and lateral heads of the triceps, the circumflex humeral vessels, the axillary nerve and the surgical neck and upper part of the shaft of the humerus, including both tuberosities. Its *anterior border* is separated above from the pectoralis major by the infra-clavicular fossa, in which the cephalic vein and deltoid branch of the thoraco-acromial artery lie; lower down the two muscles are in contact and their tendons usually unite. Its *posterior border* overlies infraspinatus and triceps.

Nerve supply. The deltoid is supplied by the axillary nerve, C. **5** and 6.

Actions. The muscle is capable of acting in part or as a whole. The anterior fibres cooperate with pectoralis major in drawing the arm forwards, and they are potential medial rotators of the humerus. Conversely, the posterior fibres act with latissimus dorsi and teres major in drawing the arm backwards and they can act as lateral rotators of the humerus. The multipennate, acromial part is the strongest part of the muscle. Aided by the supraspinatus it raises the arm from the side until the inferior part of the capsule of the shoulder joint is put on the stretch, the movement being in the same plane as the body of the scapula. This point is of importance because only thus can scapular rotation have its full effect in raising the arm above the head. When the arm is actively maintained in this position of true abduction (**4**.5), the acromial fibres are strongly contracted, but the clavicular and posterior fibres are put on the stretch steadying the limb and preventing side-sway. While the deltoid is effecting this movement of the humerus on the scapula the latter is itself rotated (p. 456). In the early stages of abduction the traction exerted by the deltoid is in an upward direction, but the head of the humerus is prevented from gliding upwards on the glenoid cavity by the downward pull of the subscapularis, infraspinatus and teres minor, which come into action synergically with the deltoid. As a result deltoid and supraspinatus, on the one hand, and the subscapularis, infraspinatus and teres minor, on the other, constitute a mechanical couple which ensures the perfect performance of abduction. Electromyography suggests that deltoid contributes little to medial and lateral rotation, but otherwise the muscle is to some degree active in most movements of the shoulder. Deltoid may aid the supraspinatus in resisting downward drag of the loaded arm (*vide infra*). Perhaps the commonest action of the deltoid is arm-swinging in walking. An interesting ergonomic study of the clavicular part of the muscle by Jonsson and Hagberg (1974) demonstrates the importance of these fibres in adjusting the hand to various heights in different manual tasks.

5.61 The dorsal scapular muscles and triceps. Left side. The spine of the scapula has been divided near its lateral end and the acromion has been removed together with a large part of the deltoid.

Applied Anatomy. The muscle atrophies after division of the axillary nerve, and in this condition dislocation of the shoulder joint is simulated by flattening of the shoulder and apparent prominence of the acromion; the distance between the acromion and the humeral head is increased also, and the tips of the fingers can be inserted between them.

The subscapular fascia is a thin aponeurosis attached to the entire circumference of the subscapular fossa, and from its deep surface some of the fibres of the subscapularis arise.

The subscapularis (**5**.60) is a large, triangular muscle, which fills the subscapular fossa and arises from its medial two-thirds, including the grooved area adjoining the lateral border of the scapula. Some fibres arise from tendinous laminae which intersect the muscle and are attached to ridges on the bone, others from aponeuroses which cover the muscle and separate it from teres major and the long head of the triceps. The fibres pass laterally, gradually converging into a tendon attached to the lesser tubercle of the humerus and the front of the capsule of the shoulder joint. The tendon is separated from the neck of the scapula by a large bursa, which communicates with the shoulder joint through an aperture in its fibrous capsule and is hence really a protrusion of the joint cavity. Variation in this muscle is unusual; a separate slip may pass from the upper end of the medial scapular border to the capsule of the shoulder joint or medial to the intertubercular sulcus of the humerus.

Relations. The muscle forms a considerable part of the posterior wall of the axilla. The lower and medial two-thirds of its *anterior surface* are apposed to the serratus anterior, and its upper and lateral third is related to coracobrachialis and biceps, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. Its *posterior surface* is of course attached to the scapula and anterior to the capsule of the shoulder joint. Its *lower border* is in contact with the teres major and latissimus dorsi.

Nerve supply. The upper and lower subscapular nerves, C. 5, **6** and (7).

The supraspinous fascia completes the osseofibrous compartment in which the supraspinatus arises, and its deep surface affording attachment to part of the muscle. It is thick medially, but thinner laterally under the coraco-acromial ligament.

The supraspinatus (**5**.61) arises from the medial two-thirds of the supraspinous fossa and from the supraspinous fascia. The muscle passes under the acromion, and converges into a tendon which crosses above the shoulder joint to become attached to the highest of three facets sited on the greater tubercle of the humerus; the tendon is intimately adherent to the capsule of the shoulder joint. A slip may pass from it to the tendon of pectoralis major.

Nerve supply. The suprascapular nerve, C. 4, **5** and 6.

Applied Anatomy. The tendon of supraspinatus is separated from the coraco-acromial ligament, acromion and deltoid by the subacromial bursa; when this is inflamed, abduction of the shoulder joint is painful. The tendon is the most frequently partially or completely ruptured element of the musculo-tendinous cuff which surrounds the shoulder joint.

The infraspinous fascia covers the infraspinatus, and is fixed to the borders of the infraspinous fossa; from its deep surface some fibres of the muscle arise. It is continuous with the deltoid fascia along the overlapping posterior border of the deltoid.

The infraspinatus (**5**.61) is a thick triangular muscle occupying most of the infraspinous fossa; it arises by muscular fibres from the medial two-thirds of the fossa, and by tendinous fibres from the ridges on its surface it also arises from the infraspinous fascia, which covers it and separates it from the teres major and minor. The fibres converge to a tendon, which glides over the lateral border of the spine of the scapula, and, passing across the posterior part of the capsule of the shoulder joint, is attached to the middle facet on the greater tubercle of the humerus. The tendon is sometimes separated from the capsule of the shoulder joint by a bursa, which may communicate with the joint cavity. The muscle is sometimes fused with teres minor.

Nerve supply. The suprascapular nerve, C. (4), **5** and 6.

The teres minor (**5**.61) is a narrow, elongate muscle, which arises from the upper two-thirds of a flattened strip on the lateral part of the dorsal surface of the scapula, immediately adjoining the lateral border, and from two aponeurotic laminae, one

separating it from infraspinatus, and the other from teres major. It runs obliquely upwards and laterally; its upper fibres end in a tendon attached to the lowest of the three facets on the greater tubercle of the humerus; the lower fibres are inserted directly into the humerus immediately below this impression and just above the origin of the lateral head of the triceps. The tendon passes across, and is united with, the lower part of the posterior surface of the capsule of the shoulder joint. The muscle may be fused with infraspinatus.

Nerve supply. The axillary nerve, C. (4), **5** and 6.

Actions. The subscapularis, supraspinatus, infraspinatus and teres minor together have an essential steadying effect on the head of the humerus, maintaining it in stable apposition to the glenoid cavity and controlling its tendency to excessive sliding (p. 458). (As we have seen—p. 459—swings of the humerus at the glenohumeral joint are accompanied by complex movements between the articular surfaces which contain elements of rolling, sliding and often spinning. In the absence of a closely integrated muscular control, excessive degrees of sliding can easily occur at such a shallow articulation.) During the initial stages of abduction the subscapularis, infraspinatus and teres minor counteract the strong upward component of the pull of the deltoid and thus, aided by the supraspinatus, enable the force component which is *perpendicular* to the humeral shaft to draw the arm away from the body. Infraspinatus and teres minor, in association with the posterior fibres of the deltoid, act as lateral rotators of the humerus, and the subscapularis assists in medial rotation when the arm is by the side. The above four muscles are widely termed the '*rotator cuff*' of the shoulder joint, for obvious reasons. When the loaded, or unloaded, upper limb is hanging by the side, the tendency for downward translation of the humeral head in relation to the glenoid cavity is resisted by supraspinatus rather than deltoid, according to electromyographic data; the lack of tension in deltoid can also be appreciated by palpation alone. On the contrary, anterior and posterior drag on the humerus are strongly resisted by the corresponding parts of deltoid.

The teres major (**5**.61) is a thick, somewhat flattened muscle which arises from the oval area on the dorsal surface of the inferior angle of the scapula, and from the fibrous septa interposed between the muscle and teres minor and infraspinatus; the fibres are directed upwards and laterally and end in a flat tendon, about 5 cm long, which is attached to the medial lip of the intertubercular sulcus of the humerus. At its insertion the tendon lies behind the tendon of the latissimus dorsi, from which it is separated by a bursa, the two tendons being, however, united along their lower borders for a short distance. The muscle may be united with the scapular part of latissimus dorsi, and a slip of it may join the long head of triceps or the brachial fascia.

Nerve supply. The lower subscapular nerve, C. **6** and 7.

Actions. The teres major draws the humerus medially and backwards, and rotates it medially. Electromyographic studies, however, evince some disagreement upon the muscle's role during even violent active movements, but its activity during the maintenance of static postures and during arm-swinging appears well established. Note that, despite their common name, the teres major and teres minor have different nerve supplies and belong to different functional groups.

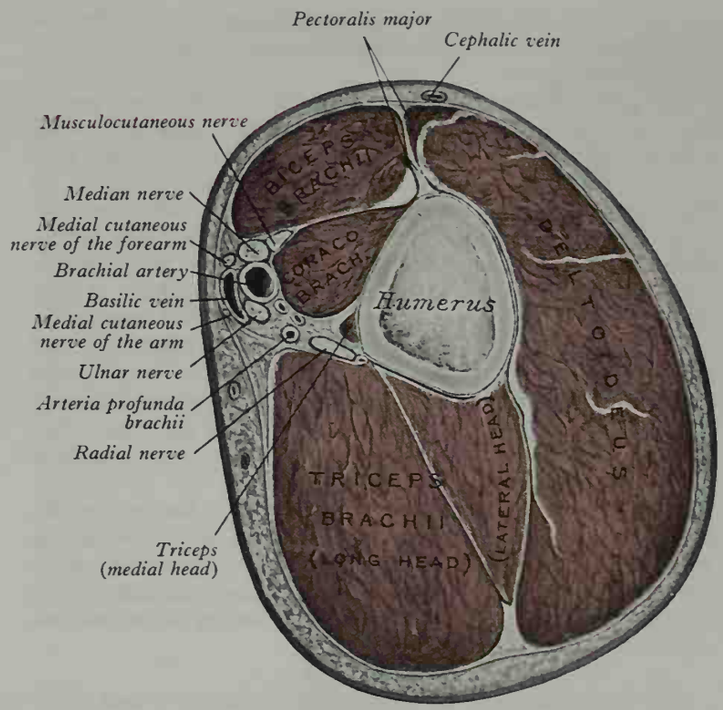
IV. The Muscles of the Upper Arm

This group comprises the coracobrachialis, which acts only on the shoulder joint; the biceps and triceps which cross both the shoulder and elbow joints; and brachialis which alone acts entirely upon the latter joint.

The brachial fascia, or deep fascia of the upper arm, is continuous with that covering the deltoid and pectoralis major; it forms a thin, loose sheath for the muscles of the upper arm, and sends septa between them. It is thin over biceps, but thicker where it covers triceps, and over the epicondyles of the humerus; it is strengthened by fibrous aponeuroses derived from pectoralis major and latissimus dorsi medially, and from deltoid laterally. On each side it gives off a strong intermuscular septum, which is attached to the corresponding supracondylar ridge and epicondyle of the humerus.

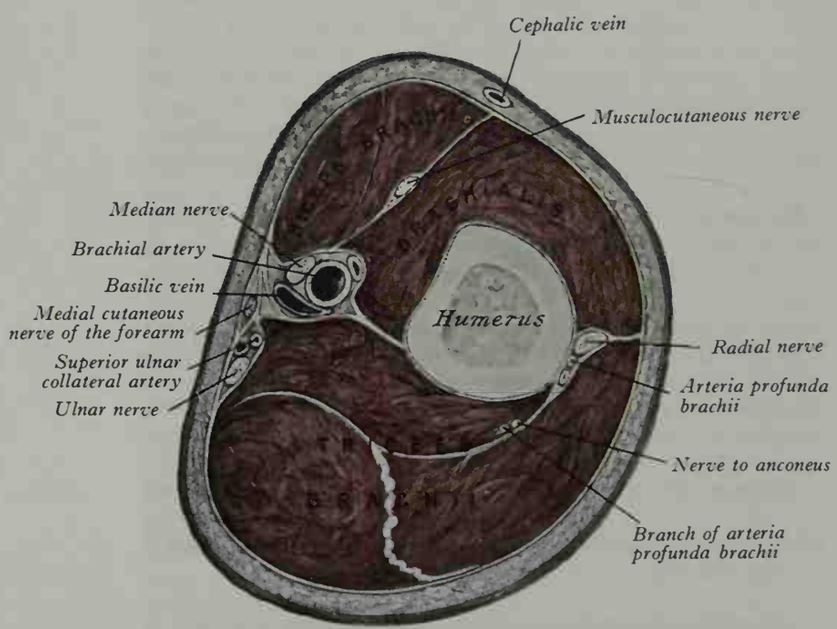
The *lateral intermuscular septum* extends from the lower part of the lateral lip of the intertubercular sulcus, along the lateral supracondylar ridge, to the lateral epicondyle; it is blended with the tendon of deltoid, gives attachment to triceps behind, to brachialis, brachioradialis and extensor carpi radialis longus in front, and is perforated at the junction of its upper and middle thirds by the radial nerve and the radial collateral branch of the arteria profunda brachii. The *medial intermuscular septum*, thicker than the preceding, extends from the lower part of the medial lip of the intertubercular sulcus below teres major, along the medial supracondylar ridge to the medial epicondyle; it is blended with the tendon of coracobrachialis, and affords attachment to triceps behind and brachialis in front. It is perforated by the ulnar nerve, the superior ulnar collateral artery, and the posterior branch of the inferior ulnar collateral artery.

At the elbow, the brachial fascia is attached to the epicondyles of the humerus and the olecranon of the ulna, and is continuous with the antebrachial fascia. Just below the middle of the medial side of the upper arm, the basilic vein and some lymphatic vessels pass through it, and at various points, branches of the brachial cutaneous nerves.



The coracobrachialis (**5**.60, 62) arises from the apex of the coracoid process, in common with the tendon of the short head of biceps, and by muscular fibres from the upper 10 cm of this tendon; it is attached to an impression, from 3 to 5 cm in length, midway along the medial border of the shaft of the humerus between the attachments of triceps and brachialis. The muscle forms an inconspicuous rounded ridge on the upper part of the medial side of the arm, and the pulsations of the brachial artery can be felt, and often seen, in the depression behind it. Accessory parts of this muscle may be attached, above, to the lesser tubercle, and below, to the medial epicondyle or medial intermuscular septum.

Relations. It is perforated by the musculocutaneous nerve, and is related, in *front*, to pectoralis major above, and at its humeral attachment with the brachial vessels and median nerve, which cross it; *behind* it are the tendons of the subscapularis, latissimus dorsi, and teres major, the medial head of triceps, the humerus and the anterior circumflex humeral vessels; *medially*, are the third part of the axillary artery, the upper part of the brachial artery, the median and musculocutaneous nerves; *laterally*, the biceps and brachialis.



Nerve supply. The musculocutaneous nerve, C. 5, **6** and 7.

Actions. The coracobrachialis draws the arm forwards and medially, especially from a position of extension. When the arm is raised from the side, it acts with the anterior fibres of the deltoid to prevent side-sway.

The biceps brachii (**5**.60, 62, 63), a large, fusiform muscle in the flexor compartment of the upper arm, has received its name from the fact that it has two heads or attachments proximally. The *short head* arises by a thick flattened tendon from the apex of the coracoid process, in common with coracobrachialis. The *long head* starts within the fibrous capsule of the shoulder joint. It arises by a long narrow tendon from the supraglenoid tubercle at the apex of the glenoid cavity, and is continuous with the glenoidal labrum (p. 458). The tendon of the long head, enclosed in a sheath of the synovial membrane of the shoulder joint, arches over the head of the humerus, emerges from the joint by passing behind the transverse humeral ligament, and then descends in the intertubercular sulcus; it is retained in the groove by the transverse humeral ligament and by a fibrous expansion from the tendon of pectoralis major. Each tendon is succeeded by an elongated muscular belly, and the two bellies, although closely applied to each other, can be readily separated until within about 7 cm of the elbow joint. Here they end in a flattened tendon which is attached to the rough posterior area of the radial tuberosity, a bursa being between the tendon and the anterior area of the tuberosity. As the tendon of the muscle approaches the radius it is twisted, its anterior surface becoming lateral and then applied to the

5.62 Transverse section through the right arm at the junction of the proximal and middle thirds of the humerus. Superior (proximal) aspect.

5.63 Transverse section through the right arm, a little below the middle of the shaft of the humerus. Superior (proximal) aspect.

tuberosity of the radius. Opposite the bend of the elbow the tendon produces, from its medial side, a broad band, the *bicipital aponeurosis*, which passes obliquely downwards and medially across the brachial artery, and fuses with the deep fascia covering the origins of the flexor muscles of the forearm (**5**.65 and **6**.70). With little force the tendon of insertion can be split distally as far as the radial tuberosity, when it can be verified that its anterior part receives the fibres of the short head, and the posterior those of the long head.

A third head to the biceps often occurs (10 per cent), arising at the upper and medial part of the brachialis, with which it is blended, and attached to the bicipital aponeurosis and medial side of the tendon of the muscle; in most cases this additional slip lies behind the brachial artery. In some instances the third head consists of two slips, which pass down, one in front of, the other behind the artery. Less often, a further part may spring from the lateral aspect of the humerus, or the intertubercular sulcus. Other additional 'heads' may occur.

Relations. The biceps is overlapped above by pectoralis major and deltoid; in the rest of its extent it is superficial, being covered only by the fasciae and skin, and it forms a conspicuous elevation on the front of the arm. Its long head passes through the shoulder joint, and its short head is anterior to the joint and to the upper part of the humerus; below, it is anterior to brachialis, the musculocutaneous nerve, and supinator. Its *medial border* is contiguous with coracobrachialis, and overlaps the brachial vessels and median nerve; its *lateral border* is related to the deltoid and brachioradialis.

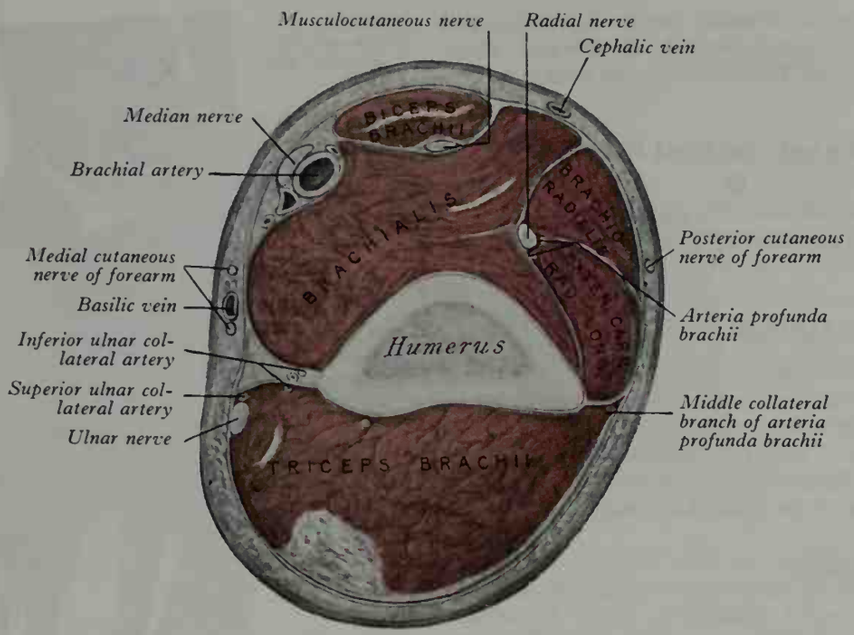
Nerve supply. The musculocutaneous nerve, C. 5 and **6**, which gives a branch to both bellies.

Actions. The biceps is a powerful supinator, employed when the movement is rapid or carried out against resistance; it also flexes the elbow joint, most effectively with the forearm in supination, and is also to a slight extent a flexor of the shoulder joint. Through the bicipital aponeurosis, it is also attached to the posterior border of the ulna, the distal end of which is drawn medially in supination (p. 462). The long head helps to prevent the head of the humerus from gliding upwards during contraction of the deltoid. When the elbow is flexed against resistance, the tendon of insertion of the biceps can be grasped between the finger and thumb and the bicipital aponeurosis can be traced down from its medial edge to the deep fascia covering the origins of the flexor muscles of the forearm.

It should be noted that many habitual movements involve *increasing tension* of contraction, with *increasing length*. For example, if the hand holding an object is lowered to a table under the influence of gravity, the extension of the elbow joint involved is controlled by such activities in the joint *flexors*. As the loaded hand descends and the elbow extends, the load is carried further and further from the fulcrum of movement at the joint and the effective load increases.

Applied Anatomy. The long tendon of the biceps is sometimes dislocated from its groove on the humerus. When this occurs, the arm is fixed in a position of abduction, but the head of the humerus can be felt in its proper position. The tendon can generally be replaced by flexing the forearm on the arm and rotating the limb.

The brachialis (**5**.60, 63, 64) arises from the lower half of the front of the humerus, commencing above at the insertion of deltoid, which it embraces by two pointed processes, and extending below to within 2·5 cm of the margin of the articular surface. It also arises from the intermuscular septa, but more extensively from the medial than from the lateral; it is separated from the lower part of the lateral intermuscular septum by brachioradialis and extensor carpi radialis longus. Its fibres converge to a thick and broad tendon which is attached to the tuberosity of the ulna and the rough impression on the anterior surface of the coronoid process. The brachialis may be divided into two or more parts. It may be fused with the brachioradialis, pronator teres, or biceps. It may send a tendinous slip to the radius or bicipital aponeurosis.



Relations. Biceps, the brachial vessels, musculocutaneous and median nerves are *anterior* to it; *posteriorly* are the humerus and capsule of the elbow joint, *medially*, pronator teres, and also the medial intermuscular septum, which separates it from triceps and the ulnar nerve; *laterally*, are the radial nerve, radial recurrent and radial collateral arteries, the brachioradialis and extensor carpi radialis longus.

Nerve supply. The musculocutaneous nerve, C. 5 and **6**, and the radial nerve (C. 7) to a small lateral part of the muscle (Ip and Chang 1968).

Action. The brachialis is a flexor of the elbow joint with the forearm either prone or supine, with or without resistance to the movement.

The triceps (**5**.61, 64), in the extensor compartment of the upper arm, is of large size, and arises by three heads (long, lateral and medial), hence its name.

The *long head* arises by a flattened tendon from the infraglenoid

5.64 Transverse section through the right arm, a little proximal to the medial epicondyle of the humerus. Superior (proximal) aspect.

tubercle of the scapula, blended above with the fibrous capsule of the shoulder joint; the muscular fibres pass downwards medial to the lateral head and superficial to the medial head, and join them in a common tendon of insertion.

The *lateral head* arises by a flattened tendon from a narrow ridge on the posterior surface of the shaft of the humerus, from the lateral border of the humerus and the lateral intermuscular septum. The bony origin extends upwards with varying obliquity from the lateral border of the humerus above the radial groove, behind the posterior limb of the deltoid tuberosity, to the surgical neck medial to the insertion of teres minor. These fibres converge towards the common tendon.

The *medial head*, which is overlapped posteriorly by the lateral and the long heads, arises from the posterior surface of the shaft of the humerus, below the radial groove; it is narrow and pointed above, and extends from the insertion of teres major to within 2·5 cm of the trochlea of the humerus; it also arises from the medial border of the bone and from the back of the whole length of the medial and lower part of the lateral intermuscular septa. Some of the muscle fibres are directed downwards to the olecranon, while others converge to the common tendon.

The tendon of triceps begins about the middle of the muscle. It consists of two aponeurotic laminae, one of which is superficial in the lower half of the muscle; the other is in the substance of the muscle. After receiving the muscular fibres, the two layers unite above the elbow, and are attached, for the most part, posteriorly on the upper surface of the olecranon; on the lateral side a band of fibres is continued downwards, over the anconeus, to blend with the antebrachial fascia.

The long head descends between teres minor and teres major, dividing the triangular interval between these two muscles and the humerus into two smaller parts, one triangular, the other quadrangular (**5**.61). The triangular space contains the circumflex scapular vessels; it is bounded by teres minor above, teres major below, and the long head of triceps laterally. The quadrangular space transmits the posterior circumflex humeral vessels and the axillary nerve; it is bounded by the subscapularis, teres minor and capsule of the shoulder joint above, the teres major below, the long head of triceps medially, and the humerus laterally.

The lateral head of triceps forms an elevation, parallel with and medial to the posterior border of the deltoid; it stands out prominently when the elbow is extended actively. The mass which lies to its medial side, and disappears under cover of deltoid, is produced by the long head.

The articularis cubiti (subanconeus) is the name given to a few fibres which spring from the deep surface of the lower part of the triceps, and blend with the posterior part of the fibrous capsule of the elbow joint.

Nerve supply. The radial nerve, C. 6, **7** and **8** with separate branches supplying the three heads (p. 1101).

Actions. The triceps is the great muscle of extension of the forearm on the arm at the elbow joint. The medial head is active in all forms of extension. The actions of the lateral and long heads, however, are minimal, except when the forearm is acting against resistance (Basmajian 1967). Examples of the latter are during forward thrusting or pushing, or when the body weight is partly supported on the hands, with semiflexed elbow joints. When the flexed arm is extended at the shoulder joint, the long head of the muscle may assist in drawing the humerus backwards and in adducting it to the thorax. The long head supports the lower part of the capsule of the shoulder joint, when the arm is raised from the side. The articularis cubiti draws up the posterior part of the capsule of the elbow joint during extension of the forearm.

During forceful supination of the semiflexed forearm, involving active contraction of both supinator and biceps brachii, the triceps contracts synergically to fix the position of semiflexion at the elbow joint.

The human triceps brachii has been the subject of an interesting comparison of its geometric and dynamic parameters by Cnockaert and Pertuzon (1974).

V. The Antebrachial Muscles

The antebrachial fascia (the deep fascia of the forearm), continuous above with the brachial fascia, is a dense general sheath for the muscles in this region; it is attached to the olecranon and posterior border of the ulna, and from its deep surface many intermuscular septa pass inwards for muscle attachment, some reaching bone. Muscles also arise from its internal aspect especially in the upper forearm, and it also ensheathes the different muscles. Transverse septa occur in the anterior and posterior regions of the forearm, separating deep from superficial muscles. It is much thicker posteriorly and in the lower part of the forearm. It is strengthened above by tendinous fibres derived from the biceps in front and triceps behind. Two localized thickenings, the *flexor* (p. 583) and *extensor retinacula* (p. 583), occur in it near the wrist. These retain the digital tendons in position and so increase their efficiency. Apertures exist in the fascia for the passage of vessels and nerves; one of these, of large size and anterior to the elbow, transmits a venous communication between superficial and deep veins.

The antebrachial or forearm muscles consist of anterior and posterior groups which are morphologically flexors and extensors, though some are modified for more complex activities.

1. The Anterior Antebrachial Muscles

These muscles can be divided into two groups, superficial and deep, the superficial flexors being largely attached proximally to the humerus, the deep group to the radius and ulna.

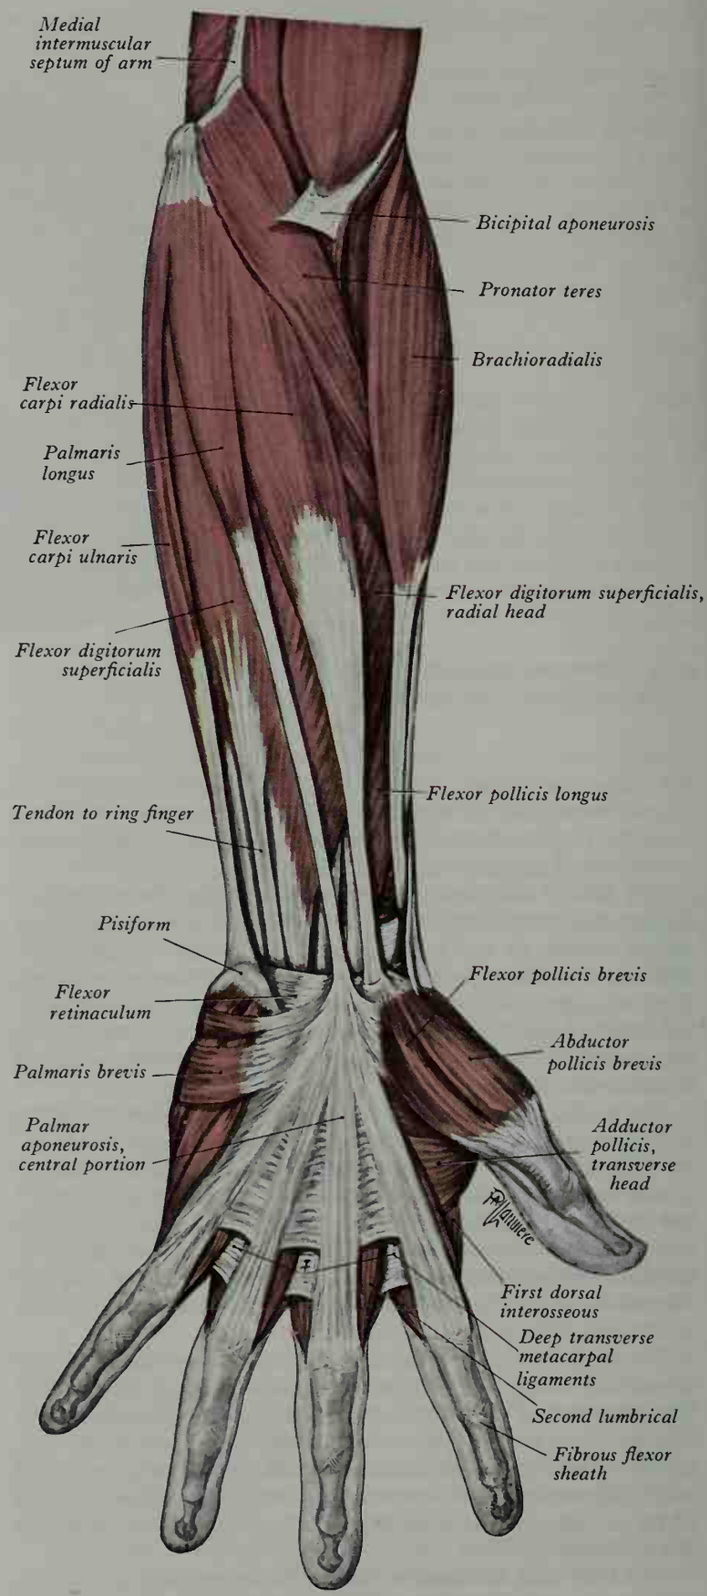
SUPERFICIAL FLEXOR GROUP

The muscles of this group take origin from the medial epicondyle of the humerus by a common tendon, and are the pronator teres, the palmaris longus, flexores carpi radialis et ulnaris, and flexor digitorum superficialis (**5**.65, 66). They have additional attachments to the antebrachial fascia near the elbow, and to the septa which pass from this between the individual muscles.

The pronator teres (**5**.65, 66) has humeral and ulnar attachments. The *humeral head*, larger and more superficial, arises immediately above the medial epicondyle, from the tendon common to the origin of the flexor muscles, from the intermuscular septum between it and flexor carpi radialis and from the antebrachial fascia. The much smaller *ulnar head* arises from the medial side of the coronoid process of the ulna below the attachment of flexor digitorum superficialis, and joins the humeral head at an acute angle. The median nerve usually (83 per cent of cases, *see* p. 1098) enters the forearm between the parts of the muscle, and is separated from the ulnar artery by the ulnar head. The muscle passes obliquely, across the forearm and ends in a flat tendon, attached to a rough area midway along the lateral surface of the radial shaft. The lateral border of the muscle is the medial boundary of the triangular hollow in front of the elbow joint termed the *cubital fossa*. The coronoid attachment of the muscle may be absent. Additional slips may be derived from a supracondylar process of the humerus, if present, from biceps, or brachialis, or the medial intermuscular septum.

Nerve supply. The median nerve, C. 6 and **7**.

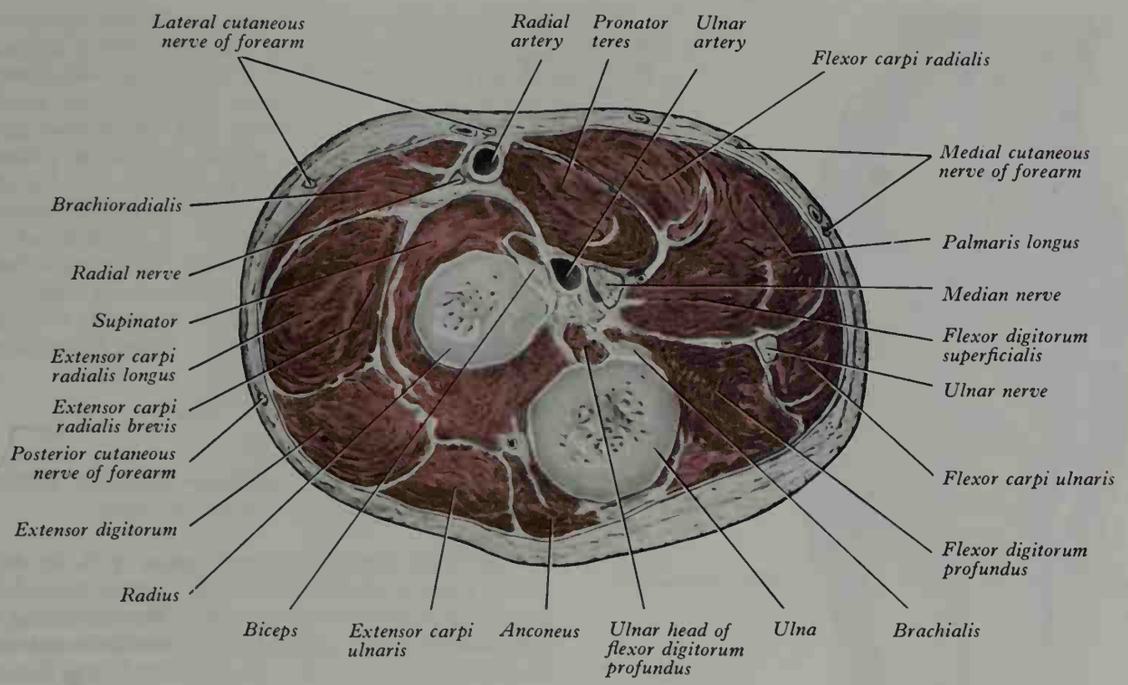
Actions. The pronator teres rotates the radius upon the ulna, turning the palm of the hand backwards, i.e. it pronates the forearm and hand; it is also a weak flexor of the elbow joint. It acts with pronator quadratus which is always active during any act of pronation. Pronator teres reinforces the quadratus only during rapid or forcible pronation, but its activity is always less than that of quadratus (Basmajian and Travill 1961).



The flexor carpi radialis (**5**.65, 66, 69) is medial to pronator teres and arises from the medial epicondyle by the common flexor tendon, from the antebrachial fascia, and from the intermuscular septa between it and the adjacent muscles. Its belly is fusiform and, rather more than halfway down the forearm, ends in a long tendon, which passes through a canal in the lateral part of the flexor retinaculum and occupies a groove on the trapezium which is lined by a synovial sheath to the palmar surface of the base of the second metacarpal bone, sending a slip to the base of the third metacarpal bone. These attachments are hidden by the oblique head of the adductor pollicis (**5**.80). In the lower part of the forearm the radial artery is between the tendon of this muscle and that of brachioradialis.

The muscle may be absent. Proximally it may have additional slips from the biceps tendon, bicipital aponeurosis, coronoid process or radius. Distally it may be additionally attached to the flexor retinaculum, trapezium, or fourth metacarpal.

Nerve supply. The median nerve, C. 6 and **7**.



Actions. Acting with the flexor carpi ulnaris, and sometimes the flexor digitorum superficialis, the flexor carpi radialis flexes the wrist; acting with the radial extensors of the wrist, it helps to abduct the hand.

The palmaris longus (**5**.65, 66, 79) is slender, fusiform and medial to flexor carpi radialis. It arises from the medial epicondyle of the humerus by the common tendon, from intermuscular septa between it and adjacent muscles, and from the antebrachial fascia.

5.65 The superficial flexor muscles of the left forearm, the palmar aponeurosis, and the digital fibrous flexor sheaths.

It ends in a long slender tendon, which passes in front of the flexor retinaculum to be attached to the anterior surface of its distal half and the central part of the palmar aponeurosis, frequently sending a tendinous slip to the thenar muscles. Just proximal to the wrist the median nerve lies deep to the tendon, and projects a little beyond its lateral edge. This muscle is often absent on one or both sides, and is much subject to variation (Machado and DiDio 1967). It may have a proximal tendon, or be reduced to a tendinous strand. It may be digastric or reduplicated. It may end in the antebrachial fascia, tendon of flexor carpi ulnaris, the

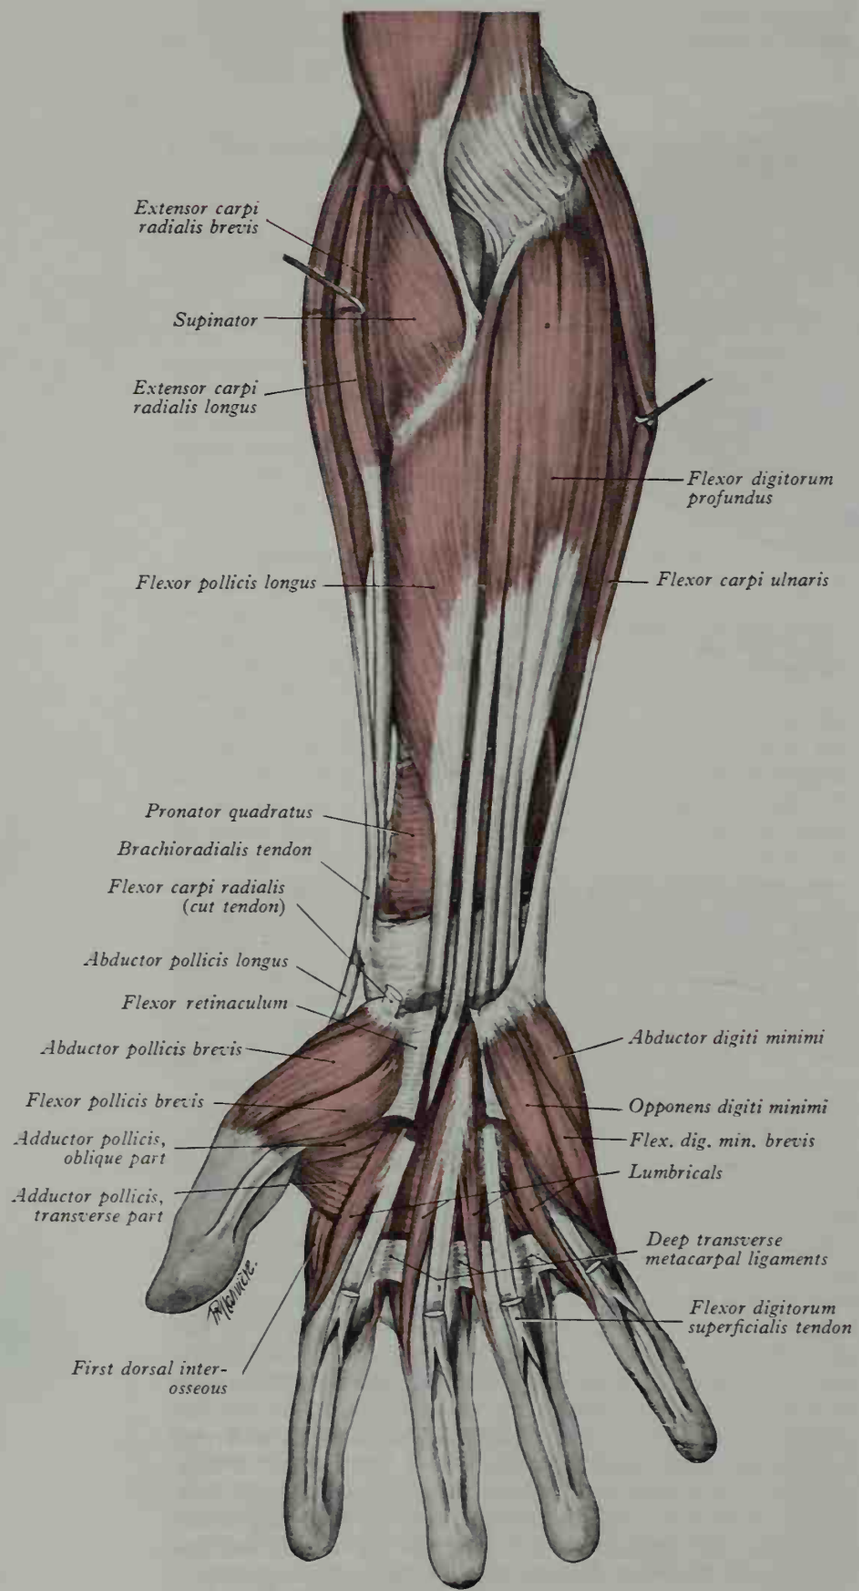
5.66 Transverse section through the forearm at the level of the radial tuberosity.

pisiform, scaphoid, etc. Reimann *et al.* (1944) found the muscle absent in 281 of 2205 specimens (12·7 per cent); the muscle displayed accessory slips in 15 instances and was double in 4 forearms.

Nerve supply. The median nerve, C. 7 and 8.

Actions. The palmaris longus flexes the wrist, and may act as a tensor of the palmar fascia.

The flexor carpi ulnaris (**5**.65, 66, 69) is the most medial of the superficial forearm flexors. It arises by two heads, humeral and ulnar, connected by a tendinous arch, beneath which the ulnar nerve passes distally and the posterior ulnar recurrent artery proximally. The *humeral head* is small and arises from the medial epicondyle of the humerus by the common tendon, the *ulnar head* from the medial margin of the olecranon, and the upper two-thirds of the posterior border of the ulna by an aponeurosis common to it and extensor carpi ulnaris and flexor digitorum profundus, and from the intermuscular septum between it and the flexor digitorum superficialis. A tendon is formed along the anterolateral border of the muscle in its distal half and is attached to the pisiform bone, whence it is prolonged to the hamate and fifth metacarpal bones by the so-called pisohamate and pisometacarpal ligaments (**4**.50); it is also attached by a few fibres to the flexor retinaculum. A coronoid slip is sometimes present, and distally a more substantial attachment to the flexor retinaculum, or to the fourth or fifth metacarpal bones may be observed. The ulnar vessels and nerve lie on the lateral side of its tendon of insertion.



Nerve supply. The ulnar nerve, C. 7 and **8**.

Actions. With flexor carpi radialis, palmaris longus when present, and flexor digitorum superficialis, the flexor carpi ulnaris flexes the wrist; with the extensor carpi ulnaris, it adducts the hand. Both the flexor and extensor carpi ulnaris act as synergists to prevent abduction of the hand when the thumb is actively extended at its carpometacarpal joint, as can easily be confirmed by palpation. Flexor carpi ulnaris also fixes the pisiform bone during abduction and flexion of the little finger.

When the wrist is flexed against resistance, two tendons are prominent; the lateral is the flexor carpi radialis and medial is the palmaris longus, approximately in the middle line of the limb. Flexor carpi ulnaris can also be identified proximal to the pisiform bone.

The flexor digitorum superficialis (sublimis) (**5**.65, 66, 69) is deep to the preceding muscles; it is the largest of the muscles of the superficial flexor group, and arises by two heads, humero-ulnar and radial. The *humero-ulnar head* arises from the medial epicondyle of the humerus by the common tendon, from the anterior band of the ulnar collateral ligament of the elbow joint, from the intermuscular septa between it and the preceding muscles, and from the medial side of the coronoid process, above the ulnar origin of pronator teres. The *radial head* which is a thin sheet of muscle, arises from the anterior border of the radius, extending from the radial tuberosity to the insertion of pronator teres. The median nerve and the ulnar artery pass downwards through the gap which intervenes between these two heads. The muscle usually separates into two strata of muscular fibres, superficial and deep; the superficial, joined laterally by the radial head, divides into two tendons for the middle and ring fingers; the deep stratum gives off a muscular slip to join the part of the superficial stratum associated with the tendon of the ring finger, and then ends in two tendons for the index and little fingers. As the four tendons pass behind the flexor retinaculum, they are arranged in pairs, the superficial pair going to the middle and ring, the deep pair to the index and little fingers. The tendons diverge in the palm, and opposite the bases of the proximal phalanges each divides, to allow the passage of a tendon of the flexor digitorum profundus; the surfaces of the two slips so formed become reversed and they then reunite, partially decussate, and form a grooved channel for the profundus tendon. Finally the superficialis tendon divides again and ends on the sides of the shaft of the middle phalanx. The dimensions of these tendons have been described in detail by Shrewsbury and Kuczynski (1974), who have also estimated the tendon excursions during activity, and the bowing ranges of the tendons. They have, in addition, attempted to correlate these data with an analysis of their fibrous architecture, in particular the significance of the *scissural bands* and *chiasmata*, during digital flexor activity.

The flexor digitorum superficialis is subject to several variations. The radial head may be absent. The slip from the deep stratum may provide most or all of the muscular fibres acting on the index. The part of the muscle for the fifth digit may be absent and replaced by a separate slip arising from the ulna, flexor retinaculum, or palmar fascia. The number and formation of the tendons may also vary. Dylevský (1968) has advanced developmental

5.67 The deep flexor muscles of the right forearm.

explanations of such variations in the deep and superficial digital flexors, which he regards as derived from separate strata, and not from a single blastema. However, Chaplin and Greenlee (1975), following development of digital tendons in human embryos and fetuses confirmed the usual description—an initial single blastemal arrangement of the digital flexor tendons.

Relations. *In the forearm*, the flexor digitorum superficialis is deep to palmaris longus, flexor carpi radialis, pronator teres, brachioradialis, the radial artery and the radial nerve. It is in front of flexor digitorum profundus, the upper part of the ulnar artery, the median nerve (which is closely bound to it by fibroareolar tissue) and flexor pollicis longus. *At the wrist*, the tendons of flexor digitorum superficialis pass behind the flexor retinaculum, lying in front of the tendons of flexor digitorum profundus in a common synovial sheath (5.76); flexor pollicis longus tendon and the median nerve lie to their lateral side. *In the hand*, the tendons lie behind the palmar aponeurosis, superficial palmar arch and digital branches of the median and ulnar nerves, but in front of the tendons of flexor digitorum profundus and the lumbricals.

Nerve supply. The median nerve, C. 7 and **8** and T. 1.

Actions. The flexor digitorum superficialis flexes first the middle and then the proximal phalanges. It is also a flexor of the wrist. It is particularly involved in rapid, forceful flexion of the digits in grasping movements, being electromyographically silent in gentle unresisted flexion.

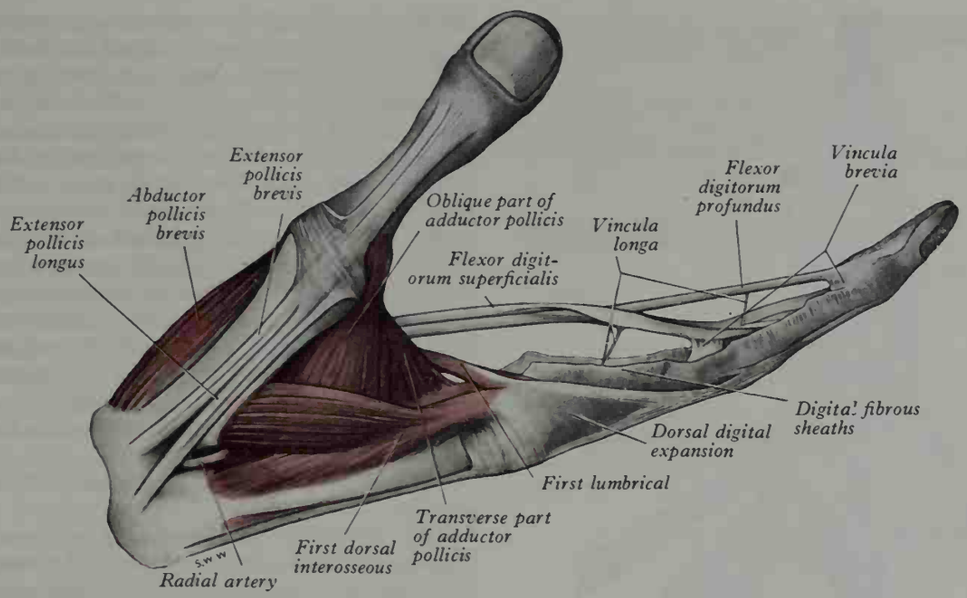
DEEP FLEXOR GROUP

The group consists of the flexor digitorum profundus, flexor pollicis longus, and the pronator quadratus.

The flexor digitorum profundus (5.66, 67, 69) arises deep to the superficial flexors from the upper three-fourths of the anterior and medial surfaces of the ulna, embracing the insertion of brachialis above, and extending to within a short distance of pronator quadratus below. It also arises from a depression on the medial side of the coronoid process, and from the upper three-fourths of the posterior border of the ulna by an aponeurosis, in common with flexor and extensor carpi ulnaris; it also springs from the anterior surface of the ulnar half of the interosseous membrane. The muscle ends in four tendons, which run posterior to the tendons of flexor digitorum superficialis (and hence posterior to the flexor retinaculum). The part of the muscle acting on the index finger is usually distinct throughout, but the tendons for the middle, ring and little fingers are connected together by areolar tissue and tendinous slips, as far as the palm. Anterior to the proximal phalanges the tendons pass through openings in the tendons of flexor digitorum superficialis (p. 575), to their attachments on the palmar surfaces of the bases of the distal phalanges. The tendons of the profundus undergo changes in shape with rearrangement of their constituent fibre bundles (Wilkinson 1953; Martin 1958) as they pass between the diverging halves of the superficialis tendons.

Flexor digitorum profundus forms most of the muscular elevation which can be seen and felt on the dorsum of the forearm medial to the subcutaneous posterior border of the ulna.

The muscle may be joined by accessory slips from the radius (acting on the index), and from the flexor superficialis, flexor pollicis longus, the medial epicondyle, or the coronoid process.



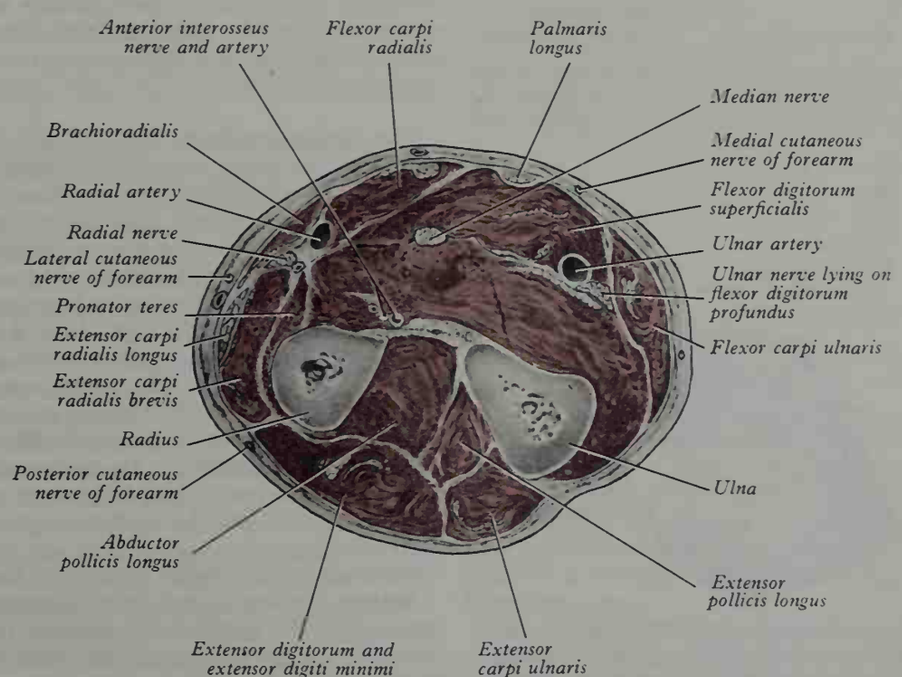
Nerve supply. The medial part of the muscle is supplied by the ulnar and the lateral part by the anterior interosseous branch of the median nerve, C. **8** and T. 1.

Actions. The flexor digitorum profundus flexes the distal phalanges, after the flexor digitorum superficialis has bent the middle phalanges; it can also assist in flexing the wrist. When all the fingers are flexed, the digital extensors relax, but when individual digits are flexed, activity is sustained in the antagonist extensors (Person and Roschina 1958). More complex movements involve the synergic action of the interossei and lumbricals (p. 589). Electromyographic observations (Long 1964) suggest that the flexor digitorum profundus is alone active in gentle, unresisted flexion of the fingers, the superficialis coming into play when greater force and/or velocity are required.

The lumbricals are attached to the tendons of the flexor digitorum profundus in the palm, and are described with the muscles of the hand (p. 589).

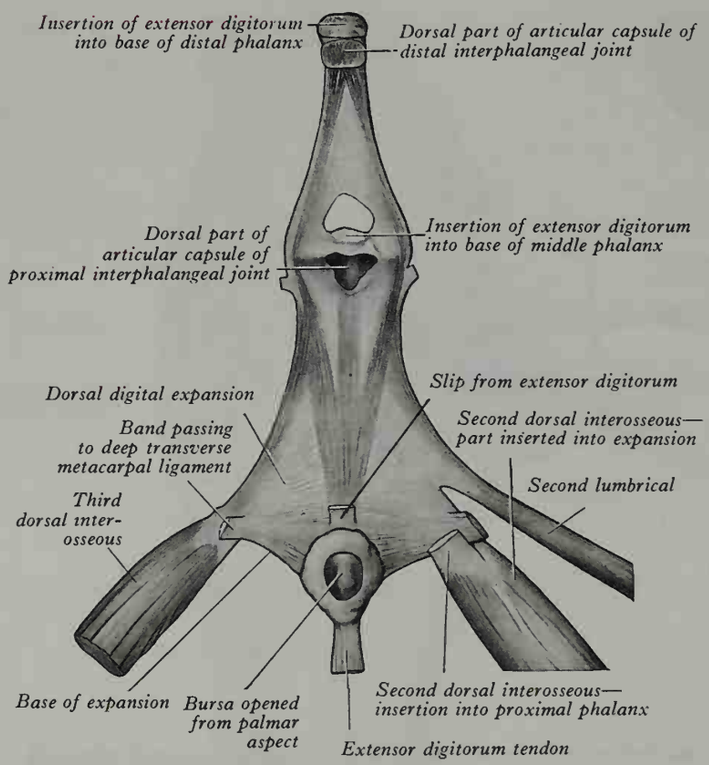
Fibrous Sheaths of the Flexor Tendons

In the digits the tendons of the flexores digitorum superficialis et profundus lie in osseo-aponeurotic canals (5.77, 79), formed behind by the phalanges, and by fibrous bands, the *digital fibrous sheaths*, which arch across the tendons anteriorly, and are attached to the margins of the phalanges and to the palmar ligaments of the interphalangeal joints. Anterior to the middle of the proximal and middle phalanges the bands are very strong, and the fibres are



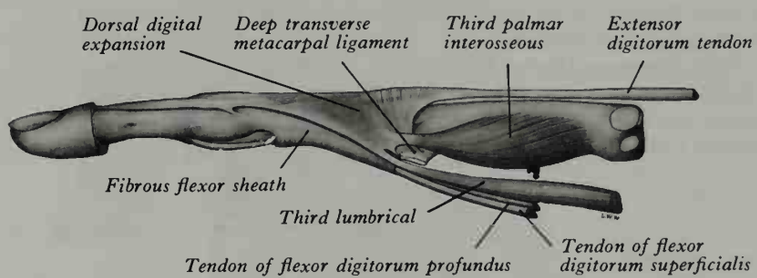
5.68 Lateral part of the right hand showing the tendons and vincula tendinum of the index finger and the muscles in the first intermetacarpal space.

transverse (*annular part*); but opposite the joints they are much thinner, and consist of oblique fibres (*cruciform part*). Each canal is lined by a synovial sheath, which is reflected on to the contained tendons. The synovial membrane is directly adherent to the fibrous sheath.

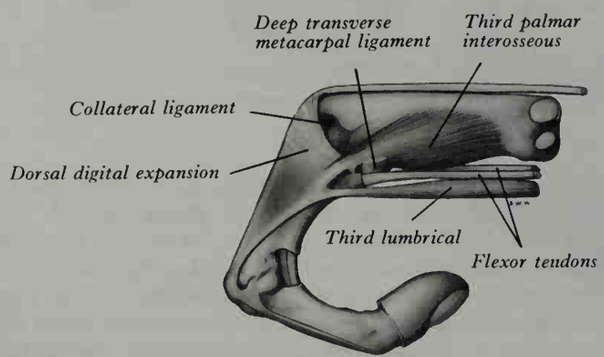


As the flexor tendons approach their attachments they are connected to the dorsal parts of the enclosing synovial sheaths by triangular or thread-like bands of synovial membrane termed *vincula tendinum* (5.68), which convey minute vessels to them. They are of two kinds, (*a*) vincula brevia and (*b*) vincula longa.

The *vincula brevia*, two in number in each finger, are triangular bands attached to the deep surfaces of the tendons close to their attachments; one connects the tendon of the flexor digitorum superficialis to the front of the proximal interphalangeal joint and adjacent part of the proximal phalanx, and the other the tendon of the flexor digitorum profundus to the front of the distal interphalangeal joint and adjacent part of the middle phalanx. The *vincula longa* are thread-like slips, of which two are usually attached to each tendon of the flexor digitorum superficialis, and one to each tendon of the flexor digitorum profundus. Those of the flexor digitorum superficialis are connected to the slips of that tendon where these fold over the tendon of the flexor digitorum profundus, and, passing one on each side of the latter tendon, are attached to the sheath at the lateral margins of the proximal end of the proximal phalanx. That of the flexor digitorum profundus is fixed to its tendon shortly after the latter has pierced the tendon of the flexor digitorum superficialis. It runs upwards and backwards, perforates one of the two slips of the latter tendon, or passes between the two slips; thereafter it blends with the vinculum breve of the flexor digitorum superficialis and is attached to the dorsal wall of the synovial sheath at the distal end of the proximal phalanx.



The flexor pollicis longus (5.67, 76) is lateral to the flexor digitorum profundus. It arises from the grooved anterior surface of the radius, extending from immediately below its tuberosity to within a short distance of pronator quadratus. It arises also from



5.69 A transverse section through the middle of the left forearm.

5.70A The dorsal digital expansion of the middle finger, showing some of its principal connexions. Viewed from the palmar surface, the basal angles having been drawn out and the whole expansion kept taut and flattened. Compare with 5.70B and C. Immediately distal to the bursa which overlies the metacarpophalangeal joint, a small slip from the extensor digitorum tendon is inserted into the base of the proximal phalanx. This slip is not always present.

5.70B The ring finger dissected to show the dorsal digital expansion and its principal connexions. Lateral aspect. Note the position of the base of the expansion when the finger is extended and compare with 5.70C.

5.70C The dorsal digital expansion of the ring finger in flexion. Compare with 5.70B, and note that the base of the expansion has moved distally. Compare 5.70A, B and C which were prepared by Professor James Whillis. Additional details and nomenclature are shown in 5.71A, B and C.

the adjacent part of the interosseous membrane, and frequently by a variable slip from the lateral or, more rarely, the medial border of the coronoid process, or from the medial epicondyle of the humerus (Martin 1958). The fibres end in a flattened tendon, which passes behind the flexor retinaculum, between the opponens pollicis and the oblique head of the adductor pollicis, and enters an osseo-aponeurotic canal similar to those for the flexor tendons of the fingers, to be attached to the palmar surface of the base of the distal phalanx of the thumb. The anterior interosseous nerve and vessels descend on the front of the interosseous membrane between the flexor pollicis longus and flexor digitorum profundus. The long flexor of the thumb is also sometimes connected by slips to the flexor digitorum superficialis, or profundus, or pronator teres. The interosseous attachment may be absent, as may the whole muscle.

Nerve supply. The anterior interosseous branch of the median nerve, C. **8** and T. 1.

Action. The flexor pollicis longus flexes the phalanges of the thumb.

The pronator quadratus (5.67) is a flat, quadrilateral muscle, extending across the front of the lower parts of the radius and ulna. It arises from the oblique ridge on the lower part of the anterior surface of the shaft of the ulna (3.141), from the medial part of the anterior surface of the lower fourth of the ulna and from a strong aponeurosis which covers the medial third of the muscle. The fibres pass laterally and slightly downwards, to be attached to the lower fourth of the anterior border and surface of the shaft of the radius; the deeper fibres are inserted into the triangular area above the ulnar notch of the radius.

Nerve supply. The anterior interosseous branch of the median nerve, C. **8** and T. 1.

Action. This muscle is the principal pronator of the forearm, and its activity is only reinforced by pronator teres during rapid or forceful pronation. The deeper fibres of pronator quadratus oppose separation of the lower ends of the radius and ulna when upward thrusts are transmitted through the carpus.

2. The Posterior Antebrachial Muscles

These muscles are divided for convenience of description into two groups, superficial and deep.

SUPERFICIAL EXTENSOR GROUP

All the muscles in this group (5.72, 75), except brachioradialis and anconeus, which act on the elbow alone, act on a series of joints as extensors. The extensores carpi radiales longus et brevis and the extensor carpi ulnaris act on the radiocarpal and carpal joints, the extensores digitorum et digiti minimi extend the digits and may also extend the wrist.

The brachioradialis (5.65, 66, 69) is the most superficial muscle on the radial side of the forearm and forms the lateral border of the cubital fossa. It arises from the upper two-thirds of the lateral supracondylar ridge of the humerus, and from the anterior surface of the lateral intermuscular septum. The radial nerve and the anastomosis between the arteria profunda brachii and the radial recurrent artery are between it and brachialis. The fibres end above the mid level of the forearm in a flat tendon attached to the lateral side of the lower end of the radius, just above the styloid process. The tendon is crossed at its termination by those of abductor pollicis longus and extensor pollicis brevis; the radial artery is on its ulnar side. The muscle is often fused proximally with brachialis. Its tendon may divide into two or three separately attached slips. Rarely it is double or absent. Its radial attachment may be much more proximal than the base of the styloid process.

Nerve supply. The radial nerve, C. 5, **6** and (7).

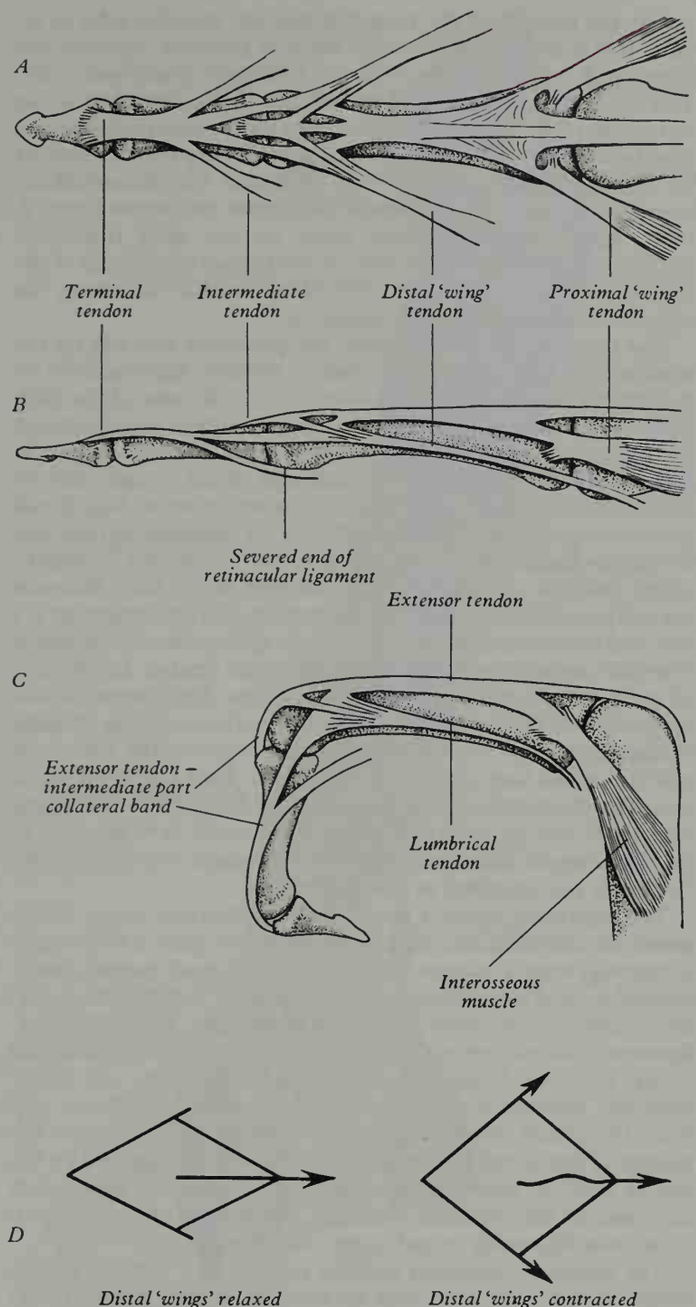
Action. The brachioradialis is a flexor of the elbow joint, but is supplied by the nerve of the extensor muscles, i.e. the radial nerve. It acts to best advantage when the forearm is in the midprone position and stands out prominently in the living subject when the semi-pronated forearm is flexed forcibly; it

shows little activity in slow, easy flexion movements, or when the forearm is supine. It is active in *rapid* movements of *both flexion and extension* of the elbow, when it is considered to function as a 'shunt' muscle (p. 528), providing a centripetal force towards the elbow joint which balances the centrifugal force generated by a rapid swing of the forearm in either direction (MacConaill 1949; Basmajian 1959). (But see also p.529.)

The extensor carpi radialis longus (5.69, 72) is partly overlapped by the brachioradialis. It arises mainly from the lower one-third of the lateral supracondylar ridge of the humerus and the front of the lateral intermuscular septum, but a few fibres come from the common tendon of origin of the forearm extensors. The muscle ends at the junction of the upper and middle thirds of the forearm in a flat tendon, which runs along the lateral surface of the radius, deep to abductor pollicis longus and extensor pollicis brevis; it then passes under the extensor retinaculum, where it lies on the back of the radius in a groove immediately behind the styloid process. It is attached to the radial side of the dorsal surface of the base of the second metacarpal bone. It may also send slips to the first or third metacarpal bones and it contributes to inter-metacarpal ligaments in the region (F. Bojsen-Møller 1978).

Nerve supply. The radial nerve, C. 6 and 7.

The extensor carpi radialis brevis (5.69, 72, 76) is shorter than the preceding muscle and is covered by it. It arises from the lateral epicondyle of the humerus, by a tendon common to it and other forearm extensors (*vide infra*), from the radial collateral ligament of the elbow joint, from a strong aponeurosis which covers its surface, and from the intermuscular septa between it and adjacent muscles. Its belly ends about the middle of the forearm in a flat tendon which closely accompanies that of the preceding muscle to the wrist; it passes deep to abductor pollicis longus and extensor pollicis brevis, then under the extensor retinaculum. It is attached to the dorsal surface of the base of the third metacarpal bone, on its radial side and distal to its styloid process, and into the adjoining part of the base of the second metacarpal bone. Under the extensor retinaculum the tendon is on the back of the radius in a shallow groove, on the ulnar side of the groove occupied by the tendon of extensor carpi radialis longus, and separated from it by a variably marked ridge.



Nerve supply. The extensor carpi radialis brevis is supplied by the posterior interosseous nerve, C. 7 and 8.

The tendons of the two preceding muscles pass through the same compartment of the extensor retinaculum in a single synovial sheath. They can be identified on the back of the carpus in the living subject, when the fist is alternately clenched and relaxed.

Both the radial carpal extensors may display splitting of their tendons into two or three slips, variably attached to the second and third metacarpal bones. They may be united or exchange muscular slips.

Actions. Both the preceding muscles act synergically with the flexors of the fingers, and this action can readily be appreciated when the fist is clenched. Working with the extensor carpi ulnaris, they extend the wrist; working with the flexor carpi radialis, they abduct the hand. It should be noted that they are more often called into action as synergic muscles than as prime movers. This applies particularly to the extensor carpi radialis longus which is much less active than the brevis in pure wrist extension (Tournay and Paillard 1953), even when this is rapid. In contrast the longus is synergically much more active than the brevis in grasping or clenching.

The extensor digitorum (5.69, 72, 76) arises from the lateral epicondyle of the humerus by the common extensor tendon, from the intermuscular septa between it and adjacent muscles, and from the antebrachial fascia. It divides below into four tendons, which pass, together with that of the extensor indicis, through a separate tunnel under the extensor retinaculum, with a common synovial sheath. The tendons then diverge on the dorsum of the hand, one to each finger. The tendon to the index is accompanied by extensor indicis, which lies medial to it. On the dorsum adjacent tendons are variably tied by three *intertendinous connexions*, directed obliquely downwards and laterally. The most

5.71 A–C Detailed diagrams to illustrate the digital extensor mechanisms. A—viewed from dorsal aspect with digit in full extension. B—viewed from the side, also in full extension. C—viewed from the side, in full flexion. Note particularly the terminal and intermediate parts of the long extensor tendon, the proximal and distal 'wing' tendons, the dorsal extensor expansion, the diamond-shaped complex of tendons dorsal to the proximal interphalangeal joint, and the retinacular ligaments. Note also the changing disposition of the tendinous and ligamentous elements in relation to the digital joints, as the digit passes from extension (B) to flexion (C). D is a diagram showing changes in the 'diamond' complex with contraction of the lumbrical musculature. *See* text for discussion. (Modified from diagrams by Mr. Graham Stack, 1962, and 1963.)

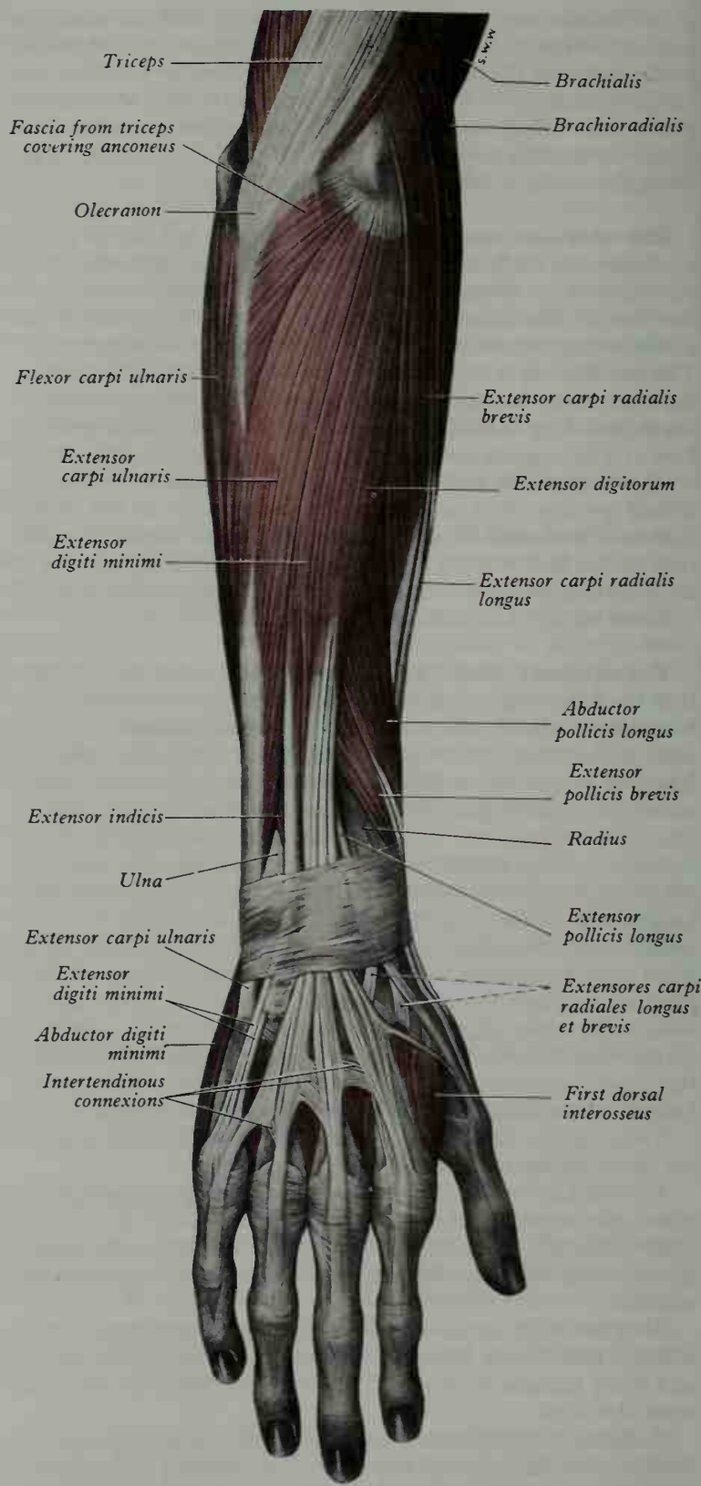
medial is strong and draws the tendon of the fifth digit towards that of the fourth. The intertendinous connexion between the tendons to the third and second digits is weak and may be absent (Leslie 1954). The effect or function of these bands is not clear; they *may* affect independent extension of the digits, and it is a tenet of apocryphal anatomy that they have been divided to benefit pianists.

The digital attachments are complicated by a fibrous expansion dorsal to the proximal phalanx in which the lumbrical, interosseous and digital extensor tendons all participate.

The dorsal digital expansion is a small aponeurosis which

covers the dorsum of the proximal phalanx and the sides of its base. It is triangular and its base, which is proximal, enwraps the dorsal and collateral aspects of the metacarpophalangeal joint. The extensor digitorum tendon blends with the expansion along its median region, and is separated from the metacarpophalangeal joint by a small bursa (**5**.70A). The base of the expansion connects the extensor digitorum tendon on each side with the adjoining interosseous muscles and contains numerous transverse fibres. A short band links each basal angle to the deep transverse metacarpal ligament; it separates the *phalangeal* attachment of the dorsal interosseous from the rest of the muscle and from the palmar interosseous and lumbrical.

The margins of the expansions are thickened laterally by the tendons of lumbrical and interosseous muscles and medially by the tendon of an interosseous alone, or, in the case of the fifth digit, the abductor digiti minimi. These points of attachment of the intrinsic digital muscles are often termed '*wing tendons*' in clinical practice. Distinct proximal and distal 'wings' can be identified in the fingers (**5.** 71) usually on both sides of each dorsal extensor expansion. The attachments of the interossei to these has led to the classification of these muscles as 'distal' and 'proximal' rather than the more usual palmar and dorsal (p. 589). Between the margins and the extensor digitorum tendon the expansion is a thin and translucent sheet (**5**.70A). As it approaches the proximal interphalangeal joint the extensor digitorum tendon divides into an intermediate part and two collateral slips. The former, which receives some fibres from the lumbrical and interosseous tendons (Landsmeer 1949), passes over the dorsal aspect of the joint to be attached to the base of the middle phalanx. Each collateral slip is joined by the corresponding thickened border of the dorsal digital expansion, and the two then converge and unite to be attached to the dorsal aspect of the base of the distal phalanx. The distal 'wing tendon' is just proximal to this attachment.



The expansion forms a movable hood (Bunnell 1949), which passes distally when the metacarpophalangeal joint is flexed, and proximally when it is extended, in which position it is most closely applied around the metacarpophalangeal joint. Landsmeer (1949) and Haines (1951) have described *retinacular ligaments* (*'link' ligaments*) which correlate movements at the interphalangeal joints (**5**.71A–C). From a proximal attachment to the side of the proximal phalanx where the fibrous sheath reaches bone, and from the sheath itself, they extend distally to blend with the margin of the dorsal extensor expansion, which is formed by the lateral band of the extensor tendon **5.** 71C). They thus reach the base of the terminal phalanx. There are, of course, two retinacular ligaments in each digit. (See also p. 591.)

The extensor digitorum tendons may be to a variable degree deficient, but more often they are doubled or even tripled in the case of one or more digits, more often the index or middle fingers. A slip of tendon to the thumb occasionally exists.

Nerve supply. The posterior interosseous nerve, C. **7** and 8.

Actions. The extensor digitorum extends the fingers at the metacarpophalangeal and interphalangeal joints in opening the hand to relax the grip or in preparation for grasping. It is also an equal prime move with the carpal extensors in extending the wrist (McFarland *et al.* 1962). It tends to abduct the index, ring and little fingers as it extends them, but it has no corresponding action on the middle finger. The attachment of the lateral bands of the extensor tendons to the deep transverse metacarpal ligaments (as noted above) greatly limits the extensor effect of these tendons at the interphalangeal joints, an action which can only be completed by virtue of the attachments of intrinsic muscles, especially the lumbricals, to the lateral extensor bands *distal* to the metacarpophalangeal joints.

The movement of *flexion* of the metacarpophalangeal joint combined with *extension* of the interphalangeal joints, and its converse, enter into most of the fine movements of the digits, especially in the activities of the index finger and thumb. They can be illustrated well by attempts to thread a needle; but the fine adjustments effected, in approach (flexion at the metacarpophalangeal and extension at interphalangeal joints) and withdrawal (extension at metacarpophalangeal and flexion at interphalangeal joints) of the thread, are, of course, used in many other and commoner activities. The metacarpophalangeal flexion, for which

5.72 Muscles of the extensor aspect of the right forearm, superficial layer.

lumbricals and interossei are responsible, allows sufficient relaxation of the digital flexors to enable the extensor digitorum to extend the interphalangeal joints (Braithwaite *et al.* 1948). It should be noted, however, that the interossei, working over the distal border of the deep transverse metacarpal ligaments, are not disadvantageously placed to produce extension of the interphalangeal joints through the medium of the dorsal digital expansion, and can in fact be trained to do so in cases of radial nerve palsy (Sunderland 1945).

The extensor digiti minimi (**5**.72) is a slender muscle medial to, and usually connected with, extensor digitorum. It arises from the common extensor tendon by a thin tendinous slip and from intermuscular septa shared with adjacent muscles. Its tendon

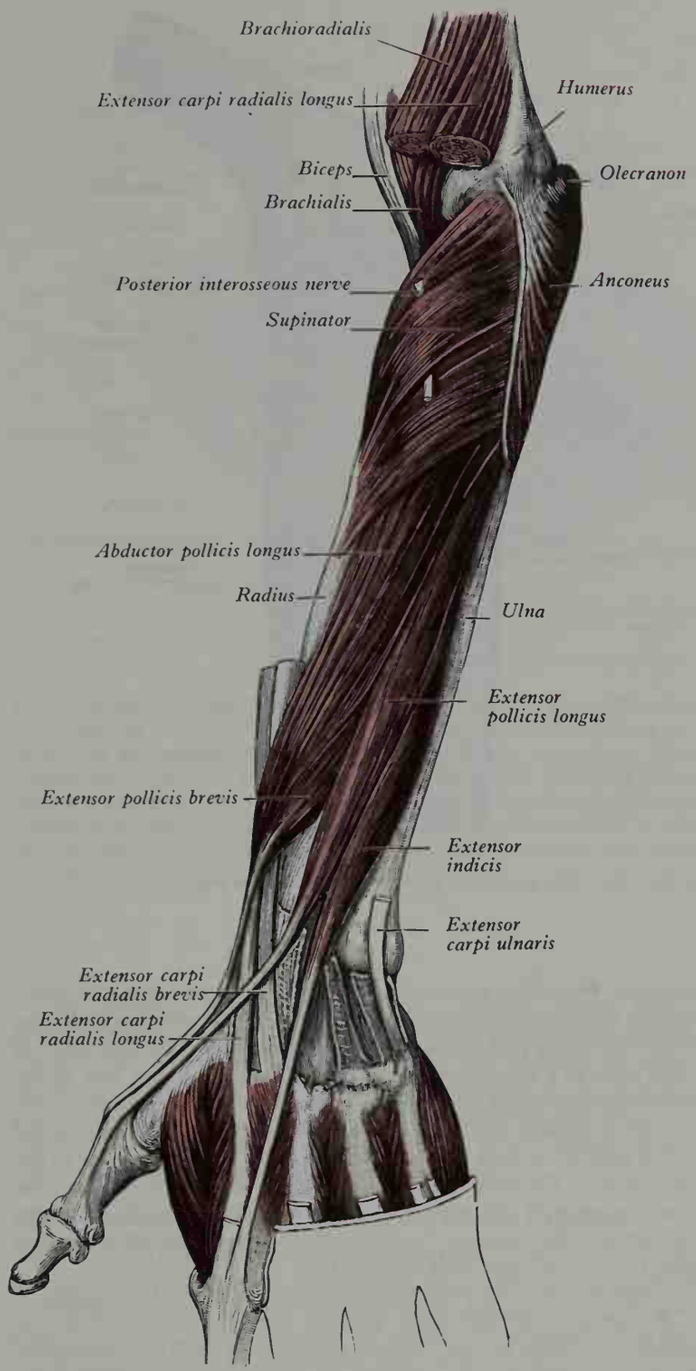
runs through a separate compartment of the extensor retinaculum behind the inferior radio-ulnar joint, then divides into two, the lateral slip being joined by the tendon of extensor digitorum (5.72). All are attached to the dorsal digital expansion of the fifth digit, which conforms with that of the other digits. This muscle usually arises in addition from the antebrachial fascia. Its tendon does not always divide and it may send a slip of tendon to the fourth digit. It is rarely absent, but sometimes fused with the extensor digitorum.

Nerve supply. The posterior interosseous nerve, C. **7** and 8.

Actions. The extensor digiti minimi extends the little finger and the wrist working in conjunction with extensor digitorum.

The extensor carpi ulnaris (5.69, 72) arises from the lateral epicondyle by the common extensor tendon, from the posterior border of the ulna by an aponeurosis shared with flexor carpi ulnaris and flexor digitorum profundus, and from the antebrachial fascia. It can be identified immediately lateral to the groove which overlies the posterior border of the ulna. It ends in a tendon which slides in the groove between the head and the styloid process of the ulna, in a separate compartment of the extensor retinaculum, and is attached to the tubercle on the medial side of the base of the fifth metacarpal bone.

Nerve supply. The posterior interosseous nerve, C. 7 and **8**.



Actions. In association with the extensores carpi radiales, longus et brevis, the extensor carpi ulnaris acts synergically with the flexors of the fingers in order to extend and fix the wrist when objects are being gripped or when the fist is clenched. Simple observation shows that it is impossible to grip strongly unless the wrist is extended. Acting with the extensores carpi radiales, it extends the wrist; acting with the flexor carpi ulnaris, it adducts the hand.

The anconeus (5.72, 73) is a small, triangular muscle at the back of the elbow joint, and is partially blended with triceps, of which it is an integral part in many other primates. It arises by a separate tendon from the posterior surface of the lateral epicondyle of the humerus; its fibres diverge medially towards the ulna, covering the posterior aspect of the annular ligament. They are attached to the lateral side of the olecranon and upper fourth of the posterior surface of the shaft of the ulna.

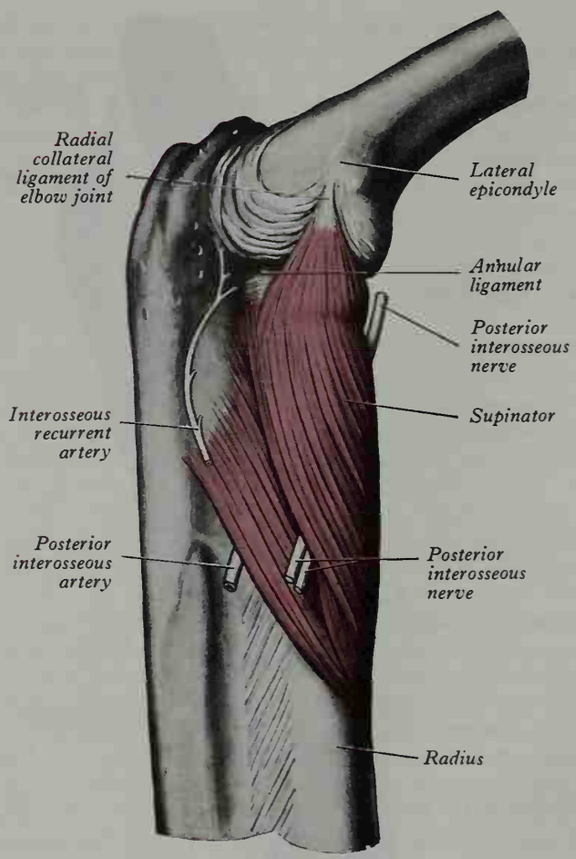
The muscle varies in its degree of fusion with triceps or extensor carpi ulnaris.

Nerve supply. The radial nerve, C. 7, 8 and (T. 1).

Action. Anconeus assists triceps in extending the elbow joint and is often held to be responsible for the movement of the ulna in pronation (p. 465). Electromyographic studies, however, contradict this opinion (Basmajian and Griffith 1972). The abduction of the ulna in pronation, which is necessary if the forearm is to turn over the hand without translating it medially, can be voluntarily inhibited. A tool in the hand can hence be revolved 'on the spot', or it can be swept through an arc.

5.73 The deep extensor muscles of the left forearm.

DEEP EXTENSOR GROUP



The deep forearm extensor muscles (5.73, 75) consist of three acting on the thumb (abductor pollicis longus and extensores pollicis longus et brevis), the extensor indicis, and also the supinator. Apart from the latter, all are attached proximally to the forearm bones alone.

The supinator (5.67, 73, 74) surrounds the upper third of the radius, and consists of superficial and deep parts, between which the posterior interosseous nerve passes (5.73). The two arise in common—the superficial by tendinous and the deep by muscular fibres—from the lateral epicondyle of the humerus, from the radial collateral ligament of the elbow joint and the annular ligament of the superior radio-ulnar joint, from the supinator crest of the ulna and from the posterior part of the triangular depression in front of it, and from an aponeurosis covering the muscle. The muscle is attached distally to the lateral surface of the proximal third of the radius, reaching as far as the distal attachment of pronator teres. The radial attachment extends on to its anterior and posterior aspects, for the anterior and posterior borders of the bone incline medially at their proximal ends (p. 364, 3.142).

Nerve supply. The posterior interosseous nerve, C. 5 and **6**.

Action. The supinator rotates the radius so as to turn the palm of the hand forwards, and acts alone in slow, unopposed supination, and even in fast supination if the forearm is extended. The muscle is joined by biceps brachii in forceful supination particularly when the forearm is flexed. It is worthy of note that objects, which may be heavy, are picked up frequently with the forearm pronated. The more powerful supinators lift it against gravity, and the rotation is often combined with increasing elbow flexion to bring the hand's burden up towards the face.

The abductor pollicis longus (5.69, 72, 73) is distal to supinator and closely related to extensor pollicis brevis. It arises from the lateral part of the posterior surface of the shaft of the ulna below the anconeus, from the interosseous membrane, and from the middle third of the posterior surface of the radius immediately distal to the attachment of supinator. It passes downwards and

5.74 The right supinator muscle. Posterolateral aspect.

laterally, becoming superficial in the distal quarter of the forearm, visible there as an oblique elevation (5.72). It ends in a tendon which becomes free of muscle fibres just proximal to the wrist. It then runs in a groove on the lateral side of the lower end of the radius accompanied by the tendon of extensor pollicis brevis. The tendon is usually split into two components, one attached to the radial side of the base of the first metacarpal bone, the other to the trapezium. Further fasciculi of the tendon may become continuous with the opponens pollicis or the fleshy belly of the abductor pollicis brevis. Occasionally the whole muscle is divided into two, or cleavage may be partial.

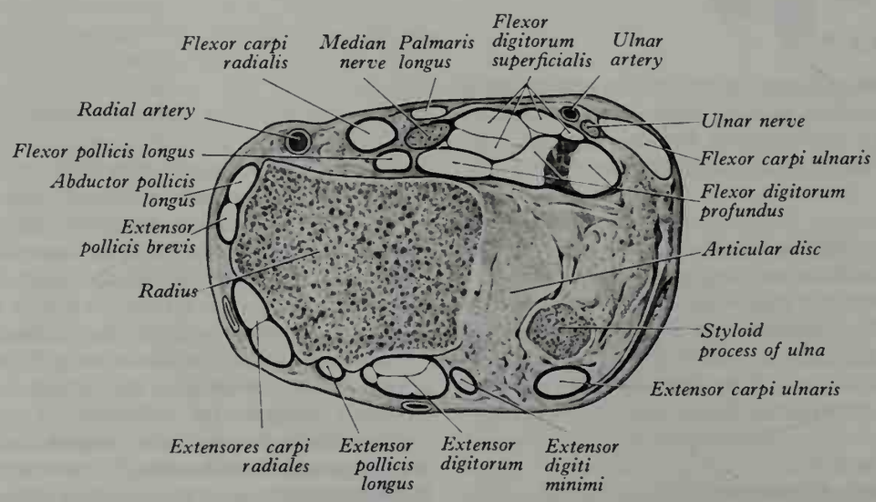
Nerve supply. The posterior interosseous nerve, C. 7 and **8**.

Actions. The abductor pollicis longus, acting with the abductor pollicis brevis, abducts the thumb; with the extensores pollicis, it extends the thumb at the carpometacarpal joint (p. 471).

The extensor pollicis brevis (5.72, 73) is medial to, and closely connected with, the abductor pollicis longus. It arises from the posterior surface of the radius below the abductor, and from the interosseous membrane. Its direction is similar to that of the abductor pollicis longus, its tendon passing through the same groove on the lateral side of the lower end of the radius, to be attached to the dorsal surface of the base of the proximal phalanx of the thumb. There is often an additional attachment to the base of the distal phalanx usually through a fasciculus which joins the tendon of extensor pollicis longus (Muller 1959). The muscle may be absent or completely fused with the abductor longus. Its tendon sometimes fuses completely with that of the long extensor.

In the lower third of the forearm the abductor pollicis longus and extensor pollicis brevis become superficial by emerging between the extensor carpi radialis brevis and extensor digitorum. Thence obliquely crossing the tendons of the radial extensors they cover the termination of brachioradialis, and, passing through the most lateral compartment of the extensor retinaculum in a single synovial sheath, cross superficial to the styloid process of the radius and the radial artery.

Nerve supply. The posterior interosseous nerve, C. 7 and **8**.



Actions. The extensor pollicis brevis extends the proximal phalanx of the thumb and, in continued action, helps to extend the metacarpal bone.

The extensor pollicis longus (5.72, 73) is larger than the extensor pollicis brevis, the proximal attachment of which it partly covers. It arises from the lateral part of the middle third of the posterior surface of the shaft of the ulna below abductor pollicis longus, and from the interosseous membrane. It ends in a tendon which passes through a separate compartment of the extensor retinaculum, in a narrow, oblique groove on the back of the distal end of the radius. It then crosses obliquely the tendons of the extensores carpi radiales longus et brevis (5.73), and is separated from the extensor pollicis brevis, when the thumb is fully extended, by a triangular depression, jocularly termed the 'anatomical snuff-box', in which the radial artery can be felt. Finally, the tendon reaches its attachment to the base of the distal phalanx of the thumb. On the dorsum of the proximal phalanx the lateral and medial sides of the tendon are joined by expansions from the tendons of the abductor pollicis brevis, and of the first palmar interosseous and adductor pollicis respectively.

Nerve supply. The posterior interosseous nerve, C. 7 and **8**.

Actions. The muscle extends the distal phalanx of the thumb and, acting in association with the extensor pollicis brevis and abductor pollicis longus, it extends the proximal phalanx and the metacarpal. In continued action, owing to the obliquity of the course of its tendon, the extensor pollicis longus adducts the extended thumb and rotates it laterally (p. 471).

Applied Anatomy. Avascular necrosis is probably a causative factor in rupture of the tendon of the extensor pollicis longus which may follow Colles' fracture or occur spontaneously. Above

5.75 Transverse section, passing through the distal end of the right radius and the styloid process of the right ulna, made with the hand and forearm in full supination. Distal (inferior) aspect.

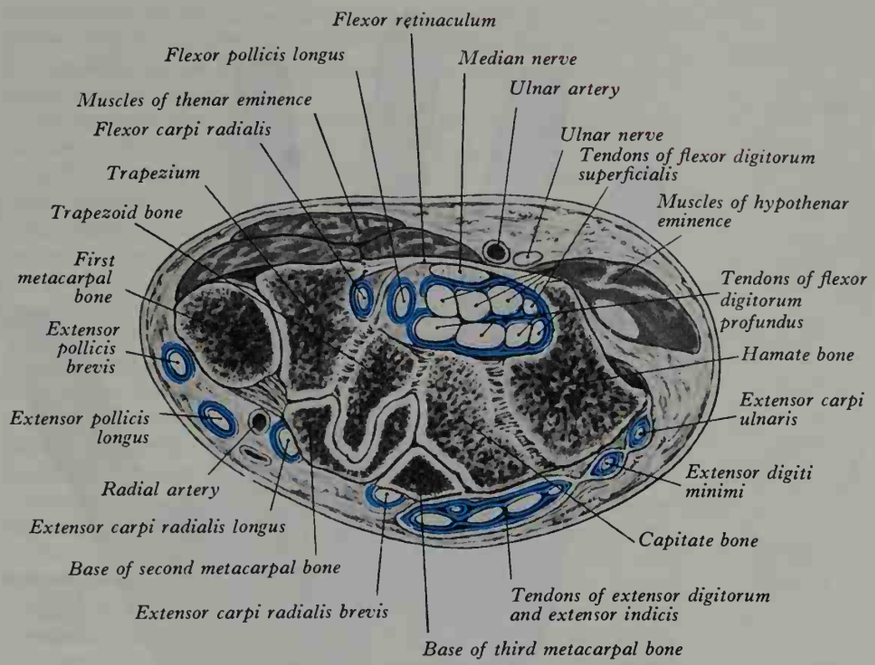
the wrist the blood supply is derived mainly from the anterior interosseous artery and below this joint from the radial artery and blood vessels of the thumb (Davies 1951).

The extensor indicis (5.73) is a narrow, elongated muscle, medial to, and parallel with, the preceding. It arises from the posterior surface of the ulna below the extensor pollicis longus, and from the interosseous membrane. Its tendon passes under the extensor retinaculum in the compartment containing the tendons of extensor digitorum; opposite the head of the second metacarpal bone it joins the ulnar side of the tendon of the extensor digitorum for the index finger. The muscle occasionally sends accessory slips to the extensor tendons of other digits. Rarely its tendon may be interrupted on the dorsum of the hand by an additional muscle belly (*'extensor indicis brevis manus'*).

Nerve supply. The posterior interosseous nerve, C. 7 and **8**. The distribution of muscle spindles in this muscle has been studied by Gorp and Kennedy (1974). The greatest density is concentrated near the point of entry of its nerve supply.

Actions. The muscle helps to extend the index finger and can assist in extending the wrist.

The Hand



Human hands, acting with the eyes in a complex synergy mediated by central nervous connexions of apparently unlimited variability, have been a paramount factor in the evolution of human skills; and, despite the production of an astonishing multitude of tools and techniques to extend these skills, one may presume that the hands will continue in this role, in further refinement, development and invention. Being put to such multiple and frequent uses they are subject to much injury; and for both reasons a large literature, impossible to quote even in skeleton here, has accumulated on the structure, activities, injuries and reparative surgery of the hand. For guidance to this literature the works of Wood Jones (1941), Napier (1965), Kaplan (1966), Stack (1973) and Landsmeer (1976) are particularly valuable, especially since each has contributed notably to knowledge in this field.

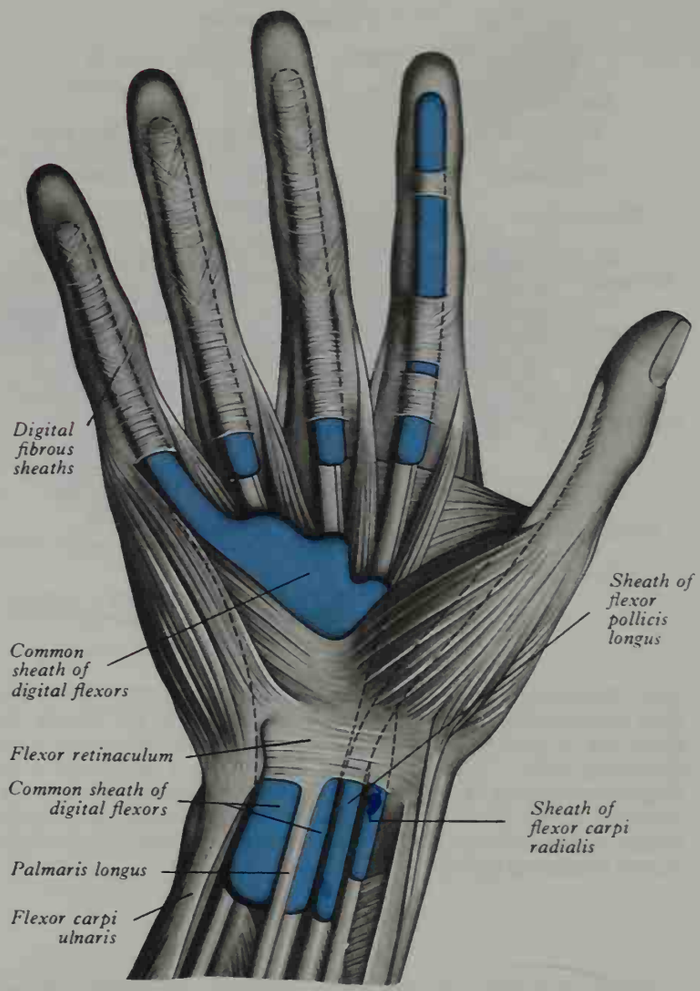
The Retinacula, Fasciae, and Synovial Sheaths of the Wrist and Hand

Before proceeding to the muscles of the hand, it is appropriate to consider first the disposition of the retaining bands and deep fascia, and the synovial tendon sheaths of the region.

The flexor retinaculum (5.76, 77), a strong, fibrous band, crosses the front of the carpus and converts its anterior concavity into the *carpal tunnel*, through which pass the flexor tendons of the digits and the median nerve (p. 1102). The retinaculum is transversely short, measuring a mere 2·5 to 3 cm, with a similar breadth. It is attached, medially, to the pisiform and the hook of the hamate; laterally, it splits into two laminae, a superficial attached to the tubercles of the scaphoid and trapezium, and a deep, to the medial lip of the groove on the latter bone (5.76). With the groove on the trapezium the two laminae form a tunnel, lined by a synovial sheath containing the tendon of flexor carpi radialis. The retinaculum is continuous, proximally, with the fascia covering flexor digitorum superficialis and the antebrachial fascia. It is these two layers which separate on reaching the trapezium. The retinaculum is crossed superficially by the ulnar vessels and nerve, and the palmar cutaneous branches of the median and ulnar nerves. To its anterior surface the tendons of palmaris longus and flexor carpi ulnaris are partly attached; distally some of the short muscles of the thumb and little finger are attached to it, and it is continuous with the deep fascia of the palm, including its central longitudinal or aponeurotic fibres, which are associated with palmaris longus.

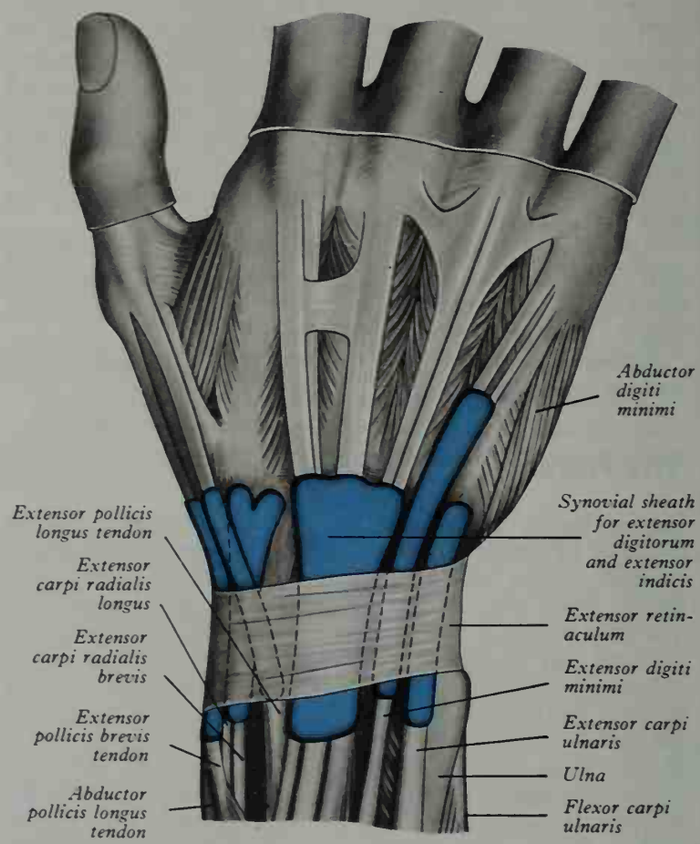
A localized thickening in the general investing layer of the antebrachial fascia which extends laterally from the pisiform is termed the *superficial part of the flexor retinaculum*. It crosses superficial to the ulnar vessels and nerves and blends with the rest of the retinaculum lateral to them.

5.76 Transverse section through the left wrist, showing the tendons and their synovial sheaths. The section is slightly oblique and divides the distal row of the carpus, and the bases of the first, second and third metacarpal bones. The arrangement of the tendons of the flexors of the fingers shown in the figure is not diagrammatic but represents the actual condition at this level. Observe that the carpometacarpal joint of the thumb is separate from the joint between the trapezium and the base of the second metacarpal bone.



The extensor retinaculum (5.78), a strong, fibrous band, extends obliquely across the back of the wrist, consisting of part of the antebrachial fascia, strengthened by the addition of some obliquely transverse fibres. It is attached laterally to the anterior border of the radius, medially to the triquetral and pisiform bones, and, in its passage across the wrist, to the ridges on the posterior aspect of the distal end of the radius.

The Synovial Sheaths of the Carpal Flexor Tendons



Two synovial sheaths envelop the flexor tendons as they traverse the carpal tunnel, one for the flexores digitorum superficialis et profundus, the other for flexor pollicis longus (5.76). These sheaths extend into the forearm for about 2·5 cm proximal to the flexor retinaculum, and occasionally communicate with each other deep to it. The sheath of the flexores digitorum tendons reaches about halfway along the metacarpal bones, where it ends in blind diverticula around the tendons to the index, middle and ring fingers (5.77). It is prolonged around the tendons to the little finger and is usually continuous with their digital synovial sheath. A transverse section through the carpus (5.76) shows that the tendons are invaginated into the sheath from the lateral side. The parietal layer lines the flexor retinaculum and the floor of the carpal tunnel and is reflected, laterally, on to the tendons of flexor digitorum superficialis from in front, and on to those of flexor digitorum profundus from behind. Medially a recess formed by the inner layer of the sheath is insinuated between the two groups of tendons and passes laterally for a variable distance. The sheath of the flexor pollicis longus, which is usually separate but occasionally communicates with the common flexor sheath behind the flexor retinaculum, is continued along the thumb as far as the insertion of the tendon. The fibrous sheaths enveloping the terminal parts of the tendons of the flexores digitorum have already been described (p. 576).

The Synovial Sheaths of the Carpal Extensor Tendons

Deep to the extensor retinaculum there are six tunnels for the passage of the extensor tendons, each containing a synovial sheath (5.78). They are as follows: 1, on the lateral side of the styloid

5.77 The synovial sheaths of the tendons on the front of the right wrist and hand. (Preparation by Professor J. C. B. Grant.) Where they are exposed, the synovial sheaths are shown in blue, but where they are hidden by overlying structures, their margins are indicated by interrupted black lines.

5.78 The synovial sheaths of the tendons on the back of the right wrist. (Preparation by Professor J. C. B. Grant.) The synovial sheaths are shown in blue, but they have not been coloured where they lie deep to the extensor retinaculum. In this situation, and where one sheath lies deep to another, the margins of the sheaths are indicated by the broken lines.

process of the radius, for the tendons of abductor pollicis longus and extensor pollicis brevis; 2, behind the styloid process, for the tendons of the extensores carpi radiales longus et brevis; 3, on the medial side of the dorsal tubercle of the radius, for the tendon of the extensor pollicis longus; 4, on the medial side of the latter, for the tendons of the extensor digitorum and extensor indicis; 5, opposite the interval between the radius and ulna, for extensor digiti minimi; 6, between the head and the styloid process of the ulna, for the tendon of extensor carpi ulnaris. The sheaths of the tendons of the abductor pollicis longus, extensores pollicis brevis et longus, extensores carpi radiales, and extensor carpi ulnaris stop immediately proximal to the bases of the metacarpal bones, while those of the extensor digitorum, extensor indicis and extensor digiti minimi are sometimes prolonged to the junction of the proximal with the intermediate third of the metacarpus.

Fascial Arrangements in the Hand

No region of the body has provided so fertile an arena for dissection of connective tissue as the hand, with the consequent identification and naming of numerous sheets, septa, bands and ligaments. From a great number of studies, spread over more than two centuries, the larger features have received general accord, and these include the fibrous flexor sheaths, dorsal digital expansions ('wing tendons') of the digital extensor tendons, the transverse metacarpal ligaments, and the palmar fascia or aponeurosis. As Wood Jones (1941) emphasized, every structure—muscle, tendon, nerve and vessel—is surrounded by connective tissue separating it from adjacent structures to a degree dependent upon the local need of individual mobility. Recognized thickenings of such 'sheaths' also serve to restrain or bind together some structures; and in the hand (as in the foot) the subcutaneous tissue is traversed by numerous localized dense bands or 'skin ligaments', which tie the skin to the deeper fasciae and hence to bone, for obvious functional reasons. These are little developed on the dorsum of the hand but marked in the palm and flexor aspects of the phalanges, especially in the pulps of the terminal digital segments. The deeper connective tissue is densely compacted and in places even aponeurotic, and it blends with periosteum whenever nothing else intervenes, extending as strong septa between certain groups of muscles.

Successive studies have added many details to this description. Since in such finer points authorities differ, individual variation doubtless occurs, and functional comprehension is not always advanced by them, such complexities must be here reduced to simpler concepts. At the simplest it is clear that the deep (muscular) fasciae of the hand are extensively connected on one side to skin and on the other to bone, including not only the carpals, metacarpals, and phalanges, but also proximally the radius and ulna. At well-recognized places, and especially where cutaneous flexion furrows are apparent, skin fixation is most marked. Between these regions of maximum stability large numbers of smaller fixation bands exist, but these are interspersed by cushioning pads of adipose tissue. These, though largely restrained by the connective tissue bands, permit a small range of tangential movement; and, since some displacement is possible the skin and subcutaneous tissue are also easily indented, with an

immediate resilient recovery when the distorting external force is removed. It is obvious that these arrangements have a protective value; the fat pads which exist in the interdigital webs are said to separate and 'protect' the digital vessels and nerves from adjacent tendons, and the thenar and hypothenar pads are clearly useful cushions when these parts of the hand are used to apply force to various tools. Less obvious, but equally necessary is the pliant conformation of the grasping surfaces of the hand to the contours of the object grasped, however irregular and potentially damaging. The hand can thus evaluate the shape, weight and consistency of an infinite number of external objects (*see* p. 583), putting them to a limitless variety of uses, often involving large forces, the skilful and safe transmission of which is as much due to the skin and fasciae of the hand as to muscles and tendons. Like the latter, the skin and fasciae respond to use by hypertrophy, as may the bones while still capable of growth. The skin commonly shows not only a general responsive thickening but also various localized callosities (over the metacarpal heads, for example), sometimes characteristic of particular occupations. The palmar fascia, including its central aponeurosis sometimes responds to an excessive degree, with resultant disabling contractures. For further details regarding the fasciae of the hand, including their diseases and injuries consult Kaplan (1966), Stack (1973), Bojsen-Møller and Schmidt (1974), and Landsmeer (1976).

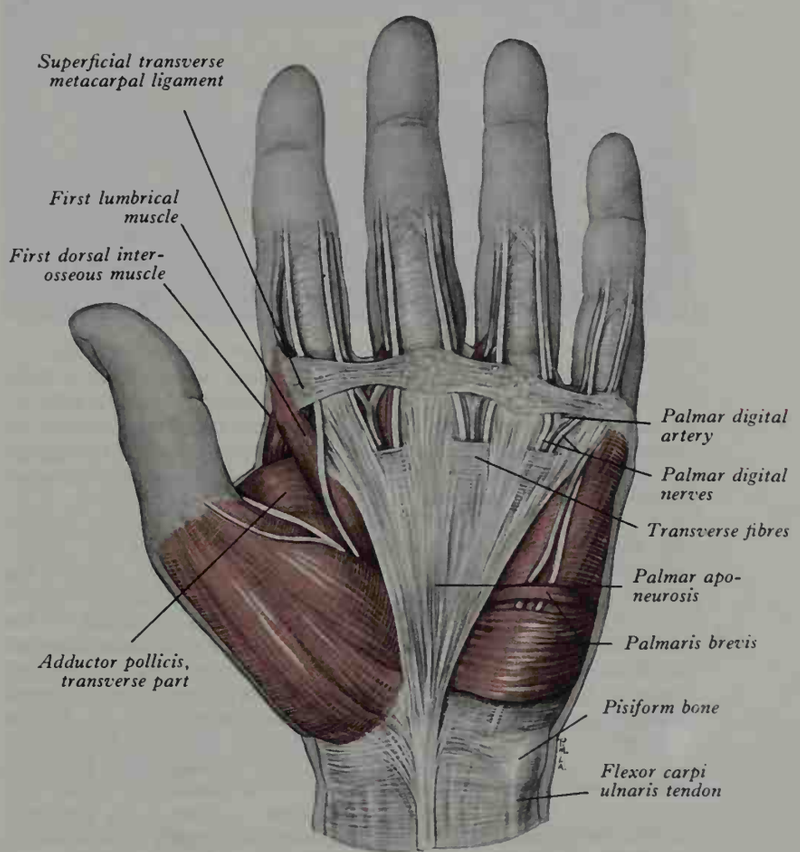
In addition to the functions noted above, the fasciae of the hand also help to maintain the concavity of the palm, to restrain the flexor tendons, and perhaps to aid in venous return.

The palmar aponeurosis (5.79) is in direct relation with the muscles of the palm, and accordingly consists of central, lateral and medial parts.

The *central part* is triangular, and of marked strength and thickness. Its apex is continuous with the distal margin of the flexor retinaculum, and the expanded tendon of palmaris longus is attached to it. Its base divides into four slips, extending to each finger. Superficial fibres of them reach the skin of the palm and fingers; those to the palm join the dermis at the furrow corresponding to the metacarpophalangeal joints, those to the fingers pass into it at the transverse folds at the roots of the fingers. The deeper part of each slip divides into two processes which are continuous with the fibrous sheaths of the flexor tendons; from the sides of these processes offsets are attached to the deep transverse metacarpal ligaments, the capsule of the metacarpophalangeal joint and the sides of the base of the proximal phalanx. By this arrangement short channels are formed anterior to the heads of the metacarpal bones, through which the flexor tendons pass. The intervals between the four slips are traversed by the digital vessels and nerves, and the tendons of the lumbricals. At the divisions into slips, numerous strong, transverse fibres bind them together. The central part of the palmar aponeurosis is strongly bound to the skin by dense fibroareolar tissue, and to the proximal part of its medial margin the palmaris brevis is attached. It covers the superficial palmar arch, the tendons of the flexores digitorum, the terminal part of the median nerve, and the superficial branch of the ulnar nerve.

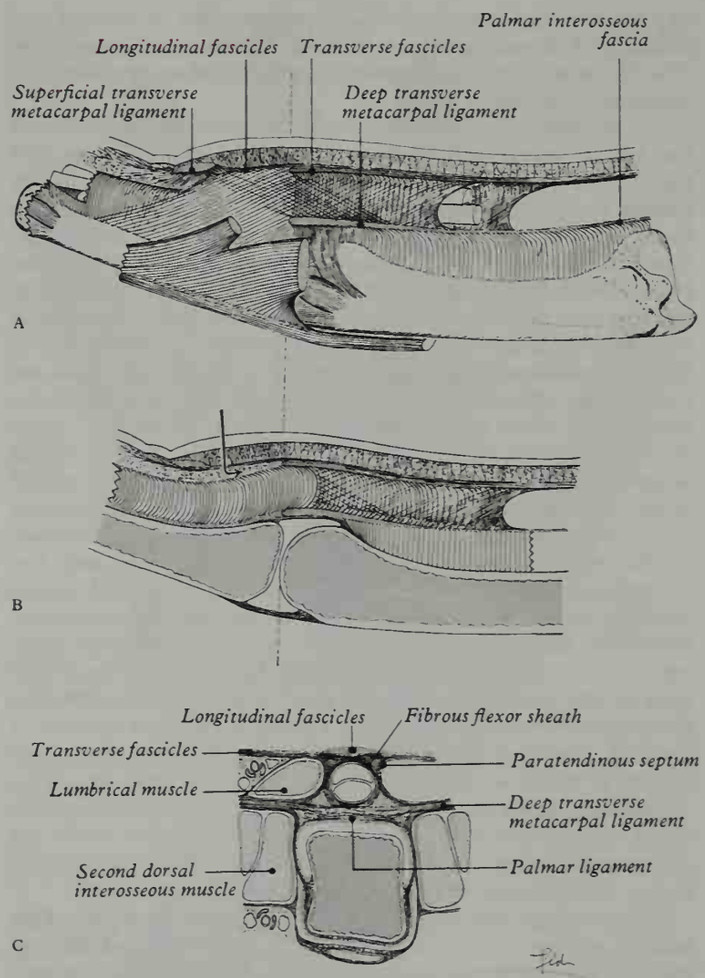
The *lateral* and *medial parts* of the palmar aponeurosis are thin, fibrous coverings of the thenar and hypothenar muscles; they are continuous with its central region and with the fascia on the dorsum of the hand.

A septum passes dorsally from each border of the central portion of the palmar aponeurosis. The *medial palmar septum* lies close to the lateral side of the opponens digiti minimi and reaches the palmar surface of the fifth metacarpal bone. Distally, it is continuous with the slip of the palmar aponeurosis to the lateral side of the fibrous sheath of the little finger; proximally it reaches the hook of the hamate bone and the pisohamate ligament and is pierced by the deep branches of the ulnar nerve and artery. The *lateral palmar septum* passes dorsally to reach the palmar surface of the first metacarpal bone. It skirts the medial side of the flexor brevis and opponens pollicis, between them and the flexor pollicis longus tendon and its synovial sheath. Proximally it reaches the tubercle of the trapezium and is pierced by the branch from the median nerve to the muscles of the thenar eminence.

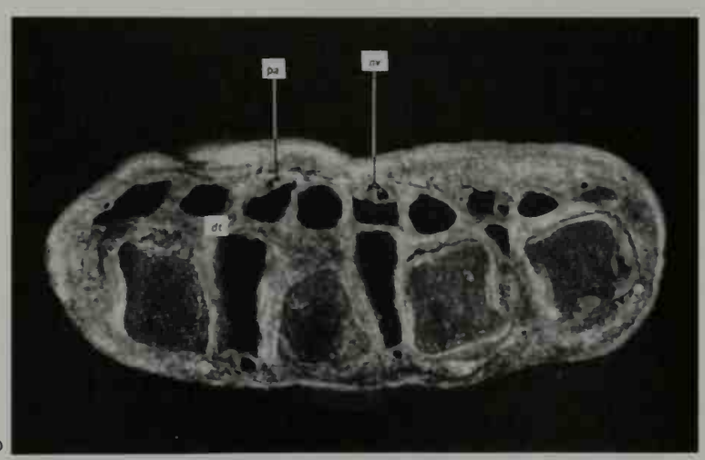


The fascial spaces of the palm. The central part of the palm, which lies behind the central region of the palmar aponeurosis and between the lateral and medial palmar septa, is divided into medial and lateral parts by a thin intermediate palmar septum. The medial area has been termed the *middle palmar space* and the lateral area the *thenar space*.

The intermediate palmar septum is between the flexor tendons of the index finger laterally and the second lumbrical muscle medially. Distally, it is continuous with the slip given by the palmar aponeurosis to the medial side of the fibrous sheath of the index finger and the adjoining deep transverse metacarpal ligament. Dorsally, it blends with the fasciae covering the distal part of the second palmar interosseous and the transverse head of the adductor pollicis, and it can be traced medially on the latter muscle to the third metacarpal bone. Anteriorly, it is attached to the deep surface of the palmar aponeurosis, but at its proximal end it meets the common flexor synovial sheath and blends with the connective tissue on its posterior surface. However, as an anatomical entity, the intermediate palmar septum is poorly developed. Nevertheless, when pus accumulates on either side of it, the adjoining areolar tissue is compressed against it forming an effective septum, capable of determining the direction of spread.



The *middle palmar space* lies between the medial and intermediate septa. Its dorsal wall is formed by the third, fourth and fifth metacarpal bones, by the fascia covering the interosseous muscles in the third and fourth spaces and the medial part of the transverse head of the adductor pollicis. Anteriorly are the central zone of the palmar aponeurosis and, proximally, the common flexor synovial sheath. The space contains the flexor tendons of the fifth, fourth and third fingers, the fourth, third and second lumbrical muscles, the superficial palmar arch and the digital vessels and nerves for the fifth, fourth, third and ulnar side of the index finger. Distally, the space communicates with the subcutaneous tissues at the webs between the fingers; proximally, it may extend dorsal to the common flexor synovial sheath.



Bojsen-Møller and Schmidt (1974) regard the distal part of the middle palmar 'space' as divided into numerous independent channels not only for the lumbrical muscles but also for the common digital vessels and nerves (*see* 5.80D).

The *thenar space* is flanked by the lateral and the intermediate

5.79 The left palmar aponeurosis.

5.80A–D (A) Drawing of the course of the fibres of the fasciae around the left third metacarpal bone and proximal phalanx viewed from the radial side. The deep transverse metacarpal ligament connects both with the metacarpal bone and with the longitudinal and transverse fibres of the palmar aponeurosis and, via their retinacula, with the skin. The palmar interosseous fascia is connected by means of a sagittal septum to the shaft of the third metacarpal bone. (B) sagittal section through the centre of the third metacarpal bone. The fibrous sheath of the flexor tendons extends for some distance between the tranverse fascicles of the palmar aponeurosis and the deep transverse metacarpal ligament. Between the longitudinal fibres in the palmar aponeurosis, and the fibrous sheath, a connective tissue space affords cleavage for demonstration of the paratendinous septa by dissection (arrow). (C) Transverse section through the head of the third metacarpal bone showing the course of the fibres between the palmar aponeurosis and the deep transverse metacarpal ligament, and their attachments to the metacarpal bone. (D) Section through the hand at the level of the heads of the metacarpal bones (2–5). The subdivision of the distal part of the central compartment into eight narrow compartments is demonstrated. The interdigital nerves and vessels (*nv*) have been left to show their relation to the lumbrical compartments. The deep transverse metacarpal ligament (*dt*) and palmar aponeurosis (*pa*) are also shown. (From F. Bojsen-Møller and L. Schmidt 1974, by courtesy of the authors and the Cambridge University Press.)

palmar septa. Dorsally, are the fasciae covering the transverse head of the adductor pollicis and, beyond its lower border, the first dorsal interosseous muscle. Anteriorly, is the palmar aponeurosis. It contains the flexor pollicis longus tendon and its synovial sheath, the flexor tendons of the index finger and the first lumbrical muscle, and the palmar digital vessels and nerves of the thumb and radial side of the index finger. Distally the space communicates with the subcutaneous tissues of the web of the thumb; proximally it extends behind the flexor retinaculum.

All the 'spaces' described above are, of course, in fact *regions* or *localities*, in which relatively loose connective tissue, whilst allowing some mobility during normal functioning, also offers little opposition to the spread of infection, whereas their boundaries, being of denser structure, may contain an infection, temporarily at least.

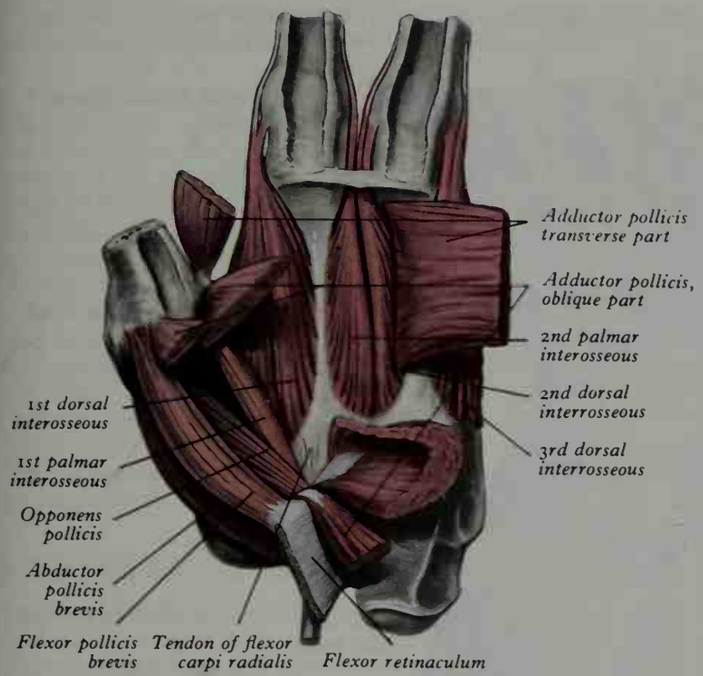
The superficial transverse metacarpal ligament is a thin band (**5**.79) which stretches across the roots of the fingers in the superficial fascia, and is attached to the skin of the clefts, and medially to the fifth metacarpal bone, forming a kind of rudimentary web. The digital vessels and nerves pass posterior to these fasciculi. Since this ligament adjoins the bases of the proximal phalanges, rather than the metacarpal heads, it would be more appropriately named the *palmar digital ligament*, according to Bojsen-Møller and Schmidt (1974).

Applied Anatomy. The palmar aponeurosis is liable to undergo contraction, producing a disabling deformity known as 'Dupuytren's contracture' (*see* Stack 1973).

Owing to their constant exposure to injury and sources of contamination, the fingers are very liable to infection. In the *pulp* over the distal three-fourths of the terminal phalanx, pus is confined under tension by strong fibrous septa which radiate between the skin and periosteum. This may lead to necrosis of the diaphysis of the terminal phalanx from obstruction of its blood supply from the digital arteries which pass through the pulp. The epiphysis of the terminal phalanx may escape because its vessels of supply leave the digital arteries before the latter enter the compartments of the pulp. Inflammation may involve and spread along the sheath of the flexor tendons. Infection of the synovial sheaths of the pollex or minimus may prove more serious than in the other digits, because their sheaths may communicate with the principal sheath of the flexor tendons, and the infective process may extend into the palm and behind the flexor retinaculum into the forearm.

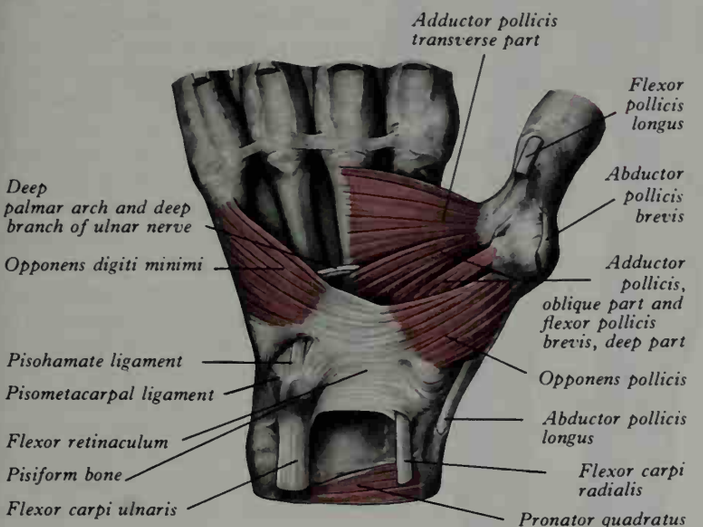
Chronic inflammation of the common flexor sheath is occasionally met with, a condition known as *compound palmar ganglion*; it presents a bilobar outline, with a swelling in front of the wrist and another in the palm of the hand, and a constriction, corresponding to the flexor retinaculum, between the two. The fluid contents can be forced from the one swelling to the other behind the retinaculum.

Although the applied, medical significance of the fasciae and ligaments of palm and digits must receive due emphasis, their basic function is, of course, to transmit tangential forces from the skin to the skeleton of the hand, Contraction of the palmaris longus and extension at the wrist and metacarpophalangeal joints both assist in tensing the palmar aponeurosis.



VI. The Muscles of the Hand

The intrinsic muscles of the hand can be considered conveniently in three groups: 1, three muscles of the thumb, which produce the *thenar eminence*; 2, those of the fifth digit, producing the *hypothenar eminence*; 3, the central palmar and interosseous muscles, together with the adductor pollicis.



1. THENAR MUSCLES, ADDUCTOR POLLICIS

The thumb has intrinsic muscles which flex, abduct, oppose and adduct it. The three former occupy the thenar eminence.

The abductor pollicis brevis is a thin, subcutaneous muscle in the radial part of the thenar eminence; its chief origin is from the flexor retinaculum, but a few fibres spring from the tubercles of the scaphoid bone and trapezium, and some arise from the

5.81A Dissection of the left hand to show the first palmar interosseous muscle and the deep head of the flexor pollicis brevis.

5.81B A dissection of the right palm, showing the opponens pollicis and opponens digiti minimi and the two parts of the adductor pollicis.

tendon of abductor pollicis longus (p. 581). Its medial fibres are attached by a thin, flat tendon to the radial side of the base of the proximal phalanx of the thumb; its lateral fibres join the dorsal digital expansion of the thumb. The muscle may also receive accessory slips from the long and short extensors of the thumb, opponens pollicis or from the styloid process of the radius.

Nerve supply. The lateral terminal branch of the median nerve, C. **8** and T. 1.

Actions. The abductor pollicis brevis draws the thumb forwards in a plane at right angles to the palm of the hand and rotates it medially. The movement occurs both at the metacarpophalangeal joint and at the carpometacarpal joint, so that in full abduction of the thumb the digit is not in line with its metacarpal bone. 'Pure' abduction cannot occur because there is some degree of conjunct medial rotation accompanying the movement at both joints.

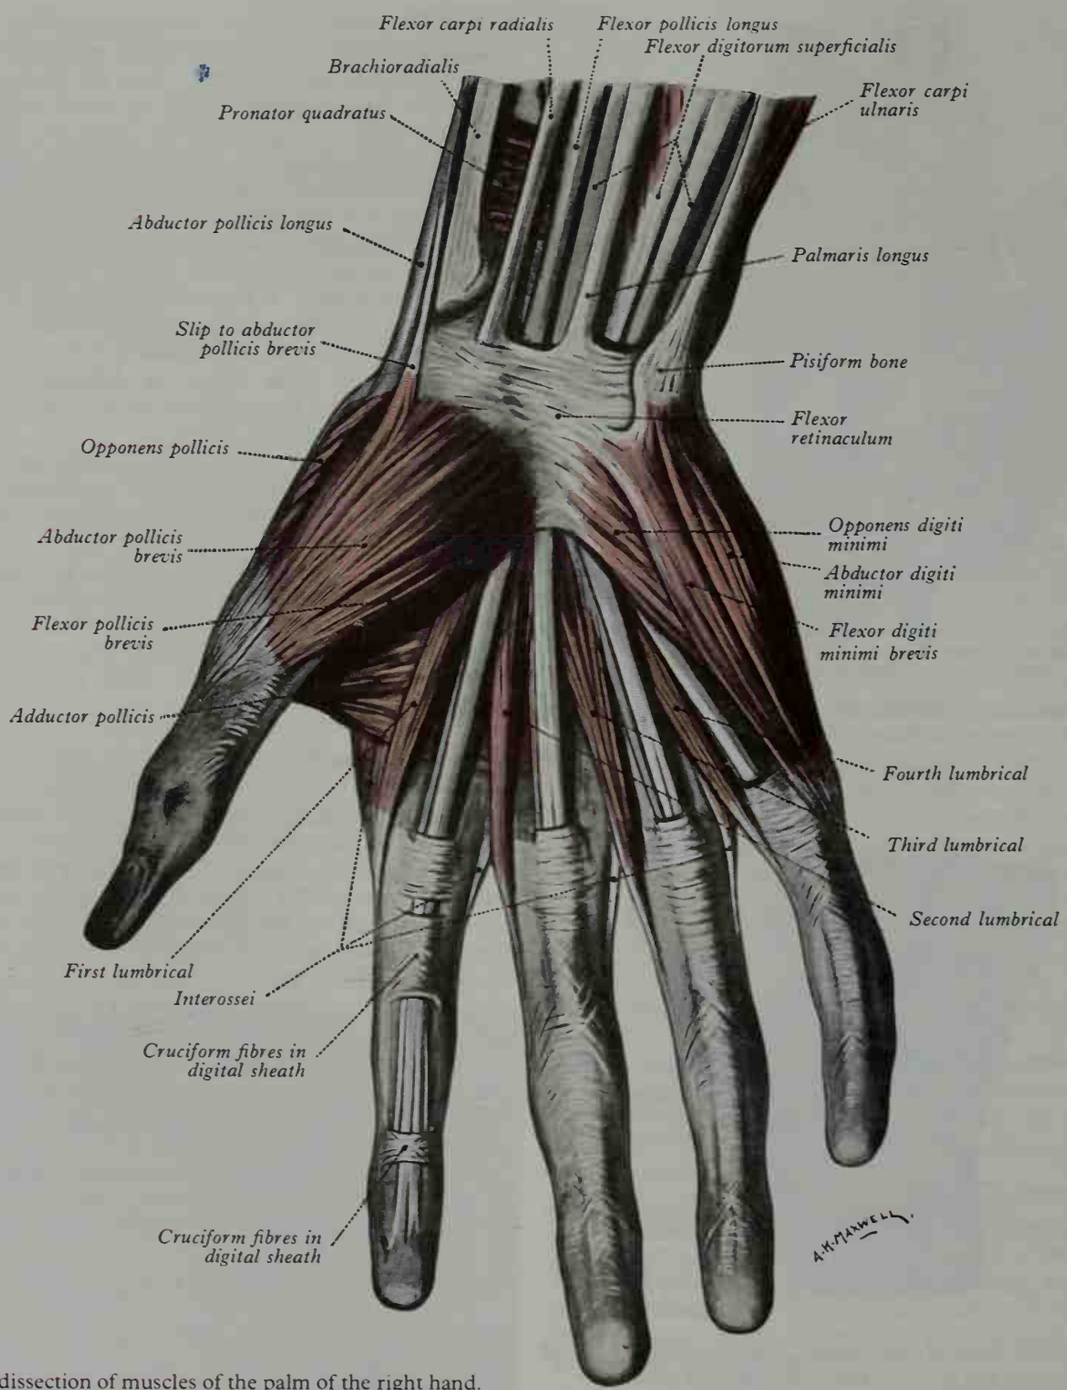
The opponens pollicis (**5**.80, 81) is deep to the abductor pollicis brevis. It arises from the tubercle of the trapezium and the flexor retinaculum, and is attached to the whole length of the lateral border, and the lateral half of the palmar surface, of the metacarpal bone of the thumb.

Nerve supply. The lateral terminal branch of the median nerve, C. **8** and T. 1 and commonly a twig from the deep terminal branch of the ulnar nerve. Dissections by Day and Napier (1961), Forrest (1967), and electromyographic tests by Harness *et al.* (1974), indicate a double innervation in 92 out of 120 hands, and this must, therefore, be regarded as the usual arrangement.

Actions. The opponens pollicis flexes the metacarpal bone of the thumb, i.e. bends it medially across the palm of the hand, and rotates it medially (p. 471). By this combination, which is termed *opposition*, the palmar ('pulpal') surface of the terminal segment of the thumb can be brought into contact with corresponding parts of any of the fingers. It should be noted that the movements of flexion and medial rotation are not sequential but occur simultaneously, and the earlier phases of the displacement are also accompanied by some degree of abduction. The continuous smooth movement of opposition involves both carpometacarpal and metacarpophalangeal joints.

During opposition of the thumb, the fingers are flexed at their metacarpophalangeal joints, and to a variable degree of their interphalangeal joints. Thus the thumb may contact any part of the palmar surface of the finger from base to tip. Flexion of the fingers is also accompanied by some degree of lateral rotation (thus partially 'meeting' the pulp of the opposing thumb *en face*). This lateral rotation is least marked in the index finger and greatest in the minimus. In the latter there are also displacement at the carpometacarpal joint (*vide infra*—opponens digiti minimi).

The flexor pollicis brevis (**5**.82) is medial to abductor pollicis brevis. It arises by superficial and deep parts. The superficial head arises from the distal border of the flexor retinaculum and the lower part of the tubercle of the trapezium; it passes along the radial side of the tendon of the flexor pollicis longus, and is attached, by a tendon containing a sesamoid bone, to the radial side of the base of the proximal phalanx of the thumb. It is frequently more or less blended with the medial border of the opponens pollicis. The deep part arises from the trapezoid and capitate bones and from the palmar ligaments of the distal row of carpal bones. It passes deep to the tendon of the flexor pollicis longus and unites with the superficial head on the sesamoid bone and base of the first phalanx. The deep head varies much in size and may even be absent.



Nerve supply. The superficial head is usually supplied by the lateral terminal branch of the median nerve and the deep head by the deep branch of the ulnar nerve, C. **8** and T. 1. Some variation of this arrangement is not uncommon (Day and Napier 1961).

Actions. The flexor pollicis brevis flexes the proximal phalanx of the thumb and, continuing to act, flexes the metacarpal bone and rotates it medially (p. 593). In the latter movement it cooperates with opponens pollicis.

The adductor pollicis (**5**.81) arises by oblique and transverse heads. The *oblique head* is attached to the capitate bone, the bases of the second and third metacarpal bones, the palmar ligaments of the carpus and the sheath of the tendon of the flexor carpi radialis. Most of its fibres converge into a tendon, which contains a sesamoid bone, unites with the tendon of the transverse head and is attached to the ulnar side of the base of the proximal phalanx of the thumb. Some of its deepest fibres may pass into the medial side of the dorsal digital expansion of the thumb. On the lateral side of the oblique head a considerable fasciculus, which passes deep to the tendon of flexor pollicis longus to join flexor pollicis brevis, has been described as the deep head of flexor pollicis brevis (Day and Napier 1961). The *transverse head* (**5**.81) is the deepest of the pollicial muscles. It is triangular, and arises from the distal two-thirds of the palmar surface of the third metacarpal; the fibres converge to be attached, with the oblique head of the muscle and the first palmar interosseous muscle, to the base of the proximal phalanx of the thumb. The two parts of the adductor vary in relative size and degree of connexion.

Nerve supply. The deep branch of the ulnar nerve, C. 8 and T. 1.

Action. The adductor pollicis approximates the thumb to the palm of the hand and it acts to greatest advantage when the abducted and flexed thumb is opposed to the fingers in gripping.

5.82 Superficial dissection of muscles of the palm of the right hand.

2. THE HYPOTHENAR MUSCLES

Apart from palmaris brevis, a superficial muscle, this group consists of muscles which flex, abduct and oppose the fifth digit (**5**.79, 81, 82).

The palmaris brevis (**5**.79) is a thin, quadrilateral muscle, beneath the skin of the ulnar side of the palm. It arises from the flexor retinaculum and the medial border of the central part of the palmar aponeurosis; it is attached to the dermis on the ulnar border of the hand. It is superficial to the ulnar artery and the superficial terminal branch of the ulnar nerve.

Nerve supply. The superficial branch of the ulnar nerve, C. 8 and T. **1**.

Action. The palmaris brevis wrinkles the skin on the ulnar side of the palm of the hand and deepens the hollow of the palm by accentuating the prominence of the hypothenar eminence. In this way it may contribute to the security of the palmar grip.

The abductor digiti minimi (**5**.82) arises from the pisiform bone, the tendon of flexor carpi ulnaris and the pisohamate ligament. It ends in a flat tendon which divides into two slips, one attached to the ulnar side of the base of the proximal phalanx of the little finger, the other to the ulnar border of the dorsal digital expansion of extensor digiti minimi. This muscle may be arranged in two or three slips; it may be fused with the flexor brevis. An additional slip may arise from the flexor retinaculum, antebrachial fascia, or tendons of palmaris longus or flexor carpi ulnaris. The muscle may be partly attached to the fifth metacarpal by a slip which sometimes arises from the pisiform.

Action. The abductor digiti minimi abducts the little finger away from the fourth. It thus takes part in the habitual spreading of the digits when they are extended.

The flexor digiti minimi brevis (**5**.82) lies on the radial side of the preceding muscle. It arises from the convex surface of the hook of the hamate bone and the palmar surface of the flexor retinaculum, and is inserted into the ulnar side of the base of the proximal phalanx of the little finger with the abductor digiti minimi. Its origin is separated from that of the abductor by the deep branches of the ulnar artery and nerve. This muscle may be missing, or may be fused with the abductor. It may have a slip attached to the distal end of the fifth metacarpal.

Action. The flexor digiti minimi brevis flexes the little finger at its metacarpophalangeal joint.

The opponens digiti minimi (5.81) is of a triangular form, and placed under cover of the flexor and abductor. It arises from the convexity of the hook of the hamate bone, and contiguous portion of the flexor retinaculum; it is inserted into the whole length of the ulnar margin of the fifth metacarpal bone. It is often divided into two lamellae by the deep branches of the ulnar artery and nerve. The muscle is to a variable degree blended with its neighbours.

Action. The opponens digiti minimi draws the fifth metacarpal bone forwards and rotates it laterally at the carpometacarpal joint, thus deepening the hollow of the palm and, together with flexion and some lateral rotation at the metacarpophalangeal and interphalangeal joints, bringing the digit into opposition with the thumb.

Nerve supply. All the muscles of the minimus are supplied by the deep branch of the ulnar nerve, C. 8 and T. **1**.

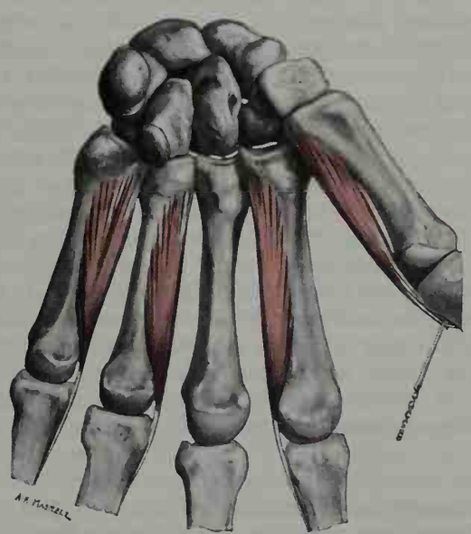
3. THE LUMBRICAL AND INTEROSSEOUS MUSCLES

The lumbricals (5.82) are four small fasciculi which arise from the tendons of flexor digitorum profundus—the first and second from the radial sides and palmar surfaces of the tendons of the index and middle fingers respectively, the third, from the adjacent sides of the tendons of the middle and ring fingers, and the fourth, from the adjoining sides of the tendons of the ring and little fingers. Each passes to the radial side of the corresponding finger, and is attached to the lateral margin of the dorsal digital expansion of extensor digitorum covering the dorsal surface of the finger (5.71). Variations in the attachments of the lumbricals are common. Any of them may be unipennate or bipennate, arising in the latter case from adjoining tendons of flexor digitorum profundus, and also from that of flexor pollicis longus when the first is bipennate (Goldberg 1970). Accessory lumbrical slips may be attached to an adjacent tendon of flexor digitorum superficialis.

Nerve supply. The first and second lumbricals are supplied by the median nerve, C. 8 and T. **1**; the third and fourth lumbricals by the deep terminal branch of the ulnar nerve, C. 8 and T. **1**. The third lumbrical frequently receives a supply from the median nerve. This arrangement is remarkably constant but the manner in which the branches to the lumbricals arise varies. The first and second are also occasionally supplied by the deep terminal branch of the ulnar nerve (Mehta and Gardner 1961).

Actions. Since the lumbrical muscles link one tendon (flexor) to another (extensor), a unique arrangement in the human body, apart from the foot, their actions are likely to be complex (p. 591), depending not only upon their own length and tension, but also on the state of these parameters in the long flexors and extensors. Descriptions of lumbrical activities often disregard these facts, being based merely upon reference to a proximal attachment (considered as fixed), an insertion into the dorsal extensor apparatus, and a direction of pull slightly ventral or palmar to the axes of the metacarpophalangeal joints. Regarded because of the last feature as flexors, the lumbricals are probably only weakly so; since the axes of these joints appear to move ventrally during flexion, the lumbrical flexor effect does not necessarily increase with increasing flexion. Through their attachments to the dorsal expansion the lumbricals would be expected to extend the interphalangeal joints, and there is direct electromyographic evidence for this. As long ago as 1954 Backhouse and Catton confirmed this action by inserting needle electrodes into a number of 2nd lumbrical muscles, and Long and Brown (1964) have made similar observations. The well-known 'claw' deformity following lesions of the ulnar nerve provides further evidence.

When the middle, ring or little finger is flexed fully at the metacarpophalangeal and the proximal interphalangeal joints, its distal phalanx can neither be flexed nor extended by voluntary effort so long as the other fingers are kept extended. The inability to extend the distal phalanx under these conditions is due to the fact that, owing to the way in which the extensor digitorum tendons are inserted, the terminal phalanx can be extended only when the middle phalanx also is extended. For a further analysis of the flexor-extensor apparatus of the digits *see* p. 591.



The *interossei* occupy the intervals between the metacarpal bones, and are divided into a dorsal and a palmar set.

The dorsal interossei (5.83A), are four bipennate muscles, each arising from the adjacent sides of two metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle passes. They are attached to the bases of the proximal phalanges and the dorsal digital expansions (p. 579). Between the double origin of each of these muscles there is a narrow triangular interval; through the first of these intervals the radial artery passes, and through each of the others a perforating branch from the deep palmar arch. The *first*, largest muscle is sometimes named the *abductor indicis*; it is attached to the radial side of the proximal phalanx of the index finger and to the capsule of the adjoining metacarpophalangeal joint. The *second* and *third* are attached to the middle finger, the former to its radial, the latter to its ulnar side. Whereas the second generally reaches the digital expansion and the proximal phalanx, the third usually extends only to the digital expansion (5.71). The *fourth*, too, may be wholly attached to the digital expansion but it often sends an additional slip to the proximal phalanx.

The palmar interossei (5.83B) are smaller than the dorsal and are upon the palmar surfaces of the metacarpal bones, rather than between them. With the exception of the first, each of the four arises from the entire length of the metacarpal bone of one

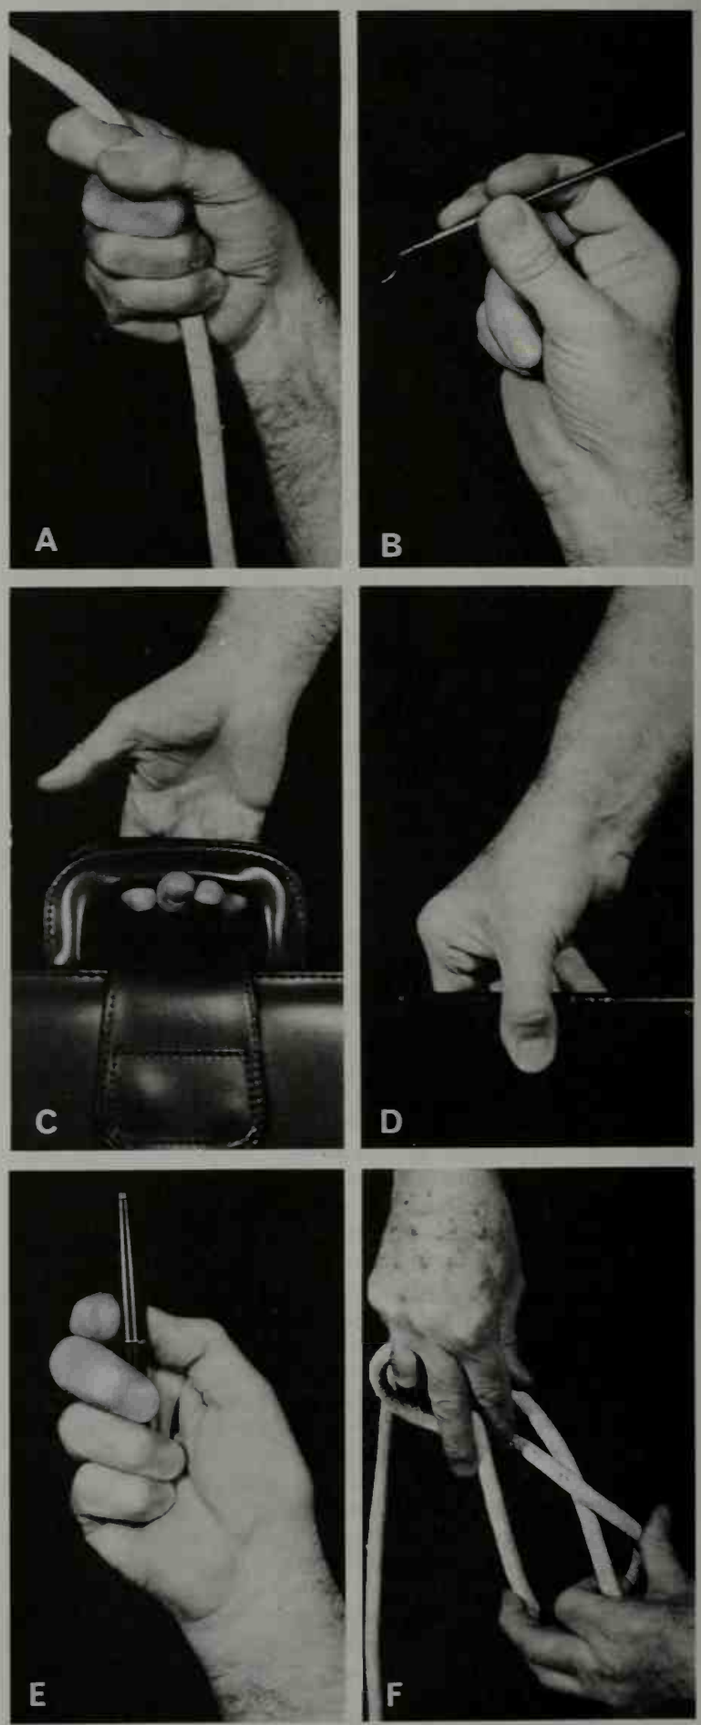
5.83A The dorsal interosseous muscles of the left hand. Palmar aspect.

5.83B The palmar interosseous muscles of the left hand. Palmar aspect.

finger, and passes to the appropriate side of the dorsal digital expansion (Salsbury 1937; Landsmeer 1949).

The *first* arises from the ulnar side of the palmar surface of the base of the first metacarpal bone and is inserted into the sesamoid bone on the ulnar side of the proximal phalanx and usually also into the dorsal digital expansion (Lewis 1965). It lies in front of the lateral head of the first dorsal interosseous muscle, and is overlapped anteriorly by the oblique head of adductor pollicis (5.81A). (Some authorities have preferred to regard the first palmar interosseous muscle as a deep stratum of the flexor pollicis brevis; but this view is now largely disregarded.) The *second* arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the digital expansion of the index finger. The *third* arises from the radial side of the fourth metacarpal bone, and is inserted in common with the third lumbrical (5.71). The *fourth* arises from the radial side of the fifth metacarpal bone, and is attached in common with the fourth lumbrical with an additional attachment to the base of the proximal phalanx. The attachment of these muscles to the base of each dorsal digital expansion (5.71) ensures the stability of the extensor tendon on the convexity of the head of the corresponding metacarpal bone during the movements of flexion and extension at the metacarpophalangeal joint. The interossei are not subject to gross variation; they are occasionally reduplicated, a condition perhaps associated with the origin of palmar interossei from paired short flexors (Lewis 1965).

Stack (1962) and others prefer to classify the interosseous muscles as 'proximal' and 'distal'. The former, chiefly the dorsal interossei, are attached to the proximal part of the extensor expansion, the '*hood*' or '*dorsière*', and to the base of the phalangeal tubercle at the base of the proximal phalanx (5.70, 71). The palmar or 'distal' interossei, apart from the first, are attached only to the extensor expansion, distal to the 'hood' and usually opposite to a lumbrical, both attachments being to the distal wing tendons (p. 579).



Nerve supply. All the interossei are supplied by the deep branch of the ulnar nerve, C. 8 and T. 1. Rarely, the first dorsal interosseous is supplied exclusively by the median nerve (Sunderland 1946).

Actions. The dorsal interossei abduct the fingers from an imaginary axis drawn longitudinally through the centre of the middle finger; the palmar interossei adduct the fingers to this axis (see also p. 592). The interossei, in conjunction with the lumbricals, flex the proximal phalanges; in consequence of their insertions into dorsal digital expansions they are able, in certain conditions (p. 592), to extend the middle and distal phalanges. The first palmar interosseous flexes and adducts the proximal phalanx of the thumb.

THE NATURE OF MANUAL DEXTERITY

The human upper limb—with its mobile base, the shoulder girdle, its extensible and folding member, the arm and forearm, and its terminal working tool, the hand—has an extraordinary range and versatility of movement. One has but to see the slow and limited performance of even the most complex mechanical manipulators yet elaborated by human ingenuity, to recognize the immensely greater skill and repertoire of the living hand. Pre-eminently adapted for reaching and grasping, it has also much potentiality for non-prehensile activities, such as pushing and manipulating objects without grasping them, striking blows, and supporting the trunk in leaning positions. When transmitting thrust or supporting body weight the whole upper limb may become, like the leg, a rigid pillar, with most joints in their close-packed positions; or it may absorb forces by controlled flexion. The hand itself may be used as a fist, or forces may be transmitted through the fingers, extended in close-packed positions at most digital joints and at the carpus, but sometimes with the first interphalangeal joints slightly flexed, as in the toes at take-off (p. 617).

However, it is specially in grasping activities that the human hand has enabled mankind to develop such skills. Despite this, the hand is in many ways primitive, and the human hand is physically capable of only a limited range of movements, though with much versatility within this range. It is important to recognize that human hands are not specialized in their movements beyond those of some other primates. Some, of course, like the gibbon, have specialized hands and have lost the power of opposition, but

5.84 A few of the many varieties of functional postures which may be adopted by the human hand, A, power grip, B, precision grip, C, hook grip, D, pincers grip, E, simultaneous power and precision grip, F, complex manipulation.

the chimpanzee, gorilla and many monkeys have the same repertoire of hand movements as man. The difference lies in the range of uses to which they are put (Jones 1941). Mankind goes far beyond any other creature in his endlessly variable applications of manipulative skills, the hands being the responsive tools of his unrivalled mental development. A note of caution must be added on use of the terms 'primitive' and 'specialized', which may lead to a semantic morass. Biologically such terms are usually employed by morphologists, with little reference to function. In this sense the human hand is obviously more generalized in structure than most mammalian extremities, though it is in many minor structural details more highly adapted to its intricate functions, and is from this point of view extremely 'specialized' (Bishop 1964).

Prehensile activities have been variously analysed—as, for example, cylinder, ball, ring, pliers and pincer grips (Griffiths 1943), but a simpler view is possible, all such grips being regarded as variants of a *power grip* and a *precision grip* (Napier 1956). A combination of the two occurs in some activities, and the *hook grip* is in some features distinct from the other forms.

In a **power grip** (5.84) the fingers are flexed around an object, with counter pressure from the thumb, which is positioned to bring either its pad or its medial border firmly against the object held. The purpose is to hold an object firmly, either to be wielded as a tool or weapon by the whole hand, or to be worked upon by the other hand. Once the grip is made, the hand is held still or moved as a whole by the rest of the limb. Any skill in movements is due to the limb, including the carpus, and relative movements of the thumb and fingers are not involved in imparting skill.

In **the precision grip** (5.84) on the contrary, not only is the method of holding more precise, but small movements of the digits are usually, but not always, the main source of the adroit activities carried out. The object is gripped between the tips of the fingers and thumb, sometimes by all the former, more often by the thumb and index, with the middle finger frequently involved as a third partner, as in the grasping of a pen, pencil or the handle of any small tool. The positioning of the instrument may be carried out at the wrist, or it may even involve supination, pronation and small adjustments at the elbow and shoulder. In the finest work, however, the most characteristic actions are those in which the lumbricals and interossei act in associating metacarpophalangeal flexion with interphalangeal extension, and vice versa. These are utilized in the motions of advancing and withdrawing any small objects to or from another (e.g. a thread to the eye of a needle), one being held still in a power grip, and the other manipulated to and fro using a precision grip. Such activities are commonplace in picking up any small object for inspection, use, or manipulation. The flexor-extensor musculature of the digits is highly organized for such activities, and their individual contributions have been described and investigated in considerable detail (Long 1968; MacConaill and Basmajian 1969; Kapandji 1970).

Relatively small objects may be held steady in a power grip by flexion of the medial three digits against the palm, while the index and thumb carry out manipulations upon them by a precision grip. For example, a fountain pen may be thus held while its cap is screwed off or on. Thus a single hand may be used simultaneously for holding and manipulating.

The hook grip (5.84) is used to suspend or pull upon objects; it may also be used like the power grip, to suspend or elevate the body in climbing. The fingers are looped around such things as handles, straps, cords, branches, rocks, etc. and flexed towards the palm, to a degree depending upon the dimensions of whatever is grasped. The thumb may or may not be involved. It is a grip for the transmission of forces and not for skilful manipulation.

Thus, by flexion and extension of the wrist and digits, adduction and abduction of the digits, and opposition of the thumb, a relatively small repertoire of manual actions is possible. Accessory to the above, it is to be noted, are minor degrees of rotation in the fingers and a freer range of this in the thumb. Though the repertoire is essentially limited, the scope of the basic movements and the nicety of control with which they can be exercised, especially with practice, are unrivalled perquisites of man. This manual skill, guided by discriminative vision, and directed by a highly imaginative and inquisitive mentality into a seemingly endless range of activities, has enabled mankind to master much of the natural environment, and to create around himself a culture of art, science and technology. The ever-increasing complexity of this artificial environment has carried us far beyond any other form of life of which we are aware.

THE MECHANICAL ANALYSIS OF MOVEMENT IN THE HAND

The mechanics of movements of the hand involve many factors, and not least amongst these are the effects of external resistance from the objects manipulated. These initiate a continuous feedback of stimuli, to which the motor apparatus, the extrinsic and intrinsic muscles, respond in intricate nuances of adaptive adjustment at a complex chain of articulations. Ignoring the carpus, each digit has four such joints (three in the thumb), whose individual changes must be concerted; and each digit is actuated by not less than six muscles (medius and annularis), and as many as nine (minimus), a total of thirty-six. It is therefore scarcely practicable to deal exhaustively with the myokinetics of manual movements, even if such analyses were fully supported by experiment or direct observation. In fact, the most detailed accounts (Wood Jones 1941; Napier 1965; Kaplan 1966; Stack 1973; and Landsmeer 1976) are a mixture of mechanical theorization and factual data. Such theoretical interpretations of the anatomical facts are, however, highly plausible, and the experimental data available are largely confirmatory. The following account is necessarily based upon this mixture of direct observation and derived interpretation.

The hand is clearly a flexor-extensor mechanism, complicated by adduction-abduction and slight rotational movements, the latter being usually conjunct in nature. To be added to this is opposition. The working, flexor aspect of the hand, the palm, is necessarily hollowed, the dynamic arching of the palm being carried proximally into the rigid concavity of the carpus. Analogies between this arched form and that of the foot have been indicated; but the hand is only occasionally weight-bearing, and this comparison will not be pursued here. In a prehensile apparatus it is to be expected that the flexors will exceed the extensors in available power. Electromyographic data show that in slow and less forceful flexion of the digits only the flexor digitorum profundus is active, the flexor digitorum superficialis adding its effect in more powerful and rapid gripping. Extension, usually accompanied by digital abduction, is of course usually a preparation for grasping. But digital manipulation demands more than simple extension and flexion; as already emphasized above, it is the dissocation of events at the metacarpophalangeal and interphalangeal joints which converts the hand from relatively crude grasping organ to an adroit manipulator. It is conceivable that separate flexors and extensors, operating in opponent pairs at each joint in the digital articular chain, might serve to produce independent flexor-extensor adjustments, as they do in the thumb. But the latter has only two phalanges; the triple phalangeal series of the other digits, with two intervening articulations, is difficult and perhaps even impossible to control completely with even such a multiplicity of long tendons from extrinsic muscles. However that may be, only one long extensor tendon is available; and this, through its attachment to the base of the proximal phalanx and to the deep transverse metacarpal ligament (p. 479 and 5.70B), is limited to extension at the metacarpophalangeal joint, at which point retraction of the extensor 'hood' becomes arrested. This entails that the part of the extensor tendon distal to this attachment must be of sufficient length to allow full interphalangeal flexion, even when the metacarpophalangeal joint is fully extended. In full flexion of an average digit the distance along its extensor aspect increases by 2 to 3 cm. Therefore there must exist some means by which the digital part of a long extensor tendon can be varied in its effective length. Mere elasticity might provide this; but elongation, to this extent, of structures which are largely collagenous is clearly impossible. In fact, the extensor apparatus (it is far more than a simple tendon) is so arranged as to exploit this apparent difficulty (5.71). The lateral bands of each extensor tendon, which end at the base of a terminal phalanx, can be tensed and drawn

proximally by the intrinsic muscles attached to them, and can also be drawn apart by the same forces. This shortens the distal part of the extensor tendon. The arrangement resembles a diamond (**5**.71C), the forces being transmitted at its four angles. An increase in the transverse width of the diamond, by traction at its lateral angles (by the intrinsic muscles), shortens the total length of the extensor apparatus. This theoretically, would permit flexion or extension at the interphalangeal joints whatever the state of the metacarpophalangeal, and this is precisely what occurs in digital movements. Moreover the existence of proximal and distal attachments of the intrinsic muscles provides a potentiality for separate extension at the two interphalangeal joints.

The interosseous and lumbrical muscles thus supply the third and balancing force between the long or extrinsic digital flexors and extensors. Without this the fine and independent control of movements at three, serially arranged digital articulations would be impossible. This can be stated with confidence; the effects on finger movements of paralysis of the intrinsic muscles are well known, and the data of electromyography are convincing, even though limited.

Something more must be added in regard to the role of the lumbrical muscles. Like the interossei, their tractive effect is slightly ventral to the metacarpophalangeal joints, and they can therefore act here as somewhat inefficient flexors. Again like the interossei, they exert traction upon the extensor expansions, at their distal wings and in their case exclusively so. In contrast to the interossei they do not act from a static proximal attachment, but from the adjustable base of the deep flexor tendons. It is difficult to envisage the precise changes in the lengths of these muscles which must occur in different states of flexor-extensor balance, nor are any direct observations available. However, Stack (1962) has contributed a detailed analysis of such changes in length of the lumbrical (and interosseous) muscles in different positions of the digits, basing his estimates of the proximal positioning of the lumbricals upon excursions of the deep flexor tendons. These excursions have been assessed at 5 to 20 mm by Bunnell (1948), Kaplan (1953), and Landsmeer (1955). As will be appreciated from the diagram in **5**.71, the lumbrical muscles are shown as most contracted and most distal in position in full digital extension, and on the contrary they are most elongated and proximal in full flexion. Stack interprets these reconstructions (which cannot be far from reality) as indicating that the intrinsic muscles, and especially the lumbricals, act as servo-mechanisms, the main power of extension being derived from the long digital extensor tendons, while the precise points of application of power at the interphalangeal joints is determined and transmitted by the intrinsic muscles. (It is perhaps reasonable, therefore, to enquire whether the *extensor* forces cannot also be exerted by the deep digital *flexor* via the lumbricals.) Whatever the real activities of the lumbrical muscles, it is undeniable that they perform a key role in digital movements. It has also been suggested that the stretch receptors in these muscles are of particular importance. This appears to be a reasonable assumption, although it is perhaps unwise to select for special emphasis any one such factor in the complex apparatus of digital movement.

The contribution of the *digital retinacular ligaments* (p. 580) to movements of the fingers is held to be an integration between the two interphalangeal joints. Flexion at the distal joints appears to tauten the ligaments on each side of the digit and to pull the proximal joint into flexion. Certainly it can be observed that when flexion at the proximal joint is prevented, flexion at the distal joint is limited by some resistance, and this seems most likely to be due to the retinacular ligaments. Similarly, the two joints are linked together in extension movements. Passive flexion of the distal joint automatically produces a like movement at the proximal joint. Stack (1962) has constructed an interesting model to illustrate these and other activities of the digits.

Nothing has yet been said of the slight rotations which occur at the digital joints. The interphalangeal joints are usually regarded as pure hinges or uni-axial articulations, but slight conjunct rotation also occurs (p. 472), more obvious rotation is present at the metacarpophalangeal joints, and rotational movements of the metacarpals at the carpometacarpal junctions also make a contribution to digital movements. When the fingers and thumb are opposed together in precise manipulations all the digits except the medius undergo slight metacarpal rotation; in the case of the fingers these rotations are considered to be effected by the appropriate interossei (Braithwaite *et al.* 1948). This is necessary to bring together the tips of the fingers and thumb in various forms of precision grip (*vide supra*), which can involve more than the pollex and index. These two provide a '*pliers*' or '*pincer*' grip; any or all of the remaining digits may be added to produce varieties of '*chuck*' grip (**5**.84). In these and other flexor actions the metacarpal movements, though small (except in the thumb), are easily observed. In gripping any object powerfully with the whole hand the more mobile metacarpals (5th, 4th, 2nd) are flexed to the relative extents indicated at their carpometacarpal joints, and the 5th, at least, may also rotate a little. These movements are, however, dependent upon the shape, dimensions, and malleability of the object grasped. For example, in grasping a long cylinder across the whole palm metacarpal rotation cannot occur, unless the object is of small diameter or yielding consistency, such as a thin rope. In the latter case the flexion and rotation of the fifth metacarpal in particular contributes to the well-known effectiveness of the minimus in gripping small, elongated objects. In all such grasping movements the ultimate events at the articulations involved depend upon the size, contours and resistances presented by the object gripped as much as upon the deployment of muscular forces. For these reciprocally adaptive adjustments the multiplicity of skeletal components, and hence articulations, in the hand appears to be peculiarly suitable.

The thumb, in the greater accessibility to direct observation of its muscles and joints, presents less problems in descriptions of its activities than the other digits. But there is much more controversy in the definition and naming of its *cardinal* movements (compare Haines 1944, Napier 1955, de la Caffiniere 1970, and Pieron 1973), and especially in how these movements contribute to the *customary* pollicial activities. These latter are not, of course, the selected actions—flexion, extension, abduction, adduction, and circumduction—of formal analysis. These actions have dictated the names of muscles involved, despite the fact that few of them have the 'pure' or cardinal effects indicated by these names. For example, the abductor pollicis brevis is not merely an abductor of the thumb, for it also assists in medial rotation towards the palm, a combination of effects which is clearly adapted to the initial stages of opposition, 'pure' abduction being a much less frequently required movement.

It is important to clarify at this point the cardinal movements alluded to. Since the carpometacarpal joint of the thumb is sellar the planes of the two sets of cardinal 'swings'—flexion-extension and adduction-abduction—must be approximately at right angles to each other; but concerning the orientation of these planes with respect to the rest of the hand there is considerable variation in different accounts, and this perhaps is the source of controversies in naming the movements. Commonly the plane of adduction-abduction is regarded as being approximately at right angles to the plane of the palm, and this entails that flexion and extension are carried out parallel to the latter plane. Inspection clearly shows, however, that major axes of the sellar carpometacarpal joint of the thumb are not so orientated, the ridge on the articular surface of the trapezium (along which the metacarpal base slides in adduction and abduction) being inclined at an angle nearer to 60° than 90° with respect to the 'palmar' plane. This entails that abduction of the thumb is not only away from the palm but also somewhat laterally. Doubtless the plane of this movement varies individually, and even to regard it as a plane is probably a simplification. The sellar surfaces at this joint are not perfectly symmetrical; Kuczynski (1974) has examined a short series (15 hands) in great detail, and has shown that the contours of the surfaces are such that pure swings are unlikely, being accompanied in fact by slight rotation. He also considers that the rotations are greater in flexion and extension. This is perhaps to be expected in a digit which is constantly moving from positions of opposition to an open grasp, with the thumb somewhere between extension and abduction. As both Kuczynski and Kapandji (1970) emphasize, movements of the thumb should be regarded in the light of what is occurring at all its joints simultaneously. The medial metacarpal rotation, which occurs

with flexion and adduction in the action of opposition, is accompanied by a similar rotation at the metacarpophalangeal joint. Medial rotation at the latter joint is usually compounded with some abduction of the proximal phalanx, as in the act of opposing the tips of the thumb and fifth digit. The movements occurring at both ends of the pollicial metacarpal could be integrated by the thenar muscles, all of which, except the opponens, act on the carpometacarpal and metacarpophalangeal joints. The muscles of the thumb, both intrinsic (thenar) and extrinsic, have been likened to a series of stays or guy-ropes, which can be altered in length to adjust either of the above-mentioned to a new position, from which the rest of the digit can then be manipulated. The movements of the terminal phalanx at the interphalangeal joint are controlled by the long flexor and extensor. Having only two phalanges the thumb does not present the same extensor problems as do the other digits, and no complex extensor expansion is required here.

In the position of rest the thumb is in contact with or, perhaps more often, close to the lateral border of the palm and the index finger. The rest of the digits are loosely flexed and to a degree increasing from the second to the fifth. The metacarpal heads form an arch, corresponding in its palmar concavity to that of the carpus, at which the hand is about half extended. The whole apparatus, though 'open', is semi-flexed or 'cupped' and ready for any grasping or oppositional effort required of it. For larger objects an initial extensor 'spread' may be necessary, but this is only a preliminary to active progress towards some form of power or precision grip. If the latter involves all the digits, as in holding a ball between their tips, the variable mobility of the metacarpals is particularly noticeable; this allows the fingertips to turn laterally towards the thumb and to space themselves at different angles around such an object. The opponens minimi digiti enables the most mobile of the metacarpals to assist in bringing the fifth digit in complete opposition to the thumb across the diameter of larger spherical objects. The influence of ligaments, especially at the carpometacarpal joint, in pollicial movements has received little attention. The intermetacarpal ligament, between the first and second metacarpal bases (described by Haines 1944), has been re-examined by Bojsen-Møller, who regards it as particularly significant in such movements.

All of the movements described above are concerned with prehension; but the hand can also be used in transmitting force to objects, as in pushing or pressing down upon surfaces. The forces to be transmitted may then be very great, amounting even to the weight of the whole body. In dynamic situations, where the hand is used to fend off moving bodies or to avoid collision with static obstructions, the forces transmitted through the outstretched and extended hand may be even greater. Most of the joints in the hand and wrist are then in the close-packed position, and structures on the flexor aspect, tendons, ligaments, and fasciae are tensed to produce maximum resistance to further extension.

The great variety and skill of manual movements is sustained by a most complex motor equipment and associated sensory apparatus, both cutaneous and neuromuscular. It is therefore not surprising that the hand monopolizes a greater area of motor and sensory cortex (7.131A) than the rest of the arm or the whole of the leg. The importance of the thumb is epitomized in the allocation to it of about half of the cortical 'areas' for the hand.

THE FASCIAE AND MUSCLES OF THE LOWER LIMB

The muscles of the lower limb may be conveniently considered in the following groups:

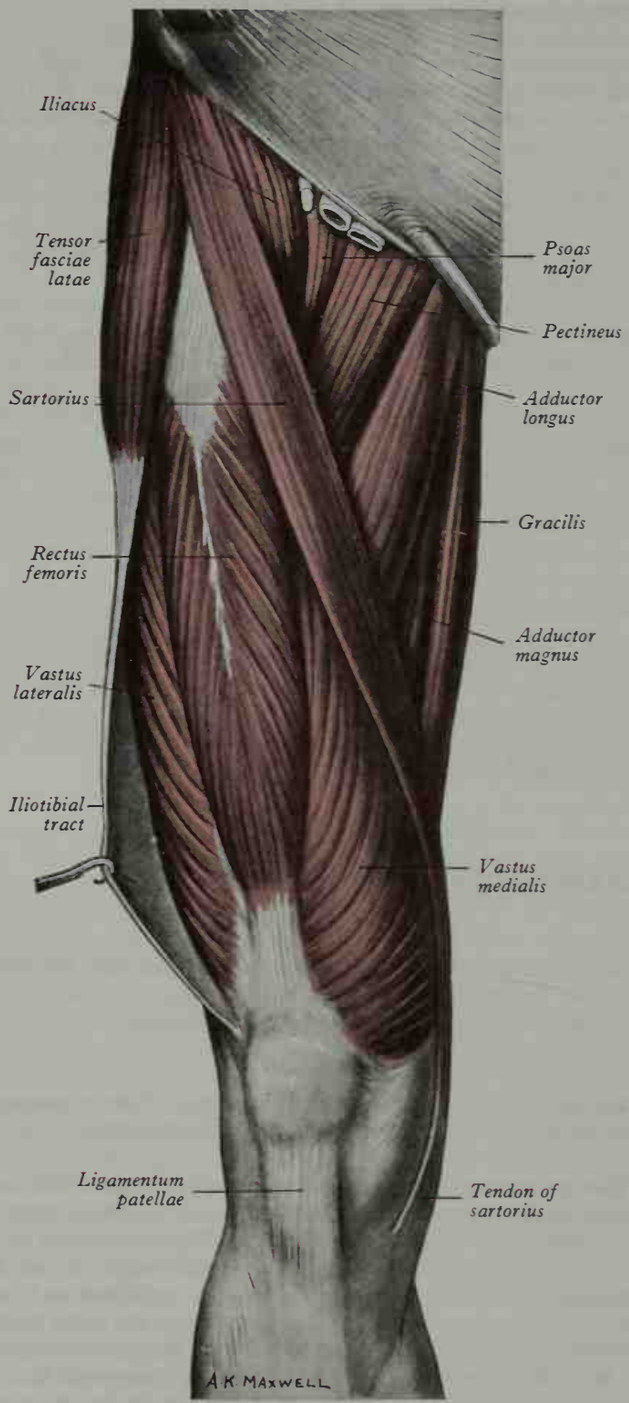
I. Muscles of the iliac region.
II. Muscles of the femoral and gluteal regions.
III. Muscles of the leg.
IV. Muscles of the foot.

I. The Muscles of the Iliac Region

The three muscles of this group arise from the lumbar vertebral column (psoas major et minor) and the iliac bone (iliacus), and two are attached together on the femur as flexors. The psoas minor falls short of this and acts on the spine and sacro-iliac joint.

The iliac fascia covers the psoas and iliacus. It is thin above, but gradually thickens towards the inguinal ligament.

The *part covering the psoas* is thickened above as the medial arcuate ligament (p. 549). Medially, the fascia over the psoas is attached by a series of arched processes to the intervertebral discs, margins of vertebral bodies, and the upper part of the sacrum. Laterally, above the iliac crest, it blends with the fascia anterior to quadratus lumborum (p. 559), below the crest, with the fascia covering the iliacus.



The *iliac part* is connected, laterally, to the whole of the inner lip of the iliac crest, and medially, to the pelvic brim, where it blends with the periosteum. It is attached to the iliopectineal eminence and there receives a slip from the tendon of the psoas minor, when present. The external iliac vessels are anterior to the fascia but the branches of the lumbar plexus are posterior to it; it is separated from the peritoneum by loose extraperitoneal tissue.

Lateral to the femoral vessels, the iliac fascia is continuous with the posterior margin of the inguinal ligament and the transversalis fascia. Medially it passes behind the femoral vessels to become the pectineal fascia and attached to the pecten pubis. At the junction of its lateral and medial parts it is attached to the iliopectineal eminence and the capsule of the hip joint. It thus forms a septum between the inguinal ligament and the hip bone dividing the space here into a lateral part, the *lacuna musculorum*, containing psoas major, iliacus and the femoral nerve, and a medial part, the *lacuna vasorum*, transmitting the femoral vessels. The downward continuation of the iliac fascia forms the posterior wall of the femoral sheath (p. 725).

It should be noted that the segmental values of the nerves to the muscles of the lower limb are those given by Sharrard (1955).

The psoas major (5.85) is a long fusiform muscle lateral to the lumbar region of the vertebral column and the pelvic brim. It arises from—(1) the anterior surfaces and lower borders of the transverse processes of all the lumbar vertebrae, (2) by five digitations, each from the bodies of two vertebrae and their intervertebral disc, the highest slip arising from the lower margin of the body of the twelfth thoracic vertebra, the upper margin of the body of the first lumbar vertebra and the interposed disc, the lowest from the adjacent margins of the bodies of the fourth and fifth lumbar vertebrae and the interposed disc; and (3) from a series of tendinous arches extending across the constricted parts of the bodies of the lumbar vertebrae between the preceding slips. The lumbar arteries and veins, and filaments from the sympathetic trunk, pass medial to these arches. The muscle descends along the pelvic brim, continues posterior to the inguinal ligament and anterior to the capsule of the hip joint, and finally converges into a tendon which, having received on its lateral side nearly the whole of the fibres of the iliacus, becomes attached to the lesser trochanter of the femur. The large subtendinous iliac bursa, which occasionally communicates with the cavity of the hip joint, separates the tendon from the pubis and the capsule of the joint. The somewhat complex vertebral attachments of the psoas major sometimes display minor numerical variations.

Relations. The upper limit of psoas major is posterior to the diaphragm in the lowest part of the posterior mediastinum. It may be in contact with the posterior extremity of the pleural sac. In the abdomen its *anterolateral surface* is related to the medial arcuate ligament, its own fascia, extraperitoneal tissue and peritoneum, the kidney, psoas minor, renal vessels, ureter, testicular (or ovarian) vessels, and genitofemoral nerve. In front the right psoas

5.85 Superficial muscles of the thigh. Extensor aspect. (From Quain's *Anatomy*, 11th edition.)

is overlapped by the inferior vena cava and crossed by the end of the ileum, and the left is crossed by the colon. Its *posterior surface* is in relation with the transverse processes of the lumbar vertebrae, and the medial edge of the quadratus lumborum. The lumbar plexus is situated posteriorly in the substance of the muscle (p. 1106). *Medially* the muscle is related to the bodies of the lumbar vertebrae and lumbar vessels. Along its anteromedial margin the muscle is in contact with the sympathetic trunk, aortic lymph nodes and, along the pelvic brim, with the external iliac artery. This margin is covered by the inferior vena cava on the right side, and on the left side lies posterior and lateral to the abdominal aorta. In the thigh it is related to the fascia lata and the femoral artery *in front*, *behind*, to the capsule of the hip joint, from which it is separated by a bursa, at its *medial border*, to pectineus and medial circumflex femoral artery, and also to the femoral vein, which may overlap it slightly, at its *lateral border*, to the femoral nerve and the iliacus. The femoral nerve descends at first through the fibres of psoas major, and then in the furrow between it and iliacus.

Nerve supply. From the ventral rami of the lumbar nerves, L. **1**, **2** and 3.

Actions. The psoas major acts conjointly with the iliacus (*vide infra*).

The psoas minor is anterior to psoas major within the abdomen. It arises from the sides of the bodies of the twelfth thoracic and first lumbar vertebrae and from the disc between them. It ends in a long, flat tendon which is attached to the pecten pubis and iliopectineal eminence and, laterally, to the iliac fascia. This muscle is absent in about 40 per cent of subjects.

Nerve supply. A branch from the first lumbar nerve.

Action. The psoas minor is a weak flexor of the trunk.

The iliacus (**5**.85) is a triangular sheet of muscle which arises from the superior two-thirds of the concavity of the iliac fossa, from the inner lip of the iliac crest, from the ventral sacro-iliac and iliolumbar ligaments, and from the upper surface of the lateral part of the sacrum (**3**.43); in front, it reaches as far as the anterior superior and anterior inferior iliac spines, and receives a few fibres from the upper part of the capsule of the hip joint. Most of its fibres converge into the lateral side of the tendon of psoas major, but some of them are attached directly to the femur for about 2·5 cm below and in front of the lesser trochanter.

Relations. In the abdomen, the *anterior surface* of iliacus is related to its fascia, which separates the muscle from extraperitoneal tissue and peritoneum, to the lateral femoral cutaneous nerve, on the right side, the caecum, on the left side, the iliac part of the descending colon; its *posterior surface* is related to the iliac fossa, its *medial border*, to the psoas major and femoral nerve. In the thigh, its *anterior surface* is in contact with the fascia lata, rectus femoris, sartorius and arteria profunda femoris, its *posterior surface* with the capsule of the hip joint, a bursa common to it and psoas major being interposed.

Nerve supply. Branches of the femoral nerve, L. **2** and 3.

Actions. The psoas major, acting from above, flexes the thigh upon the pelvis, being assisted by iliacus. Electromyographic studies do not support the commonly held view that the psoas major acts as a medial rotator of the hip joint, but activity has been described in *lateral* rotation, particularly in the young. This view has received support from dissection studies on infants (McKibbin 1968). However, because of the variety of conflicting views over a number of years, further confirmation of these results must be awaited. When the psoas major and iliacus of both sides act from below, they contract powerfully to bend the trunk and pelvis forwards against resistance, as in raising the trunk from the recumbent to the sitting posture.

Geometrical reasoning suggests that when the body is erect and the lower limb fixed in position, contraction of one psoas major might flex the vertebral column (and trunk) forwards and laterally; electromyography, however, again does not support such a prediction, indicating maximum activity when the lumbar curvature is increased. However, other investigators, who carried out direct electromyography of the muscle during the operation of sympathectomy in the lumbar region, suggest that in addition to its role as a hip flexor, it has important activities in balancing the trunk while sitting (Keagy *et al.* 1966).

In symmetrical standing, electromyographic recordings from iliopsoas have varied from electrical silence to *slight* intermittent or continuous activity. These results probably reflect differences between individuals and between techniques of investigation. Nevertheless, most are agreed that the low level of activity correlates well with the fact that the line of body weight falls behind the transverse axis of the hip joints, and that the latter are near their close-packed positions, with spiralization and tautening of the ligaments (especially the iliofemoral) and marked compression and congruence of the articular surfaces, these passive mechanisms largely counterbalancing the extending torque of the weight of the trunk.

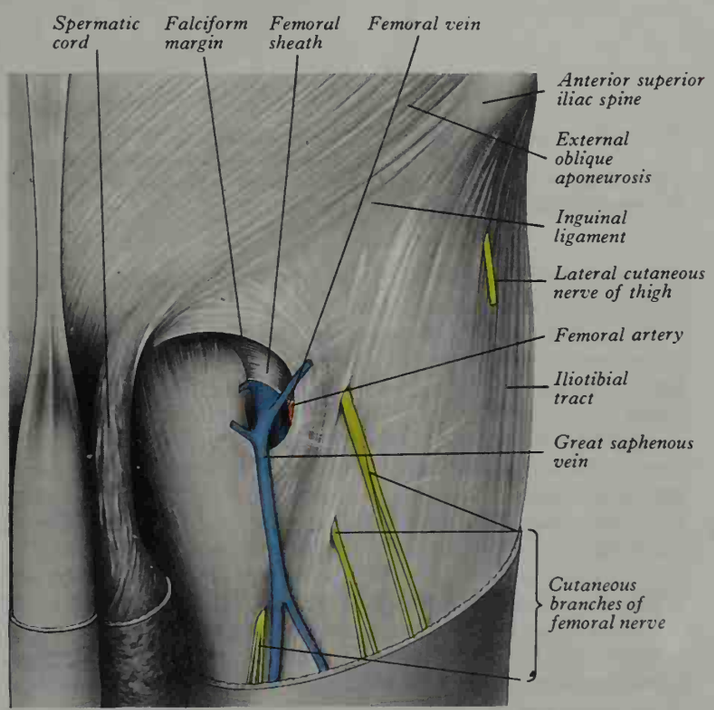
Applied Anatomy. When the neck of the femur is fractured the psoas major acts as a lateral rotator of the femur, thus accounting

for the characteristic posture of the lower limb. Occasionally pus arising from disease of the thoracic and lumbar vertebrae tracks into the thigh within the fascial sheath of the psoas major.

II. The Muscles of the Thigh and Gluteal Region

The musculature of the thigh and hip can be divided on functional and morphological grounds into flexors and extensors; but in consequence of the rotation of the limb into a new working position in land vertebrates (p. 350), the primitive dorsal or extensor surface of the thigh has become anterior, and the ventral aspect containing the flexor muscles is now posterior. This change has not affected the 'girdle' muscles; iliopsoas, a flexor, already described above, is still ventral in position, and the gluteal muscles, which represent primitive extensors, have preserved a dorsal situation. Moreover, the evolution of multiaxial function at the hip joint has been coupled with the development of adductor and abductor groups of muscles, so that the joint is surrounded on all sides, not merely ventrally and dorsally, by muscle forces collectively capable of moving the femur in any direction, or maintaining it if necessary in static postures, especially the erect position. These activities are considerably affected by gravity, which aids some movements and opposes others. Hence the muscle groups are unequal in power.

1. The Anterior Femoral Muscles



Included in this group (5.85) are the tensor fasciae latae, sartorius and rectus femoris which can act on the hip and knee joints, and the vasti medialis, lateralis, et intermedius which act only on the latter. The articularis genus, a derivative of the vastus intermedius, a retractor of the synovial capsule of the knee joint, completes the group. The rectus femoris and the vasti extend the knee joint through a common tendon and are hence considered as one muscle, the quadriceps femoris.

The superficial fascia of the thigh, consisting as elsewhere in the limbs of loose areolar tissue containing a variable amount of fat, splits into recognizable layers in places, and between these ramify superficial vessels and nerves. In the inguinal region it is thick and in two layers, between which are the superficial inguinal lymph nodes, great saphenous vein and other smaller vessels. Here, the *superficial* layer is continuous with the abdominal superficial layer; the *deep* layer, a thin fibro-elastic stratum, is best marked medial to the great saphenous vein and inferior to the inguinal ligament, extending between the subcutaneous vessels and nerves and the deep fascia, with which it fuses a little below the ligament. It completes the saphenous opening, blending with its circumference and with the femoral sheath (p. 725). Over the opening it is perforated by the great saphenous vein and other blood and lymph vessels, and is hence termed the sieve-like or *cribriform fascia*. Anterior to the patella the superficial fascia contains a large subcutaneous bursa.

The fascia lata, the **deep fascia** of the region, so termed because of its wide extent, is thicker in the proximal and lateral parts of the thigh where the tensor fasciae latae and an expansion from gluteus maximus are attached to it. It is thin posteriorly, and also in the proximal and medial region over the adductor muscles, but it is thicker around the knee, being strengthened there by expansions from the tendon of biceps femoris laterally, sartorius medially, and quadriceps femoris in front. The fascia lata is attached, above and behind, to the back of the sacrum and coccyx, laterally, to the iliac crest, in front, to the inguinal ligament and to the superior ramus of the pubis, medially, to the inferior ramus of the pubis, the ramus and tuberosity of the ischium, and the lower border of the sacrotuberus ligament. From the iliac crest it descends as a dense layer over gluteus medius to the upper border of gluteus maximus, where it splits into two layers, one passing superficial and the other deep to this muscle; at its lower border the layers reunite. Over the flattened lateral surface of the thigh, the fascia lata is specially thickened as a strong band, the *iliotibial tract*. At the upper limit of the tract, where it splits into two, the tensor fasciae latae is attached to it and, posteriorly, the greater part of the tendon of gluteus maximus. Of these two layers the superficial ascends lateral to tensor fasciae latae to reach the iliac crest; the deeper layer passes up and medially, deep to the muscle, and blends with the lateral part of the capsule of the hip joint. Distally, the iliotibial tract is attached to the lateral condyle of the tibia, where it is superficial to and blends with an aponeurotic expansion from vastus lateralis. It stands out as a strong, visible ridge anterolateral to the knee, when the leg is extended. (For a clinical, morphological and comparative study of the iliotibial tract, *see* Kaplan 1958.) Below, the fascia lata is attached to all exposed bony points around the knee joint, such as the condyles of the femur and tibia, and the head of the fibula. These remarks apply particularly to the iliotibial tract (Evans 1977). On each side of the patella it is strengthened by transverse fibres from the lower parts of the vasti, which are thereby attached to it; the stronger lateral fibres are continuous with the iliotibial tract. The fascia lata is continuous with two intermuscular septa, which are attached to the whole of the linea aspera and its prolongations above and below: the lateral and stronger septum, extending from the attachment of gluteus maximus to the lateral condyle, is between the vastus lateralis in front and the short head of biceps femoris behind, and provides partial attachment for them; the medial and thinner septum is between the vastus medialis and the adductors and pectineus. Numerous smaller septa pass between the individual muscles ensheathing them and sometimes providing partial attachment for them.

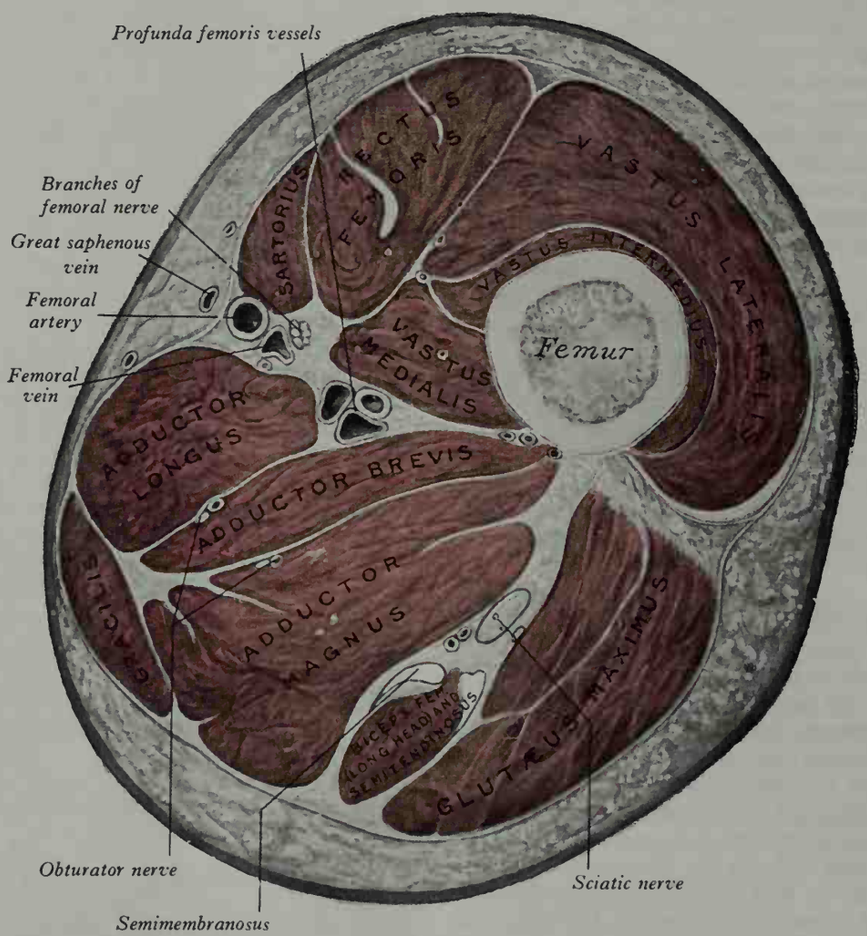
Evans (1977) has drawn attention to the ligamentous arrangement of the iliotibial tract, suggesting that it is more substantial than appears necessary to serve the tensor fasciae latae and gluteus maximus. He regards it as a ligament stretched between the ilium and tibia (*vide infra*).

The saphenous opening (5.86) is an aperture in the deep fascia lateral and a little distal to the medial part of the inguinal ligament, through which pass the great saphenous vein and other smaller vessels. (Its approximate 'centre' is, in the adult, indicated by a point some 3 cm inferior, and 3 cm lateral, to the pubic tubercle.) The cribriform fascia, which is pierced by these structures, fills in the aperture and must be removed to reveal it. The fascia lata in this part of the thigh displays superficial and deep parts (these must not be confused with the superficial and deep layers of the superficial fascia described above).

5.86 The left saphenous opening, after the removal of the cribriform fascia.

The *superficial stratum* is lateral to the saphenous opening. It is attached to the crest and anterior superior spine of the ilium, to the whole length of the inguinal ligament, and to the pecten pubis in conjunction with the lacunar ligament (p. 552). From the pubic tubercle it is reflected inferolaterally, as the arched *falciform margin*, which forms the superior, lateral and inferior boundaries of the saphenous opening (**5**.86); this margin is adherent to the anterior layer of the femoral sheath, and the cribriform fascia is attached to it. The falciform margin is considered to have *superior* and *inferior cornua*. The latter is well defined, and is continuous behind the great saphenous vein with the deep portion of the fascia lata.

The *deep stratum* is medial to the saphenous opening, and is continuous with the superficial stratum at its lower margin; traced upwards, it covers pectineus, adductor longus and gracilis, and, passing behind the femoral sheath, to which it is closely united, it is attached to the pecten pubis.



Thus these superficial and deep strata of the fascia lata are respectively anterior and posterior to the femoral sheath, the saphenous opening being formed by the continuity of the two strata.

The saphenous opening varies much in dimensions, its height varying from 1·5 to 8 or 9 cm, its width from about 1 to 3 or 4 cm. Adjacent *subsidiary openings* may exist, to transmit venous tributaries, but these openings are more usually in the floor of the fossa.

The tensor fascia latae (**5**.85) arises from the anterior 5 cm of the outer lip of the iliac crest, the lateral surface of the anterior superior iliac spine, and part of the border of the notch below it, between gluteus medius and sartorius, and from the deep surface of the fascia lata. It descends between, and is attached to, the two layers of the iliotibial tract of the fascia lata and ends about the junction of the middle and the upper third of the thigh. The muscle, however, varies in length, and its fibres may even reach the lateral femoral condyle. Its proximal attachment may extend on to the aponeurotic fascia superficial to gluteus medius.

Nerve supply. The superior gluteal nerve, L. 4 and 5.

Actions. The tensor fasciae latae acting through the iliotibial tract, extends the knee with lateral rotation of the leg; it may also assist in abduction and medial rotation of the thigh, but its role as an abductor has been denied (Kaplan 1958). In the erect posture, acting from below, it helps to steady the pelvis on the head of the femur; through the iliotibial tract it steadies the condyles of the femur on the tibia and thus helps to maintain the erect attitude. When the thigh is flexed against gravity and the knee is extended, an angular depression becomes apparent immediately below the anterior superior iliac spine. Its lateral boundary is formed by the tensor fasciae latae, which is active in flexion. The muscle aids gluteus medius in postural abduction at the hip joint (*see* p. 617). Kaplan (1958) and Evans (1977) regard the iliotibial tract as of greater importance in steadying the pelvis than the tensor fasciae latae (*see* p. 595).

5.87 Transverse section through the right thigh at the level of the apex of the femoral triangle. Proximal (superior) aspect.

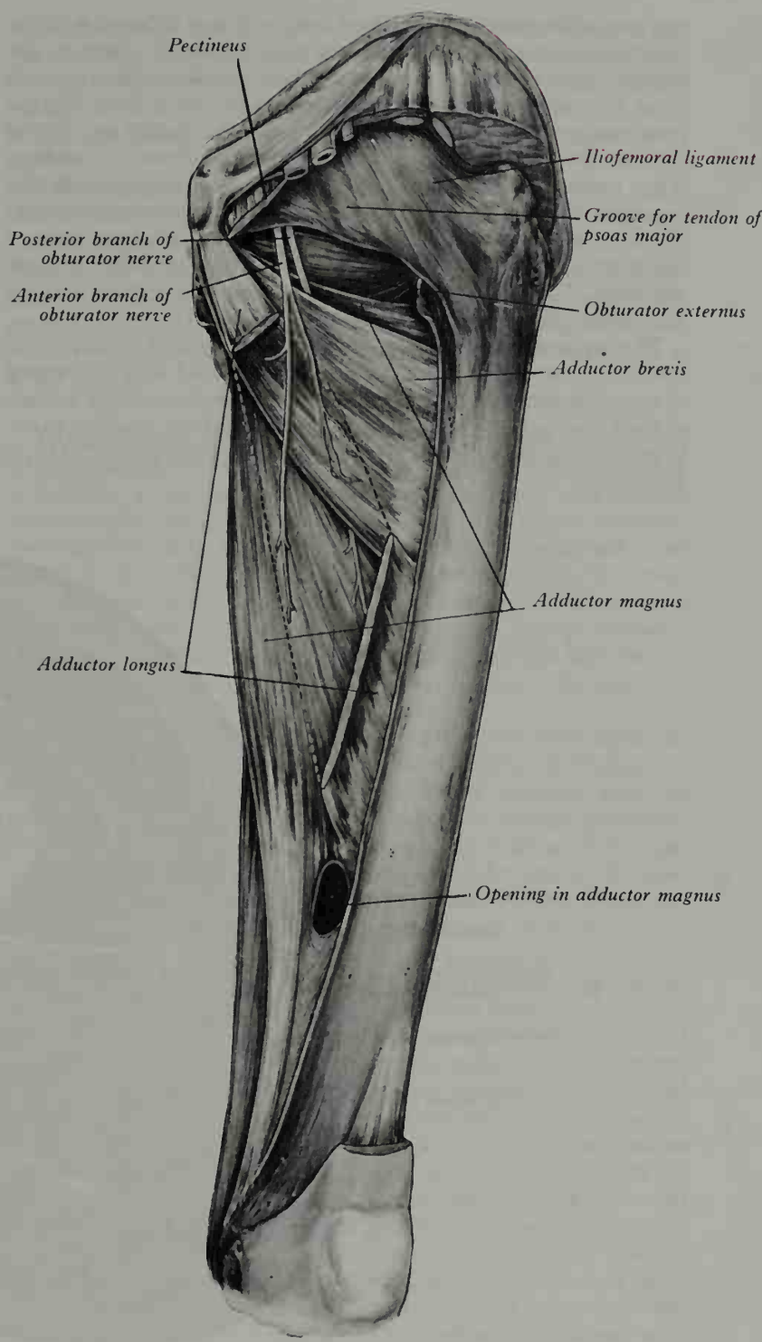
The sartorius (**5**.85, 87, 89) is a narrow strap muscle, and incidentally the longest in the body. It arises by tendinous fibres from the anterior superior iliac spine and the upper half of the notch below it. It crosses the thigh obliquely to the medial side, then descends more vertically to the medial side of the knee, where a thin, flattened tendon replaces the muscle fibres and curves obliquely forwards to expand into a broad aponeurosis attached in front of gracilis and semitendinosus to the upper part of the medial surface of the tibia (**5**.98). The upper part of the aponeurosis is curved backwards over the upper edge of the tendon of gracilis to be attached behind it. An offset, from its upper margin, blends with the capsule of the knee joint, and another, from its lower border, with the fascia on the medial side of the leg. This muscle varies little, save in relative bulk. The

muscle is, however, occasionally bicipital at its proximal end, the additional slip being attached to the pectineal line or to the femoral sheath; Bhatnagar and Narayan (1959) have described three instances. It is occasionally absent.

Relations. In the upper third of the thigh the muscle's medial border forms the lateral side of the *femoral triangle*, the medial side of which is the medial border of adductor longus, and the base the inguinal ligament; the femoral artery descends through the middle of this triangle from base to apex. In the middle third of the thigh, the femoral artery is contained in the adductor (subsartorial) canal, anterior to which is a strong stratum of deep fascia and sartorius (**5**.89). This fascia bridges the interval between the adductors and quadriceps. It must be incised to expose the vessels.

Nerve supply. The femoral nerve, L. 2 and 3.

Actions. The sartorius assists in flexing the leg on the thigh, and the thigh on the pelvis, and its action is called for particularly when the two movements are carried out simultaneously. It also helps to abduct the thigh and to rotate it laterally. (A combination of these movements, together with inversion of the foot, brings the sole of the foot into direct view.) When acting against gravity, as it usually is, the muscle can be both seen and felt in the living subject.



The quadriceps femoris (**5**.85, 87, 89) is the great extensor muscle of the leg, covering almost all of the front and sides of the femur. It can be divided into four parts, which have distinctive names. One occupies the middle of the thigh, and arises from the ilium; from its straight course it is called the *rectus femoris*. The other three arise from the shaft of the femur, which they surround, apart from the linea aspera, from the trochanters to the condyles; lateral to the femur is the *vastus lateralis*, medial to it the *vastus medialis*, and in front, the *vastus intermedius*.

The rectus femoris (**5**.85, 87, 89) is fusiform, and its superficial fibres are arranged in a bipennate manner, the deep fibres running straight down to an aponeurosis. It arises by two tendons—a straight head from the anterior inferior iliac spine, and a reflected one from a groove above the acetabulum and the fibrous capsule of the hip joint. The two unite at an acute angle, and spread into an aponeurosis which is prolonged downwards on the *anterior* surface of the muscle, and from this the muscular fibres arise. The muscle ends in a broad and thick aponeurosis which occupies the lower two-thirds of its *posterior* surface, and gradually narrows into a flattened tendon, attached to the base of the patella. This is the superficial central part of the quadriceps tendon.

The vastus lateralis (**5**.85, 87, 89) is the largest part of quadriceps femoris. It arises by a broad aponeurosis, attached to the upper part of the intertrochanteric line, the anterior and inferior borders of the greater trochanter, the lateral lip of the gluteal tuberosity, and the upper half of the lateral lip of the linea aspera (**3**.185, **5**.89). This aponeurosis covers the upper three-fourths of the muscle, and from its deep surface many additional fibres arise. A few fibres also arise from the tendon of gluteus maximus and the lateral intermuscular septum between the vastus lateralis and short head of biceps femoris. The muscular mass thus formed is attached to a strong aponeurosis on the deep surface of the lower part of the muscle; this contracts into a flat tendon, attached to the base and lateral border of the patella, and blends with the quadriceps femoris tendon (*vide infra*). It gives to the capsule of the knee joint an expansion which descends to the lateral condyle of the tibia and blends with the iliotibial tract.

The vastus medialis and intermedius appear to be inseparably united, but when rectus femoris is reflected a narrow cleft can be seen extending upwards from the medial border of the patella between the two sometimes as far as the lower part of the intertrochanteric line, where, however, the two muscles are frequently fused.

The vastus medialis (**5**.85, 87, 89) arises from the lower part of the intertrochanteric line, spiral line, medial lip of the linea aspera, upper part of the medial supracondylar line, the tendons

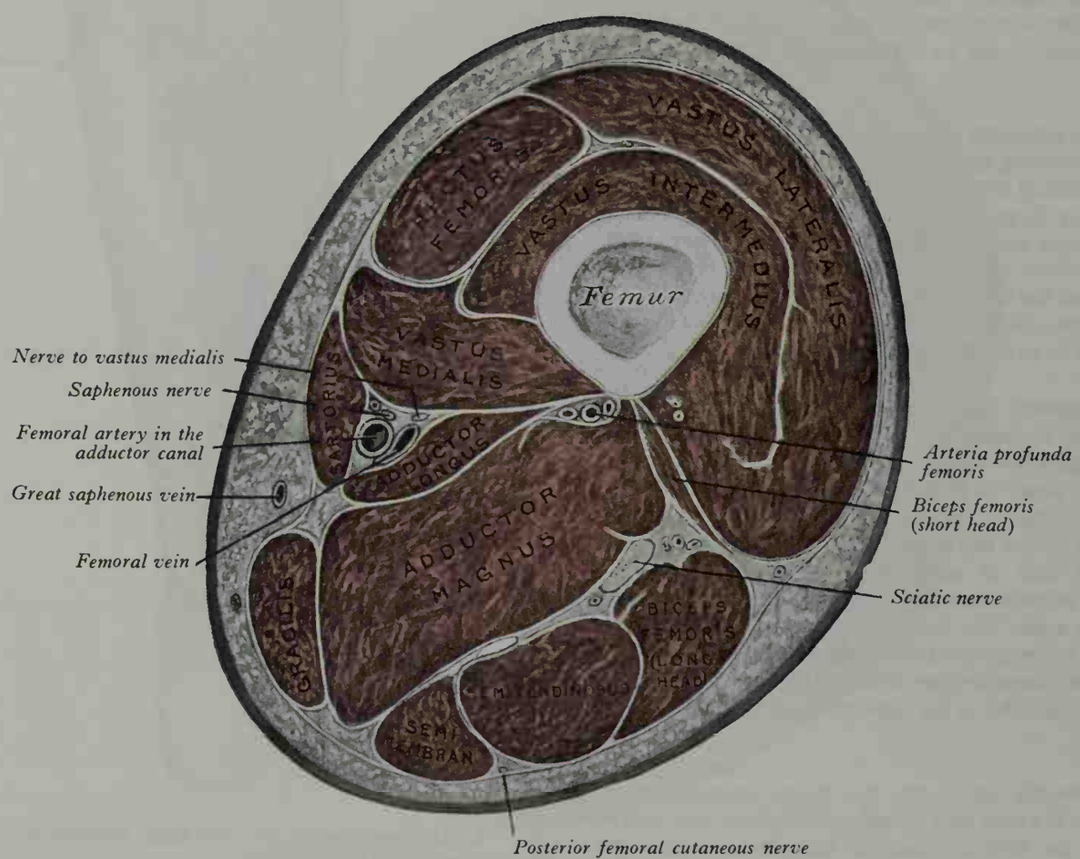
5.88 The adductor muscles of the left thigh. Anterior aspect. Part of the adductor longus has been excised.

of adductor longus and magnus, and the medial intermuscular septum (*see* p. 595). Its fibres pass downwards and forwards, and are chiefly attached to an aponeurosis on the deep surface of the muscle which is attached to the medial border of the patella and the quadriceps femoris tendon (*vide infra*). An expansion from this aponeurosis reinforces the capsule of the knee joint and is attached below to the medial condyle of the tibia. The lowest fibres are almost horizontal and form a bulge in the living subject, medial to the upper half of the patella.

The vastus intermedius (**5**.87, 89) arises from the front and lateral surfaces of the upper two-thirds of the femoral shaft, and from the lower part of the lateral intermuscular septum. Its fibres end in an aponeurosis on the anterior surface of the muscle; this aponeurosis forms the deep part of the quadriceps femoris tendon and, in addition, is attached to the lateral border of the patella and the lateral condyle of the tibia.

The tendons of the four divisions of the quadriceps unite in the lower part of the thigh to form a single strong tendon attached to

the base of the patella, some fibres passing over it to blend with the ligamentum patellae. The patella is a sesamoid bone in the quadriceps tendon, and the 'ligamentum' patellae, which extends from the patellar apex to the tubercle of the tibia, is in fact the continuation of the tendon of the muscle, the medial and lateral patellar retinacula (p. 484) being expansions from its borders. The suprapatellar bursa is between the femur and the suprapatellar part of the quadriceps tendon; the deep infrapatellar bursa is between the ligamentum patellae and the upper part of the front of the tibia (**4**.75). The quadriceps is subject to little variation. The rectus femoris may arise from the anterior *superior* iliac spine, and its reflected head may be absent.



The articularis genus, a small muscle, usually distinct from the vastus intermedius but occasionally blended with it, consists of several muscular bundles which arise from the anterior surface of the lower part of the shaft of the femur and are attached to the upper part of the synovial membrane of the knee joint (DiDio *et al.* 1967).

The articularis genus retracts the synovial membrane of the knee joint proximally during extension of the leg, thereby preventing interposition of redundant synovial folds between patella and femur (c.f. the articularis cubiti or subanconeus at the elbow—p. 573).

2. The Medial Femoral Muscles

This group is derived, as its nerve supply suggests, from both the flexors and extensors between which it lies. All five muscles—gracilis, pectineus, and the adductores longus, brevis et magnus, cross the hip joint, but only gracilis reaches beyond the knee. Collectively they are known as the adductors of the thigh, but their actions are more complex than this.

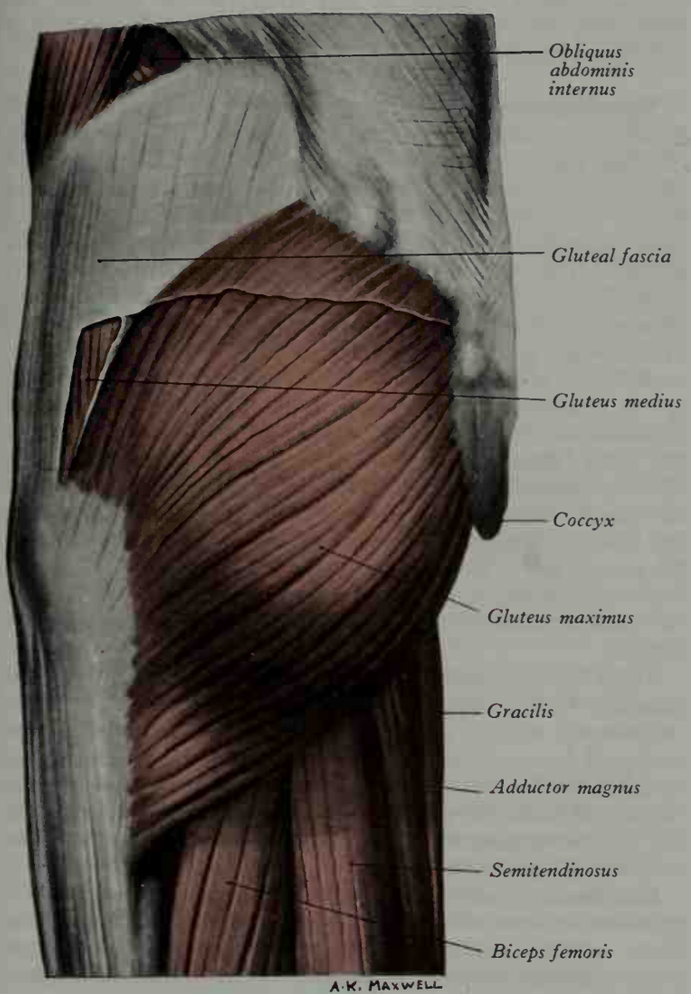
The gracilis (**5**.85, 87, 89) is the most superficial of the adductor group. It is thin and flattened, broad above, narrow and

5.89 Transverse section through the middle of the right thigh. Proximal (superior) aspect.

Nerve supply. The quadriceps femoris and the articularis genus are supplied by the femoral nerve, L. 2, **3** and **4**.

Actions. The quadriceps femoris extends the leg upon the thigh. The rectus femoris also assists in flexing the thigh on the pelvis, or, if the thigh be fixed, it helps to flex the pelvis; it is, however, remarkably quiescent in standing (Joseph and Williams 1957). The rectus can, of course, flex the hip and extend the knee simultaneously. The lower fibres of the vastus medialis contract particularly during the terminal phase of extension of the knee joint to retain the patella in its groove on the patellar surface of the femur by counteracting the natural tendency to lateral displacement of the patella, which is attributable to the angulation between the shaft of the femur and the bones of the leg (Lieb and Perry 1968). It has been suggested that the lower fibres of the vasti medialis et lateralis are involved in stabilizing the knee joint. Electromyographic studies indicate that the three vasti are not equally or synchronously active in various phases of extension of the knee or rotation of the thigh, but confirmed details are not yet available.

tapering below. It arises by a thin aponeurosis from the medial margins of the lower half of the body of the pubis, the whole of its inferior ramus and the adjoining part of the ramus of the ischium (**3**.171). The fibres descend vertically into a rounded tendon which passes across the medial condyle of the femur posterior to the tendon of sartorius. It then curves round the medial condyle of the tibia, where it becomes flattened, and is attached to the upper part of the medial surface of the tibia, below the condyle. A few fibres from the lower part of the tendon are prolonged into the deep fascia of the leg. At its termination the tendon is immediately proximal to that of semitendinosus, and its upper edge is overlapped by the tendon of sartorius, with which it is in part blended. It is separated from the tibial collateral ligament of the knee joint by the tibial intertendinous bursa (p. 487).



Nerve supply. The obturator nerve, L. **2** and 3.

Actions. The gracilis flexes the leg and rotates it medially; it may also act as an adductor of the thigh.

The pectineus (**5**.85) is a flat, quadrangular muscle, in the

femoral triangle. It arises from the pecten pubis, and to a slight extent from the bone in front of it, between the iliopectineal eminence and the pubic tubercle, and from the fascia on its own anterior surface; the fibres pass downwards, backwards and laterally, to be attached along a line leading from the lesser trochanter to the linea aspera. The muscle may be bilaminar, as it is in some other mammals, the two layers receiving separate nerve supplies (*vide infra*). It may be partially or wholly attached to the capsule of the hip joint.

Relations. Its *anterior surface* is related to the fascia lata, which separates it from the femoral vessels and great saphenous vein, its *posterior surface*, to the capsule of the hip joint, the adductor brevis, obturator externus and anterior branch of the obturator nerve, its *lateral border*, to psoas major and the medial circumflex femoral vessels, its *medial border*, to the lateral margin of the adductor longus.

5.90 The left gluteus maximus. Some of the gluteal fascia has been removed to expose part of gluteus medius.

Nerve supply. The pectineus is supplied by the femoral nerve, L. **2** and 3; and by the accessory obturator, L. 3, when present. Occasionally it receives a branch from the obturator nerve. The muscle may be incompletely divided into dorsal and ventral strata, supplied respectively by the obturator and the femoral (or accessory obturator) nerves. In a total of 800 cases investigated, only 69 displayed a partial supply by an accessory obturator nerve (Woodburne 1960).

Actions. The pectineus adducts the thigh and flexes it on the pelvis.

The adductor longus (5.88, 89), the most anterior of the three adductors, is triangular and in the same plane as pectineus. It arises by a flat, narrow tendon which is attached to the front of the pubis in the angle between the crest and the symphysis. It soon expands into a broad fleshy belly which passes downwards, backwards and laterally, and is inserted, by an aponeurosis, on to the linea aspera in the middle third of the femur, between the vastus medialis and the adductores magnus et brevis, with all of which it is usually blended. The adductor longus is occasionally double.

Relations. *Anterior* to the muscle are the spermatic cord, fascia lata, by which it is separated from the great saphenous vein, and, near its attachment, the femoral artery and vein and sartorius. *Posterior* to it are the adductores brevis et magnus, the anterior branch of the obturator nerve, and, near its attachment, the profunda femoris vessels. *Lateral* is pectineus, *medial* is gracilis.

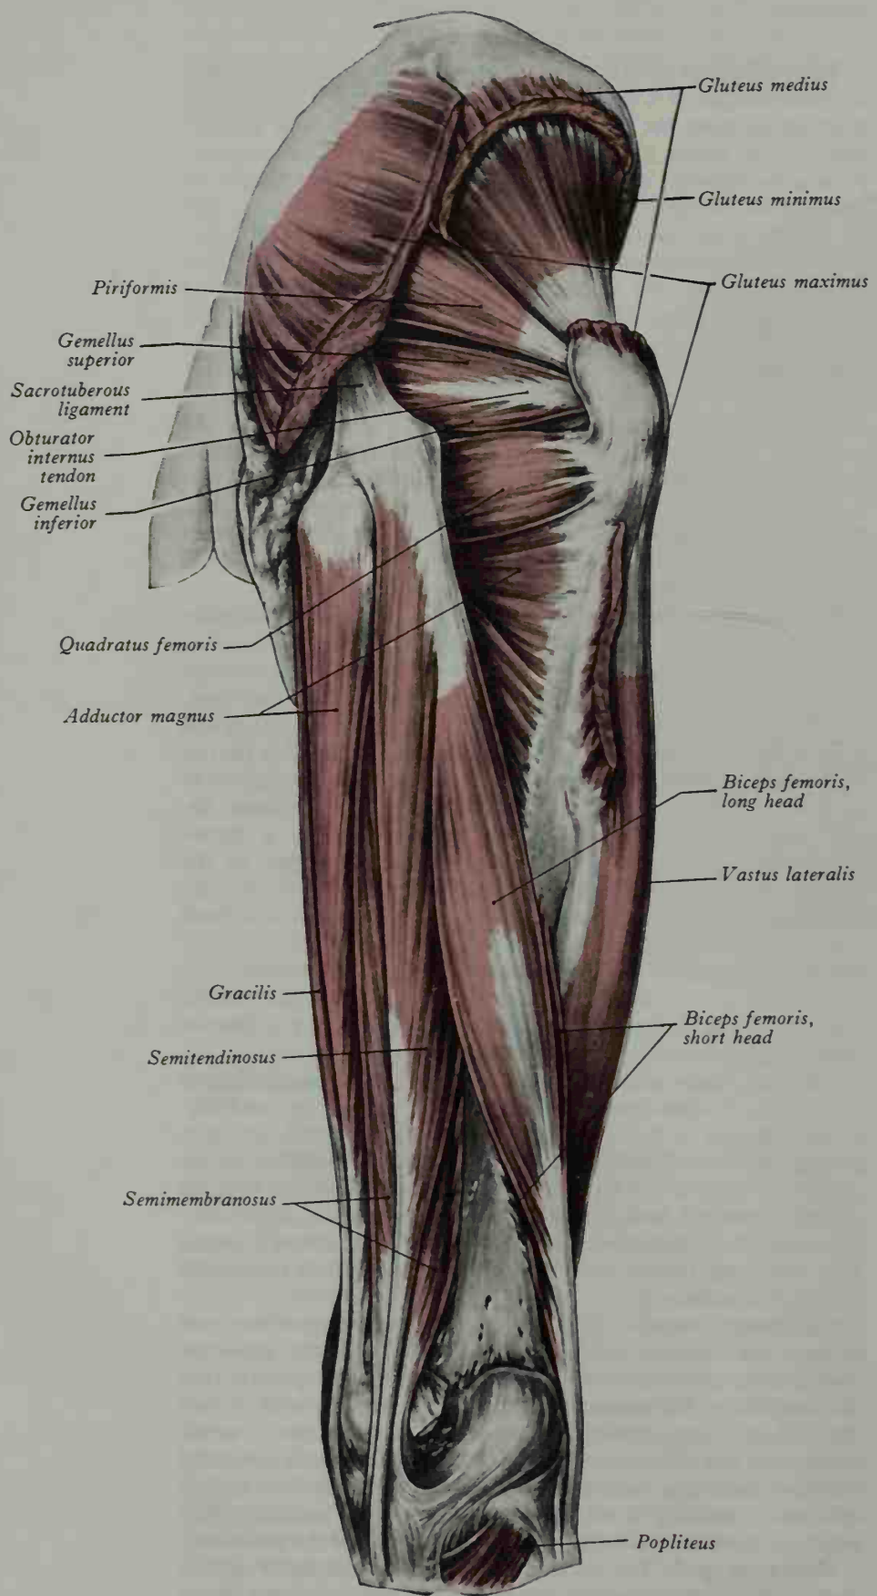
Nerve supply. The anterior division of the obturator nerve, L. 2, **3** and 4.

The adductor brevis (5.87, 88) is posterior to pectineus and adductor longus. It is somewhat triangular, and arises by a narrow attachment from the external aspect of the body and inferior ramus of the pubis, between the gracilis and obturator externus. Passing backwards, laterally and downwards, it is attached by an aponeurosis to the femur, along a line leading from the lesser trochanter to the linea aspera, and into the upper part of the latter immediately behind pectineus and the upper part of adductor longus. The adductor brevis is frequently divided into two or three separate parts, or it may be integrated into the adductor magnus.

Relations. Its *anterior surface* is related to pectineus, adductor longus, the profunda femoris artery, and anterior branch of the obturator nerve; *posteriorly*, are adductor magnus and the posterior branch of the obturator nerve; the medial circumflex femoral artery, obturator externus, and conjoined tendon of psoas major and iliacus are related to its *upper border*, and to its *lower border*, gracilis and adductor magnus. Near its attachment the second, or first and second, perforating arteries pierce it.

Nerve supply. The obturator nerve, L. 2, **3** and 4.

The adductor magnus (5.87, 88, 89), a massive triangular muscle, arises from a small part of the inferior ramus of the pubis, from the ramus of the ischium, and from the inferolateral aspect of the ischial tuberosity. The fibres from the pubic ramus are short, horizontal, and attached to the medial margin of the gluteal tuberosity of the femur, medial to gluteus maximus; this part of the muscle, anterior in plane to the rest, is sometimes described as *adductor minimus*. The fibres from the ramus of the ischium fan out downwards and laterally, to be attached by a broad aponeurosis, to the linea aspera and the proximal part of the medial supracondylar line. The medial part of the muscle, principally fibres arising from the ischial tuberosity, is a thick mass which descends almost vertically, and ends about the lower third of the thigh in a rounded tendon, palpable proximal to its attachment to the adductor tubercle (p. 394) on the medial condyle of the femur. The tendon is connected by a fibrous expansion to the medial supracondylar line.



The long, linear attachment of the whole muscle is interrupted by a series of osseo-aponeurotic openings, formed by *tendinous arches* attached to the bone. The upper four are small, and give passage to the perforating branches and the termination of the profunda femoris artery. The lowest is large, and the femoral vessels traverse it to the popliteal fossa. The vertical, ischiocondylar part of the muscle varies in its degree of separation from the rest. The upper border of the adductor magnus may be fused with the quadratus femoris.

Relations. *Anterior*, are the pectineus, adductores brevis et longus, the femoral and profunda vessels, and the posterior branch of the obturator nerve; a bursa separates the highest part of the muscle and the lesser trochanter of the femur. *Posterior*, are the sciatic nerve, gluteus maximus, biceps femoris, semitendinosus and semimembranosus. The *superior border* is parallel with the quadratus femoris, the transverse branch of the medial circumflex femoral artery passing between the muscles. The *medial border* is related to the gracilis, sartorius and the fascia lata.

Nerve supply. The adductor magnus is composite and is innervated by the obturator nerve and the tibial division of the sciatic nerve, L. 2, **3** and **4**. The latter supplies the ischiocondylar part. Both nerves are derived from *anterior* divisions in the

lumbosacral plexus, indicating a flexor origin for both parts of the muscle.

Actions. Extensive or forcible adduction of the femur is not a common action, and although the adductors can, of course, so act when required, they are essentially synergists in the complex patterns of gait activity, and partly are controllers of posture. For example, they show activity during flexion and extension of the knee (Janda and Stará 1965). The magnus and longus are probably *medial* rotators of the thigh, according to later but as yet unconfirmed data (de Sousa and Vitti 1966). The same authors have pointed out that while the adductors are *inactive* during adduction of the abducted thigh in the erect posture (where gravity assists), they *are* active in other postures such as the supine position, or during adduction of the flexed thigh when erect. The adductors are also active during flexion (longus) and extension (magnus) of the thigh at the hip joint. In symmetrical easy standing their activity is minimal or absent.

5.91 The muscles of the gluteal region and flexor aspect of the right thigh. Posterior aspect.

3. The Muscles of the Gluteal Region

The muscles of the region (5.90, 91) consist of the glutei, maximus, medius et minimis, which are extensors and abductors at the hip joint, and a more deeply situated group of smaller muscles, lateral rotators at this joint, which includes the piriformis, obturatores internus et externus, gemelli superior et inferior and quadratus femoris.

The gluteus maximus (5.90), the largest and most superficial muscle in the region, is a broad and thick quadrilateral mass, forming, together with the superadded characteristic superficial fascial adipose tissue, the prominence of the buttock. Its large size is one of the most characteristic features of the muscular system in man, associated with the frequent need of bringing the trunk upright. The muscle is remarkably coarse in its fascicular architecture, its fibres being collected into large bundles separated by fibrous septa. It arises from the posterior gluteal line of the ilium, and the rough area of bone, including the crest, immediately above and behind it, from the aponeurosis of erector spinae, from the dorsal surface of the lower part of the sacrum and the side of the coccyx, from the sacrotuberous ligament, and from the fascia (gluteal aponeurosis) covering gluteus medius. The fibres descend obliquely and laterally; the upper and larger part of the muscle, together with the superficial fibres of the lower part, end in a thick tendinous lamina which passes lateral to the greater trochanter, and is attached to the iliotibial tract of the fascia lata. The deeper fibres of the lower part of the muscle are attached to the gluteal tuberosity between vastus lateralis and adductor magnus.

Three bursae usually lie deep to this muscle. One, large and generally multilocular, separates it from the greater trochanter (*trochanteric bursa of gluteus maximus*); a second is between the tendon of the muscle and that of the vastus lateralis (*gluteofemoral bursa*); a third, often absent, between the ischial tuberosity and the muscle (*ischial bursa of gluteus maximus*). Additional slips from the lumbar aponeurosis or ischial tuberosity may occur. The muscle may also be bilaminar.

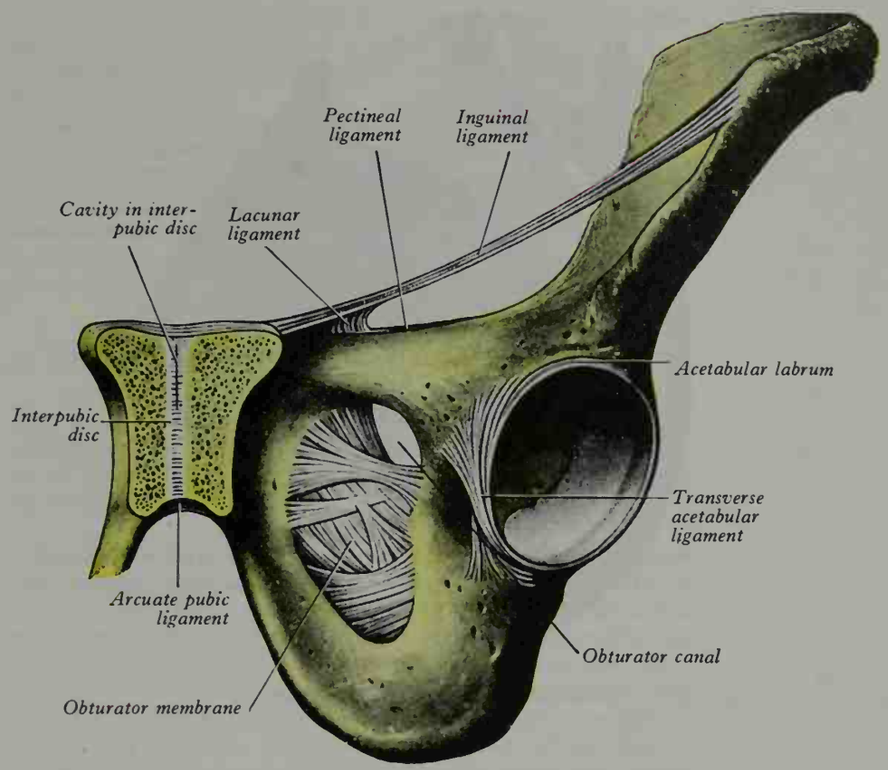
Relations. Its *superficial surface* is related to a thin fascia which separates it from subcutaneous tissue, its *deep surface*, to the ilium, sacrum, coccyx, and sacrotuberous ligament, part of gluteus medius, piriformis, gemelli, obturator internus, quadratus femoris, the tuberosity of the ischium, greater trochanter, the attachments of biceps femoris, semitendinosus, semimembranosus and adductor magnus. The superficial division of the superior gluteal artery reaches the deep surface of the muscle between piriformis and gluteus medius; the inferior gluteal and internal pudendal vessels and the sciatic, pudendal and posterior femoral cutaneous nerves and muscular branches from the sacral plexus issue from the pelvis below piriformis. The first perforating artery and the terminal branches of the medial circumflex femoral artery are also deep to the lower part of the muscle. Its *upper border* is thin, and superficial to gluteus medius. Its *lower border* is free and prominent (directed, as is the upper border, *downwards* and *laterally*) and is *crossed* by the *horizontal gluteal fold*, which is the *posterior flexure line* of the hip joint, and can be taken as marking the upper limit of the back of the thigh on the surface (5.39). (*The anterior flexure line* corresponds to the zone of fusion between the membranous layer of superficial fascia and the deep fascia below the medial part of the inguinal ligament.)

Nerve supply. The inferior gluteal nerve, L. 5 and S. 1 and 2. For details of the intramuscular distribution of the gluteal nerves consult Menning *et al.* (1974).

Actions. When the gluteus maximus acts from the pelvis, it can extend the flexed thigh and bring it into line with the trunk.

Taking its fixed point as distal, it may prevent the forward momentum of the trunk from causing flexion at the supporting hip during bipedal gait. In standing, the muscle is inactive and remains so in forward swaying at the ankle joints or during bending forwards at the hip joints to touch the toes. However, in conjunction with the hamstrings, it is active in raising the trunk, after stooping, by rotating the pelvis backwards on the head of the femur (Joseph and Williams 1957). It is active intermittently in the walking cycle and climbing upstairs, and continuously active in strong lateral rotation of the thigh. Its upper fibres are active in powerful abduction of the thigh. It is a tensor of the fascia lata, and through the iliotibial tract it steadies the femur on the tibia, when the knee extensor muscles are relaxed.

The gluteus medius is a broad, thick muscle on the outer surface of the pelvis. Its posterior third is covered by gluteus maximus; its anterior two-thirds is superficial and covered by a strong layer of deep fascia (**5**.90). It arises from the outer surface of the ilium between the iliac crest and posterior gluteal line above, and the anterior gluteal line below; it also arises from the strong fascia superficial to its upper part. The fibres converge into a flattened tendon, which is attached to the oblique ridge slanting downwards and forwards on the lateral surface of the greater trochanter. A bursa (*trochanteric bursa of gluteus medius*) separates the tendon from the anterosuperior area of the lateral surface of the trochanter, over which it glides. A deep slip of the muscle may be attached to the upper border of the trochanter. The posterior edge of gluteus medius is sometimes blended with piriformis.



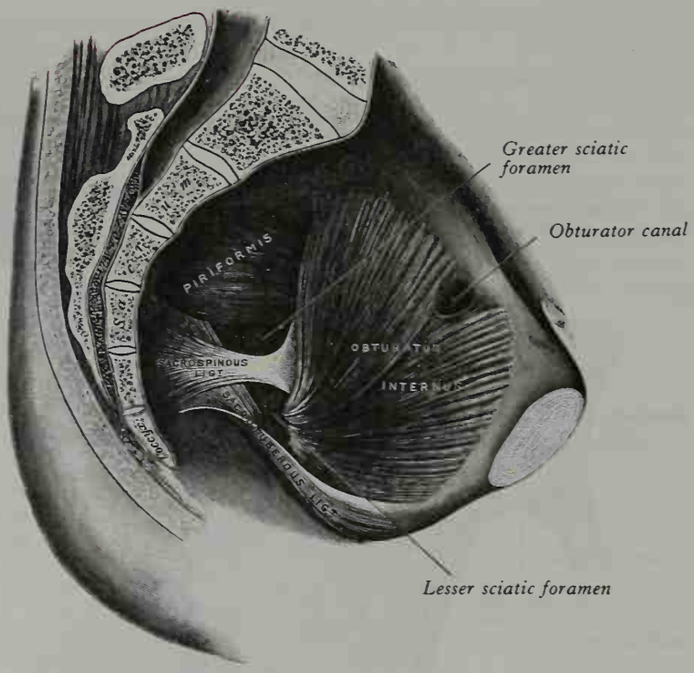
The gluteus minimus (**5**.91), the smallest of the group, is deep to the medius. It is fan-shaped, arising from the outer surface of the ilium between the anterior and inferior gluteal lines and, behind, from the margin of the greater sciatic notch. The fibres converge to the deep surface of an aponeurosis, and this ends in a tendon attached to a ridge laterally situated on the anterior surface of the greater trochanter, and gives an expansion to the capsule of the hip joint. A bursa (*trochanteric bursa of gluteus minimus*) separates the tendon from the medial part of the anterior surface of the greater trochanter. The muscle may be divided into anterior and posterior parts. Separate slips may pass to piriformis, gemellus superior, or vastus lateralis.

Relations. Between the gluteus medius and gluteus minimus are the deep branches of the superior gluteal vessels, and the superior gluteal nerve. The reflected tendon of the rectus femoris and the capsule of the hip joint are deep to the gluteus minimus.

Nerve supply. Both the gluteus medius and minimus are supplied by the superior gluteal nerve, L. **5** and S. 1.

Actions. Both the preceding muscles, acting from the pelvis, abduct the thigh and their anterior fibres rotate it medially. They play an essential part in maintaining the trunk upright when the foot of the opposite side is raised from the ground in walking and running, the body weight tending to make the pelvis sag downwards on the unsupported side. This tendency is counteracted by the gluteus medius and minimus of the supporting side, which, acting from below, exert such powerful traction on the hip bone that the pelvis is actually raised a little on the unsupported side. The muscles are inactive in symmetrical standing. It is, however, necessary to differentiate between different symmetrical standing postures. In standing 'at ease' with the feet somewhat separated, the abductor muscles are electromyographically 'silent' in most individuals. According to Jonsson and Steen (1962), in contrast, the muscles *are* active in the position adopted for Romberg's Test—with the feet placed parallel and close together. Evans (1977) considers that the iliotibial tract is the major factor in preventing descent of the pelvis on the unsupported side.

Applied Anatomy. The supportive effect of the glutei (medius and minimus) on the pelvis, when the foot of the opposite side is raised from the ground, is dependent on the following: (1) the two muscles, and of course their innervation, must be functioning normally; (2) the components of the hip joint, which forms the fulcrum, must be in their usual relation; (3) the neck of the femur must be intact and must exhibit its usual angulation to the shaft of the bone. When any one of these three conditions is not fulfilled, e.g.—(1) paralysis of the glutei, medius and minimus, (2) congenital dislocation of the hip joint, (3) ununited fracture of the neck of the femur or coxa vara, the supporting mechanism is upset and the pelvis sinks on the unsupported side when the patient stands on the affected limb. This is known clinically as the *Trendelenberg sign*.



5.92 The left obturator membrane. Ventral aspect.

Paralysis of the glutei medius et minimus is the most serious muscular disability in the region of the hip, and sufferers have a characteristically lurching gait. On the other hand, when these two muscles remain intact, even though many others acting on the hip joint are paralysed, the patient is able to walk, or even run, with remarkably little disability.

The piriformis (**5**.91) is almost parallel with the posterior margin of gluteus medius. It is partly within the pelvis, on its posterior wall, and partly posterior to the hip joint. It arises from the front of the sacrum by three digitations, attached to the portions of bone between the pelvic sacral foramina, and to the grooves leading from the foramina (**3**.43): it also arises from the gluteal surface of the ilium near the posterior inferior iliac spine, from the capsule of the adjacent sacro-iliac joint and sometimes from the upper part of the pelvic surface of the sacrotuberous ligament. The muscle passes out of the pelvis through the greater sciatic foramen, and is attached by a rounded tendon to the upper border of the greater trochanter of the femur, behind and above, but often partly blended with, the common tendon of the obturator internus and gemelli. The muscle may be blended with gluteus medius.

Relations. *Within the pelvis* the *anterior surface* of the piriformis is related to the rectum (especially on the left), the sacral plexus of nerves and branches of the internal iliac vessels, its *posterior surface* to the sacrum. *Outside the pelvis*, its *anterior surface* is in contact with the posterior surface of the ischium and capsule of the hip joint, its *posterior surface*, with gluteus maximus. Its *upper border* is in contact with gluteus medius, and the superior gluteal vessels and nerve, its *lower border*, with the coccygeus and gemellus superior. The inferior gluteal and internal pudendal vessels, the sciatic, posterior femoral cutaneous and pudendal nerves, and muscular branches from the sacral plexus appear in the buttock in the interval between piriformis and gemellus superior. The muscle is frequently pierced by the common peroneal nerve, which may divide it into two parts. The

5.93 The left obturator internus. Pelvic aspect.

sciatic nerve in fact varies frequently in its relation to piriformis; in a detailed analysis of 168 dissections Lee and Tsai (1974) observed variation in almost 30 per cent. The undivided nerve emerged *above* the muscle in 2·98 per cent, through the muscle in 1·8 per cent, with its divisions above and below in 4·2 per cent, with one division between the heads of a divided muscle and one division either above (1·2 per cent) or below (19·6 per cent), the last being the commonest variation.

In a larger series (2,250 specimens), reported by Anson (1963), the incidence of variation was only 10·7 per cent (242 specimens); in 10 per cent (222) the common peroneal division separately traversed the muscle, the whole nerve in 0·2 per cent (5), and the two divisions appeared above and below in 0·7 per cent (15); in this series the entire nerve never appeared at the upper border of the muscle.

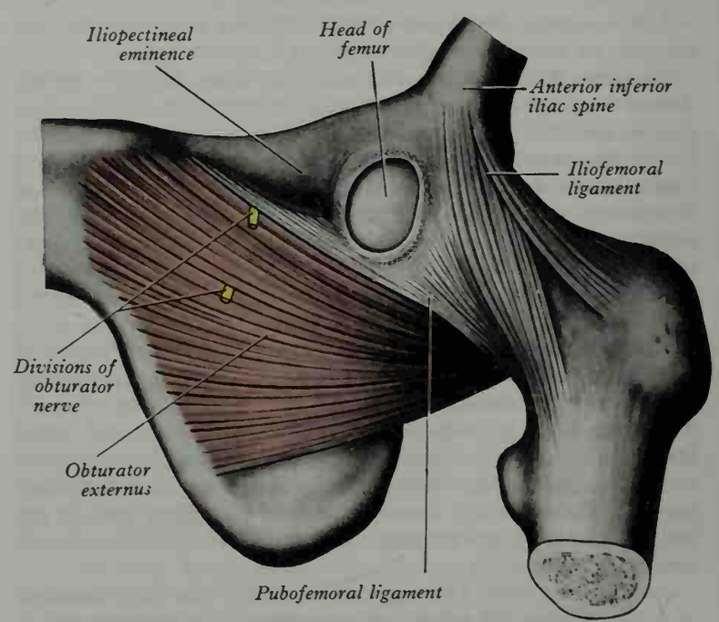
Nerve supply. Branches from L. 5. S. **1** and 2.

Actions. The piriformis rotates the extended thigh laterally, but abducts the flexed thigh.

The obturator membrane (**5**.92) is a thin aponeurosis which nearly closes the obturator foramen. Its fibres are arranged in interlacing bundles mainly transverse in direction; the uppermost bundle is attached to the obturator tubercles and completes the obturator canal through which pass the obturator vessels and nerve. The membrane is attached to the sharp margin of the obturator foramen except at its lower lateral angle, where it is fixed to the pelvic surface of the ramus of the ischium, i.e. internal to the margin of the foramen. The obturator muscles are attached on opposite surfaces of this aponeurosis, and some of the fibres of the pubofemoral ligament of the hip joint are attached to its inferior surface. The aponeurosis, of course, *obturates* its foramen.

The obturator internus (**5**.93) is situated partly within the true pelvis, partly posterior to the hip joint. It arises from the internal surface of the anterolateral wall of the pelvis, where it surrounds the greater part of the obturator foramen, being attached to the inferior ramus of the pubis, the ramus of the ischium and to the pelvic surface of the hip bone below and behind the pelvic brim, reaching from the upper part of the greater sciatic foramen above and behind, to the obturator foramen below and in front (**3**.172). It also arises from the medial part of the pelvic surface of the obturator membrane, from the tendinous arch which completes the obturator canal, and to a slight extent from the obturator fascia, which covers the muscle. The fibres converge rapidly towards the lesser sciatic foramen and end in four or five tendinous bands in the deep surface of the muscle; these bands make a right-angled bend over the grooved surface of the ischium between its spine and tuberosity. The grooved surface is covered by smooth cartilage, which is separated from the tendon by a bursa, and presents one or more ridges corresponding with the furrows between the tendinous bands. These bands leave the pelvis through the lesser sciatic foramen and unite into a single flattened tendon, which passes horizontally across the capsule of the hip joint, and, after receiving the attachments of the gemelli, is attached to the anterior impression on the medial surface of the greater trochanter anterosuperior to the trochanteric fossa. A narrow and elongate bursa usually exists between the tendon and the capsule of the hip joint; it occasionally communicates with the bursa between the tendon and the ischium.

Relations. *Within the pelvis*, the *anterolateral surface* of the muscle is in contact with the obturator membrane and inner surface of the lateral wall of the pelvis, its *pelvic surface*, with the obturator fascia, and the origin of the levator ani, and with the sheath which surrounds the internal pudendal vessels and pudendal nerve (p. 560). The pelvic surface forms the lateral boundary of the ischiorectal fossa. *Outside the pelvis*, the muscle is covered by gluteus maximus, is crossed by the sciatic nerve, and is posterior to the hip joint. As the tendon of the obturator internus emerges from the lesser sciatic foramen it is overlapped both above and below by the two gemelli, which form a muscular canal for it; near its termination the gemelli pass anterior to the tendon and form a groove in which it lies.



Nerve supply. The nerve to obturator internus, L. 5 and S. **1**.

The gemelli (**5**.91) are two small muscular fasciculi, adjacent to, partially enclosing, and finally blending with the tendon of the obturator internus.

The gemellus superior, the smaller of the two, arises from the dorsal surface of the spine of the ischium, blends with the upper part of the tendon of obturator internus, and is attached with it to the medial surface of the greater trochanter. It is sometimes absent.

Nerve supply. The nerve to the obturator internus, L. 5 and S. 1.

The gemellus inferior arises from the upper part of the tuberosity of the ischium, immediately below the groove for the obturator internus tendon. It blends with the lower part of this

5.94 The left obturator externus. Antero-inferior aspect. The bursa of psoas major tendon, which in this specimen communicated with the synovial cavity of the hip joint, has been opened to expose the head of the femur.

tendon, and is attached with it into the medial surface of the greater trochanter.

Nerve supply. The nerve to the quadratus femoris, L. 5 and S. 1.

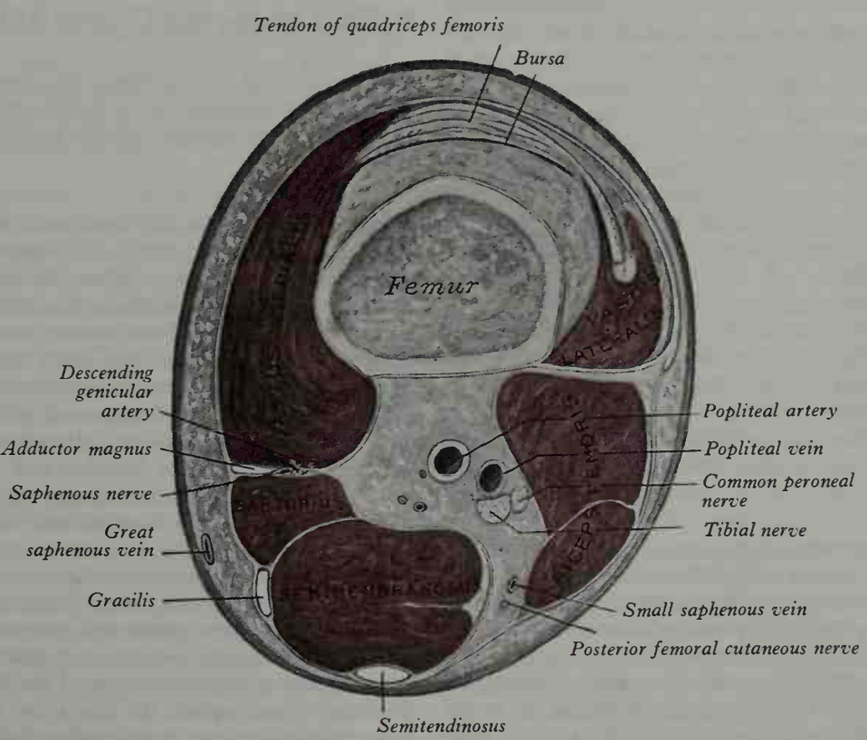
Action. The obturator internus and the gemelli rotate the extended thigh laterally; they abduct the flexed thigh.

The quadratus femoris (**5**.91) is a flat, quadrilateral muscle, between the gemellus inferior and the upper margin of adductor magnus, separated from it by the transverse branch of the medial circumflex femoral artery. It arises from the upper part of the external aspect of the tuberosity of the ischium, and is attached to a small tubercle on the upper part of the trochanteric crest of the femur and for a short distance to the bone below. As it passes to this attachment the muscle is posterior to the hip joint and the neck of the femur, but it is separated from them by the tendon of obturator externus and the ascending branch of the medial circumflex femoral artery. A bursa often exists between the front of this muscle and the lesser trochanter. The muscle may be absent.

Nerve supply. The nerve to quadratus femoris, L. 5 and S. 1. For a detailed analysis of this muscle's arterial supply (chiefly from the medial circumflex and first perforating arteries) consult Leborgne *et al.* (1973).

Action. The quadratus femoris is a lateral rotator of the thigh.

The obturator externus (**5**.94) is flat and triangular, covering the external surface of the anterior pelvic wall. It arises from bone immediately around the medial side of the obturator foramen, viz. from the rami of the pubis, and the ramus of the ischium; it also arises from the medial two-thirds of the outer surface of the obturator membrane, and from the tendinous arch which completes the obturator foramen, viz. from the rami of the pubis for a short distance on to the pelvic surface of the bone, where they obtain a narrow attachment between the margin of the foramen and the obturator membrane (p. 602). The fibres converge and pass backwards, laterally and upwards, and end in a tendon which crosses the back of the neck of the femur and lower part of the capsule of the hip joint to end in the trochanteric fossa of the femur. A bursa, which communicates with the hip joint, may be interposed between this tendon and the hip joint capsule and femoral neck. The obturator vessels lie between the muscle and the obturator membrane; the anterior branch of the obturator nerve reaches the thigh by passing in front of the muscle, and the posterior branch by piercing it (**5**.94).



Nerve supply. The posterior branch of the obturator nerve, L. 3 and **4**.

Action. The obturator externus is a lateral rotator of the thigh. The short muscles around the hip joint—the pectineus, piriformis, obturatores, gemelli and quadratus femoris—are possibly more important as postural muscles than as prime movers. They may act as adjustable ligaments of the joint in all positions, but they are in any case largely inaccessible to direct observations, and such views are necessarily speculative.

4. The Posterior Femoral Muscles

The posterior femoral muscles (**5**.91), the biceps femoris, semitendinosus, and semimembranosus, often grouped familiarly as the '*hamstrings*', span the hip and knee joints, integrating extension at the former with flexion at the latter.

The biceps femoris (**5**.87, 89, 91) is posterolateral in the thigh and has two proximal attachments—one, the long head, arising from the inferomedial impression on the upper area of the ischial tuberosity (**3**.173) by a tendon common to it and semitendinosus, and from the lower part of the sacrotuberous ligament, the other, the short head, from the lateral lip of the linea aspera, between the adductor magnus and vastus lateralis, extending almost as high as the gluteus maximus, from the lateral supracondylar line to within 5 cm of the lateral condyle, and from the lateral intermuscular septum. The fibres of the long head form a fusiform belly which descends laterally across the sciatic nerve to end in an aponeurosis which covers the posterior surface of the muscle, receives on its deep surface the fibres of the short head, and gradually narrows down into a tendon (the lateral hamstring). The main part of the tendon splits round the fibular collateral ligament and is attached to the head of the fibula. The remainder splits into three laminae, the intermediate of which fuses with the fibular collateral ligament while the others pass superficial and deep to the ligament to be attached to the lateral condyle of the tibia (Sneath 1955). The common peroneal nerve descends along the medial border of the tendon and separates it below from the lateral head of gastrocnemius. The short head may be absent. Additional slips may arise from the ischial tuberosity, linea

5.95 Transverse section through the right thigh, about 4 cm superior to the adductor tubercle of the femur. Proximal (superior) aspect.

aspera, or medial supracondylar line.

Nerve supply. The biceps femoris is supplied by the sciatic nerve; the long head through its tibial part and the short head through the common peroneal part, L. 5, S. 1 and 2, indicating the muscle's composite derivation from flexor and extensor musculature. (See also nerve supply of semimembranosus.)

The semitendinosus (5.89, 91), remarkable for the great length of its tendon, is posteromedial in the thigh. It arises from the inferomedial impression on the upper part of the ischial tuberosity, by a tendon shared with the long head of biceps femoris, and from an aponeurosis connecting the adjacent surfaces of the two muscles to the extent of about 7·5 cm from their origin. The muscle is fusiform and ends a little below the middle of the thigh in a long, rounded tendon, which lies on the surface of semimembranosus; the tendon curves around the medial condyle of the tibia, passes over the tibial collateral ligament of the knee joint, from which it is separated by a bursa, and is attached to the upper part of the medial surface of the tibia behind the attachment of sartorius and below that of gracilis. At its termination it is united with the tendon of gracilis and gives off a prolongation to the deep fascia of the leg. A tendinous interruption is usually present about the mid level of the muscle, which may also receive a muscular slip from the long head of biceps femoris.

Nerve supply. The sciatic nerve through its tibial division, L. 5, S. 1 and 2. (See also nerve supply of semimembranosus.)

The semimembranosus (5.89, 91, 95), so-called because of the flattened membranous form of its upper attachment, is posteromedial in the thigh. It arises by a tendon from the superolateral impression on the ischial tuberosity (3.173). Inferomedially its fibres are interwoven with those of the biceps femoris and semitendinosus and in addition its upper tendon receives, from the ischial tuberosity and ramus, two fibrous expansions which flank the adductor magnus. This upper tendon expands into an aponeurosis which passes downwards deep to the semitendinosus and long head of biceps femoris; from this muscular fibres arise, and converge to a second aponeurosis which is posterior to the lower part of the muscle and narrows into the tendon of lower attachment. The latter divides at the level of the knee into five components, the principal one being attached to the tubercle (sometimes called the *tuberculum tendinis*) on the posterior aspect of the medial tibial condyle (Cave and Porteous 1958). The additional attachments consist of a series of slips to the medial margin of the tibia immediately behind the tibial collateral ligament, a thin fibrous expansion to the fascia over popliteus, a thick cord-like tendon to the inferior lip and adjacent part of the groove on the back of the medial tibial condyle, deep to the tibial collateral ligament, and a variable number of fasciculi, which pass upwards and laterally to the intercondylar line and lateral femoral condyle, forming the oblique popliteal ligament of the knee joint. The muscle overlaps the upper part of the popliteal vessels and is itself partly overlapped by semitendinosus throughout its extent (5.91). (The distal tendons of semitendinosus and semimembranosus are the medial 'hamstring'.)

The semimembranosus varies much in size, and may be absent. It may be double, arising mainly from the sacrotuberous ligament. Slips to the femur or adductor magnus may occur.

Nerve supply. The sciatic nerve from its tibial portion, L. 5, S. 1 and 2. The detailed intramuscular distributions of the nerves supplying the posterior femoral muscles have been described by Himstedt *et al.* (1974).

Actions. The posterior femoral muscles, acting from above, flex the leg on the thigh. Acting from below, as extensors of the hip joint, they draw the trunk upright against gravity when it is raised from the stooping position; the biceps is the most active in this. When the knee is semiflexed, the biceps femoris can act as a lateral rotator, and the semimembranosus and semitendinosus as medial rotators of the leg. Biceps also laterally rotates the thigh when the hip is extended, the semimembranosus and semitendinosus being medial rotators in these circumstances.

As is the case with the quadriceps femoris, the adductors and gluteus maximus, the hamstrings are quiescent in easy symmetrical standing. However, any action which carries the line of body weight in front of the transverse axis of the hip joints, e.g. forward reaching, forward sway at the ankle joints, or forward bending at the hips, is immediately accompanied by strong contraction of the hamstrings. (This is in marked contrast to gluteus maximus which only contracts when powerful extensor activity at the hip joint is required.)

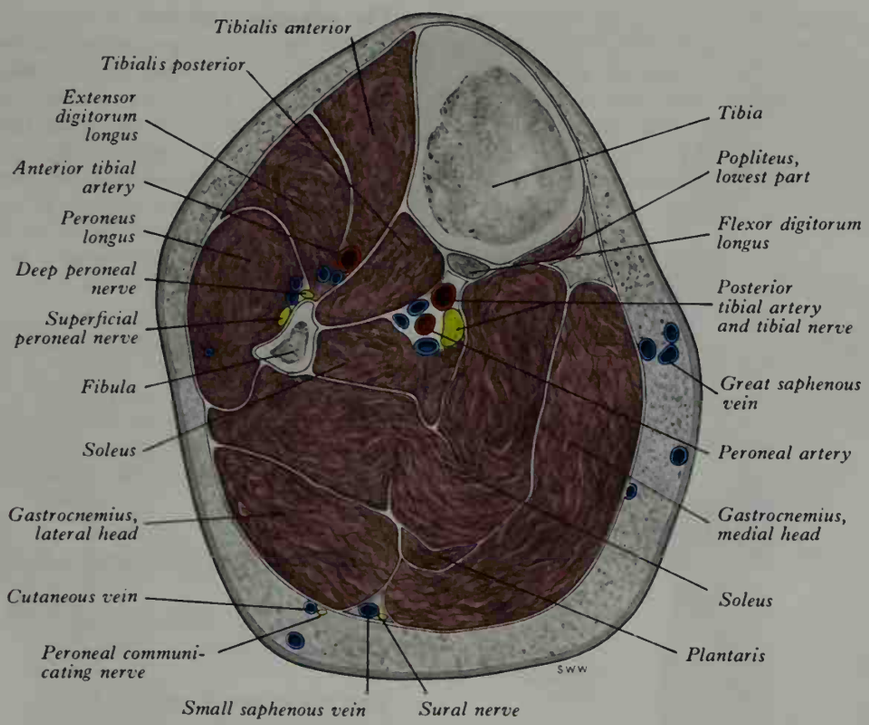
When the knee is flexed against resistance, the tendon of biceps can be felt lateral to the depression over the popliteal fossa. Medial to the fossa, the tendons of gracilis, which is the more medial, and semitendinosus stand out sharply, and in the interval between them the semimembranosus tendon can be felt, though less distinctly owing to its deep location.

There is some evidence that the semimembranosus, semitendinosus and biceps femoris, which pass over both the hip and knee joints, can produce movement at only one of these joints while at the same time offering no resistance to the antagonistic movement at the other joint on which they act (Markee *et al.* 1955). Each of these muscles, however, usually contracts as a whole, and the consequent movement at the hip or knee is determined by other muscles fixing the position of one or other articulation.

Applied Anatomy. In disease of the knee joint, contracture of the flexor tendons is a frequent complication; this causes flexion of the leg, and a partial dislocation of the tibia backwards, with a slight degree of lateral rotation, probably due to biceps femoris.

When the flexor tendons require surgical manipulation the relation of the common peroneal nerve to the medial border of the tendon of biceps femoris must be borne in mind.

The relative length of the flexors, when relaxed, shows considerable variation and in some individuals the muscles are so short that they impose a serious limitation on flexion of the trunk at the hip joints when the knees are kept extended. Such movements as stooping are then largely effected by flexion of the vertebral column or by squatting.



III. The Muscles of the Leg

This group, which consists basically of anterior extensors and posterior flexors, also includes a lateral set, derived from the extensors, the peronei.

1. The Anterior Crural Muscles

The muscles of this group (5.97) consist of a common digital extensor, an extensor of the hallux, and two dorsiflexors of the foot (with other actions), tibialis anterior and peroneus tertius.

The fascia cruris, the deep fascia of the leg, is continuous, of course, with the fascia lata, and is attached around the knee to the patella, the ligamentum patellae, the tubercle and condyles of the tibia and the head of the fibula. Posteriorly, it forms the popliteal fascia, over the popliteal fossa; here it is strengthened by transverse fibres, and perforated by the small saphenous vein. It receives expansions from the tendon of biceps femoris laterally, and from the tendons of sartorius, gracilis, semitendinosus and semimembranosus medially; it blends with the periosteum on the subcutaneous surface of the tibia and the head and malleolus of the fibula; below, it is continuous with the extensor and flexor retinacula (p. 611). It is thick and dense in the proximal and anterior part of the leg, and to its deep surface some fibres of tibialis anterior and extensor digitorum longus are attached; it is thinner behind, where it covers gastrocnemius and soleus. On the lateral side it is continuous with the *anterior* and *posterior crural intermuscular septa*, which are attached respectively to the anterior and posterior borders of the fibula; in the anterior and posterior crural regions the fascia also has several slender extensions which enclose individual muscles. A broad, transverse, intermuscular septum, the *deep transverse fascia of the leg* (5.99), passes between the superficial and deep muscles on the back of the

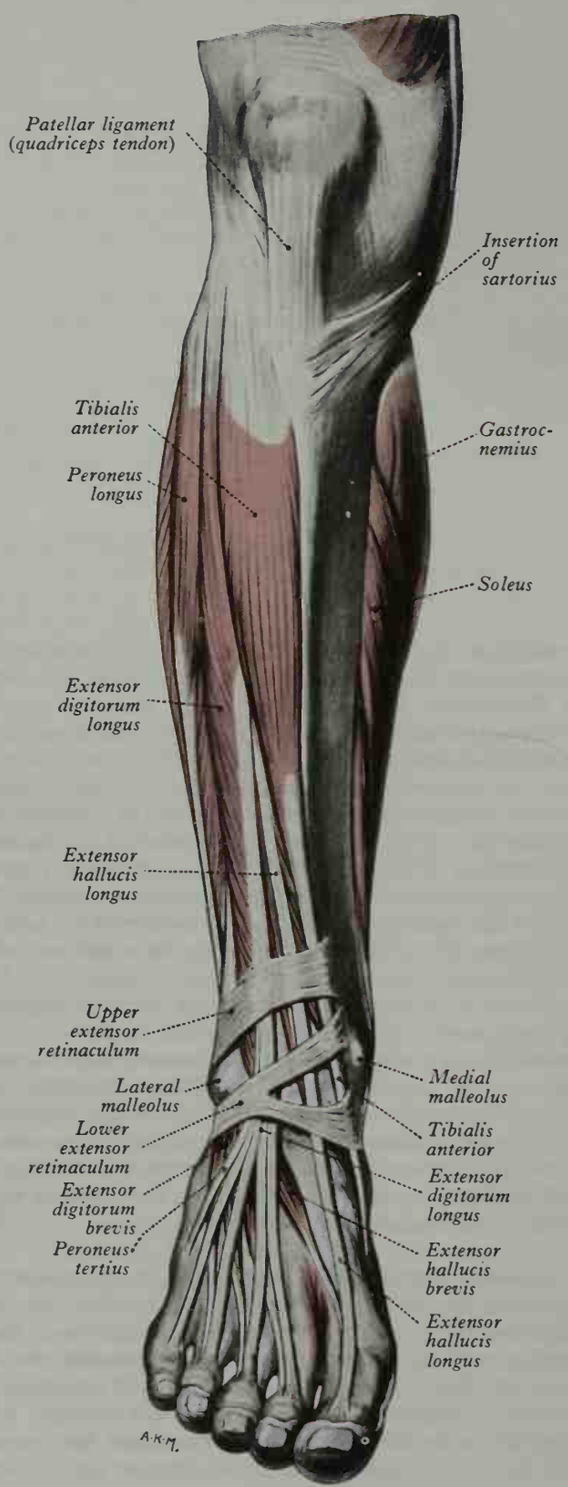
5.96 Transverse section through the right leg, about 10 cm distal to the knee joint. Distal aspect.

leg. These separately named sheets are, of course, all united together, as a kind of auxiliary, connective tissue 'skeleton'.

The tibialis anterior (5.96, 97), situated lateral to the tibia, is thick and muscular above, tendinous below. It arises from the lateral condyle and upper half or two-thirds of the lateral surface of the tibial shaft, from the adjoining part of the anterior surface of the interosseous membrane, from the deep surface of the fascia cruris, and from the intermuscular septum between it and extensor digitorum longus. The muscle descends vertically to end in a tendon on its anterior surface in the lower third of the leg; this passes through the medial compartments of the superior and inferior extensor retinacula, inclines medially, and is attached to the medial and inferior surfaces of the medial cuneiform and the adjoining part of the base of the first metatarsal bone. This muscle overlaps the anterior tibial vessels and deep peroneal nerve in the upper part of the leg. Attachments to the talus, first metatarsal head, or the base of the proximal phalanx of the hallux have been recorded.

Actions. The tibialis anterior is a dorsiflexor of the talocrural joint and invertor of the foot. It is most active when both movements are combined, as in walking. It elevates the first metatarsal and medial cuneiform and rotates them laterally. Its tendon can be seen through the skin lateral to the anterior border of the tibia and traced downwards and medially across the front of the ankle to the medial side of the foot.

In standing still the muscle is in most cases quiescent, reflecting the fact that the line of body weight passes anterior to the talocrural joints. It can act from below and assist in maintaining the balance of the body by drawing the leg forwards at the talocrural joint, when there is a tendency to overbalance in a backward direction. It is frequently said to be active during any movement which raises the summit of the longitudinal arch of the foot. Electromyographic experimentation (under somewhat artificial conditions) suggests that activity in this and other 'arch supporting' muscles is minimal in standing, but there appears to be no doubt that tibialis anterior contracts powerfully to increase the arch in the take-off and toeing of walking and running.



The extensor hallucis longus (5.97, 99) lies between and partly deep to the tibialis anterior and extensor digitorum longus. It arises from the middle two-fourths of the medial surface of the fibula, medial to the extensor digitorum longus; it also arises from the anterior surface of the interosseous membrane to a similar extent. The anterior tibial vessels and deep peroneal nerve are between it and tibialis anterior. The fibres pass down into a tendon which occupies the anterior border of the muscle. It passes deep to the superior and through the inferior extensor retinaculum, crosses to the medial side of the anterior tibial vessels near the talocrural joint, and is attached to the dorsal aspect of the base of the distal phalanx of the great toe. Opposite the metatarsophalangeal articulation a thin prolongation from each side of the tendon covers the dorsal surface of the joint. An expansion from the medial side of the tendon to the base of the proximal phalanx is usually present.

The muscle is sometimes united with extensor digitorum longus; it may send a slip into the second toe.

Actions. The extensor hallucis longus extends the phalanges of the great toe and dorsiflexes the foot. When the great toe is actively extended, relatively little external force is required to overcome the extension of the distal phalanx, whereas considerable force must be exerted to overcome the extension of the proximal phalanx. Its tendon can readily be identified on the lateral side of the tendon of tibialis anterior.

The extensor digitorum longus (5.96, 97, 99) is a pennate muscle, arising from the lateral condyle of the tibia, the upper three-fourths of the medial surface of the fibula, the upper part of the anterior surface of the interosseous membrane, the deep surface of the fascia cruris, the anterior crural intermuscular septum and the septum between it and tibialis anterior. In the upper part of the leg the anterior tibial vessels and deep peroneal nerve are between the muscle and tibialis anterior and, at a lower level, extensor hallucis longus also intervenes between them. The tendon of extensor digitorum longus passes behind the superior extensor retinaculum and within the loop of the inferior extensor retinaculum (p. 611) with the peroneus tertius (5.103). It divides into four slips, which run forward on the dorsum of the foot, and are attached in the same way as the tendons of the extensor digitorum in the hand (p. 579). Opposite the metatarsophalangeal joints the tendons to the second, third, and fourth toes are each joined on the lateral side by a tendon of extensor digitorum brevis. The *dorsal digital expansion* thus formed on the dorsal aspect of the proximal phalanx, like that on the fingers, receives

contributions from the lumbrical and interosseous muscles (pp. 615–16). Narrowing, as it approaches a proximal interphalangeal joint, the expansion divides into three slips—an intermediate, attached to the base of the middle phalanx, and two collateral, which reunite on the dorsum of the middle phalanx and are attached to the base of the distal phalanx. The tendons to the second and fifth toes are sometimes doubled. Accessory slips

5.97 Muscles on extensor aspect of right leg. (From Quain's *Anatomy*, 11th edition.)

attached to metatarsals occasionally exist, as may a slip to the hallux.

Actions. The extensor digitorum longus extends the toes, and dorsiflexes the foot in synergy with tibialis anterior and extensor hallucis longus. Acting with the latter it tautens the plantar aponeurosis (pp. 612, 617).

The peroneus tertius (5.97, 104) is a part of the extensor digitorum longus, and might be described as its fifth tendon. The muscular fibres operating on this tendon arise from the lower third or more of the medial surface of the fibula, the adjoining anterior surface of the interosseous membrane and the anterior crural intermuscular septum. The tendon passes behind the superior and within the loop of the inferior extensor retinaculum with extensor digitorum longus (5.103), and is attached to the medial part of the dorsal surface of the base of the fifth metatarsal bone, but a thin expansion usually extends forwards along the medial border of the shaft of the bone. This muscle is sometimes missing.

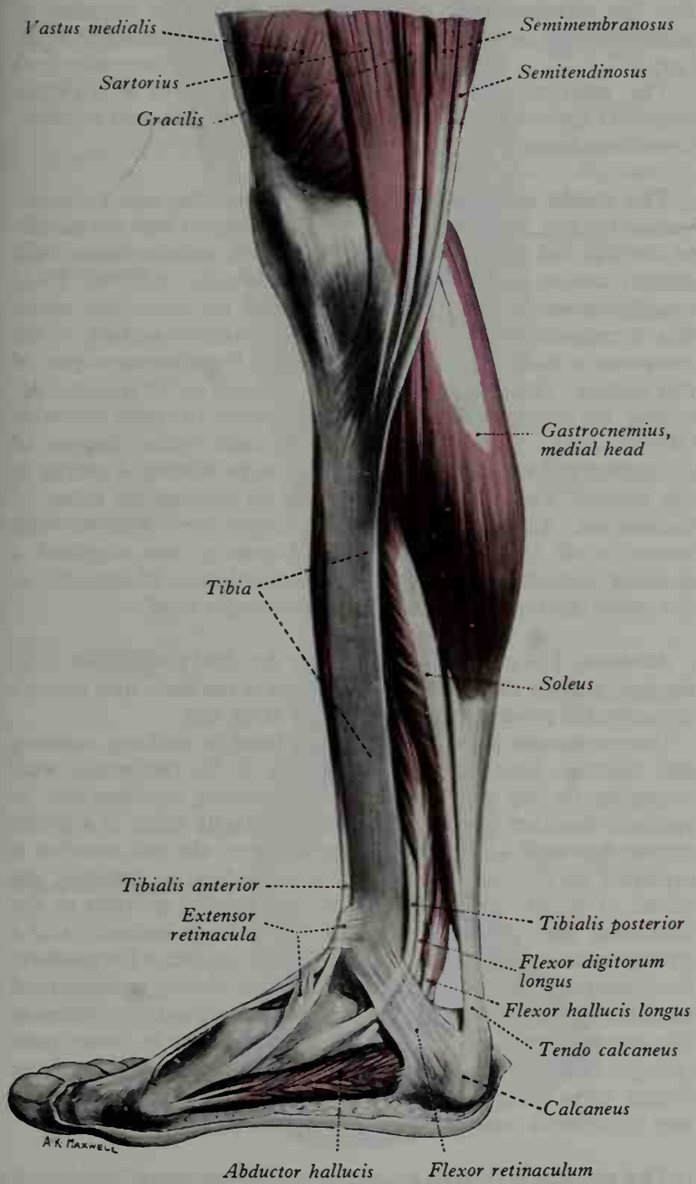
Actions. The peroneus tertius dorsiflexes the foot, acting as a part of extensor digitorum longus. It may also aid in eversion of the foot.

Nerve supply. All the anterior crural muscles are supplied by the deep peroneal nerve. The tibialis anterior is innervated by L. **4** and 5, but the others receive their supply from L. 5 and S. 1.

2. The Lateral Crural Muscles

The lateral group of leg muscles are the peroneus longus et brevis, evertors of the foot (5.96–101).

The peroneus longus (5.96, 100, 101), the more superficial, arises from the head and upper two-thirds of the lateral surface of the fibula, from the deep surface of the fascia cruris, and from the anterior and posterior crural intermuscular septa and occasionally also by a few fibres from the lateral condyle of the tibia. Between its attachments to the head and body of the fibula, there is a gap through which the common peroneal nerve passes. It ends in a long tendon, which runs behind the lateral malleolus, in a groove shared by the tendon of the peroneus brevis, behind which it lies; the groove is converted into a canal by the superior peroneal retinaculum, and the tendons are contained in a common synovial sheath (5.104). The peroneus longus tendon then runs obliquely forwards across the lateral side of the calcaneus, below the peroneal trochlea and the tendon of peroneus brevis, and beneath the inferior peroneal retinaculum (p. 611); it crosses the lateral side of the cuboid, and then runs under it in a groove converted into a canal by the long plantar ligament (4.90). It crosses the sole of the foot obliquely, and is attached by two slips to the lateral side of the base of the first metatarsal bone and the medial cuneiform; occasionally a third slip is attached to the base of the second metatarsal bone. The tendon changes its direction at two points: (*a*) below the lateral malleolus, (*b*) on the cuboid bone; in both situations it is thickened, and, in the latter a sesamoid fibrocartilage (sometimes a bone) is usually developed in it. A second synovial sheath invests the tendon as it crosses the sole of the foot.



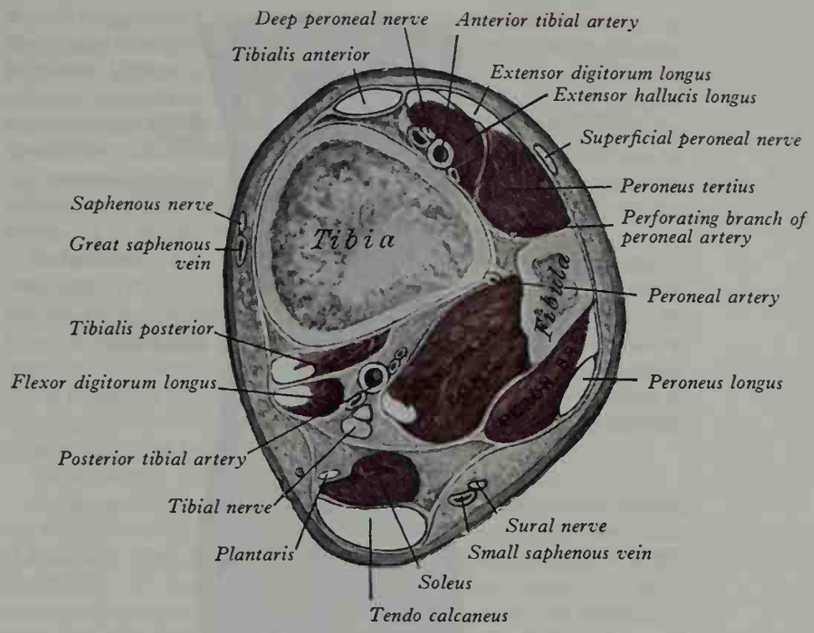
Tendinous slips to the base of the third, fourth or fifth metatarsal bone may occur, or to the adductor hallucis. Fusion of the peroneus longus and brevis is a rare variation.

Nerve supply. The peroneus longus is supplied by the superficial peroneal nerve, L. **5**, S. **1** and 2.

Actions. There is no doubt that the peroneus longus can evert and plantar-flex the foot, and perhaps act on the leg from its distal attachments. The oblique direction of its tendon across the sole also appears likely to be of some value in regard to the longitudinal and transverse arches of the foot. The question is: How do these potentialities contribute to actual movements? With the foot off the ground the eversion is unquestionable, the tendon and muscle being prominent to eye and touch. How far the same action helps to maintain plantigrade contact of the foot in standing is uncertain; however, the electromyographic evidence indicates little or no peroneal activity in standing. But peroneus longus and brevis come strongly into action to maintain the concavity of the foot in take-off and tip-toeing. In deliberate swaying to one side the peronei contract on that side, but how far they enter into postural activity between the foot and leg is not clear.

The peroneus brevis (5.99, 100) arises from the lower two-thirds of the lateral surface of the fibula, anterior to peroneus

longus, and from the anterior and posterior crural intermuscular septa. It passes vertically downwards and ends in a tendon which extends behind the lateral malleolus along with, but anterior to, that of peroneus longus, the two tendons being deep to the superior peroneal retinaculum in a common synovial sheath (p. 611). It then runs forwards on the lateral side of the calcaneus above the peroneal trochlea and the tendon of peroneus longus, to



5.98 The muscles of the right leg, medial aspect.

be attached to the tubercle on the base of the fifth metatarsal bone, on its lateral side.

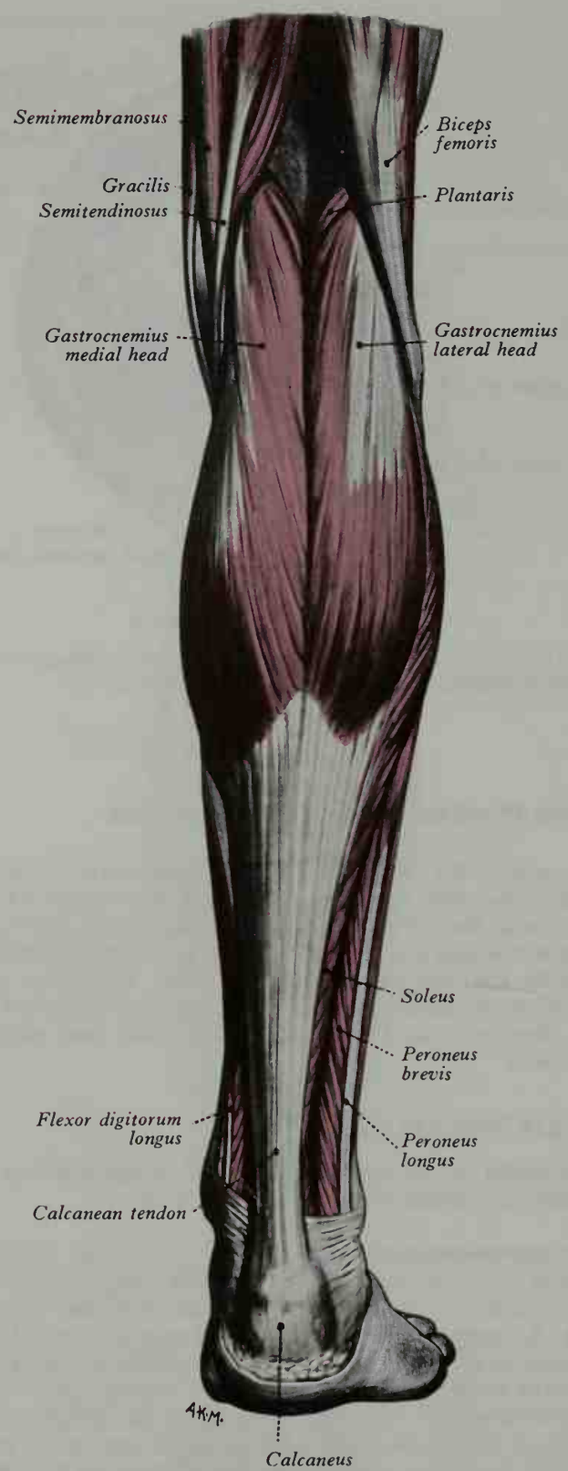
On the lateral surface of the calcaneus the tendons of the peronei longus et brevis occupy separate osseo-aponeurotic canals formed by the calcaneus and the inferior peroneal retinaculum; each tendon is enveloped by a separate forward prolongation of the common synovial sheath (5.104).

Nerve supply. The superficial peroneal nerve, L. 5, S. 1 and 2.

Action. The peroneus brevis may limit the inversion of the foot and so relieve the ligaments which are tightened by this movement (lateral part of interosseous talocalcanean, lateral talocalcanean and calcaneofibular). It participates in eversion of the foot and may help to steady the leg on the foot (cf. peroneus longus).

5.99 Transverse section through the right leg, about 6 cm superior to the tip of the medial malleolus. Proximal (superior) aspect.

3. The Posterior Crural Muscles



The muscles of the back of the leg can be regarded as two groups, superficial and deep, separated by the deep transverse fascia of the leg (pp. 604, 609). Those of the superficial group constitute a powerful muscular mass forming the calf of the leg, and capable of flexing the knee and plantar-flexing the foot. Their large size is one of the most characteristic features of the musculature of man, being directly related to his upright stance and mode of progression.

THE SUPERFICIAL GROUP

In this group (5.100), gastrocnemius and plantaris act on both knee and ankle joints, soleus on the latter alone.

The gastrocnemius (5.96, 98, 100), the most superficial muscle of the group, forms the 'belly' of the calf. It arises by two heads, which are connected to the condyles of the femur by strong, flat tendons. The medial and larger descends from a depression at the upper and posterior part of the medial condyle behind the adductor tubercle, and from a slightly raised area on the popliteal surface of the femur just above the medial condyle. The lateral head arises from a recognizable area on the lateral surface of the lateral condyle and from the lower part of the corresponding supracondylar line. Both also arise from the subjacent part of the capsule of the knee joint. Each head spreads out into a tendinous expansion which covers the posterior surface of its own part of the muscle. From the anterior surfaces of these expansions muscular fibres arise, those of the medial head extending lower than those of the lateral. The two muscular masses remain separate as far as their attachment to a broad aponeurosis on the anterior surface of the muscle. This gradually contracts and unites with the tendon of soleus, to form the *tendo calcaneus* (p. 608). Absence of the lateral head, or the whole muscle, can occur; a more frequent variation is a third head from the popliteal surface of the femur.

Relations. The fascia cruris separates the *superficial surface* of the muscle from the small saphenous vein and the peroneal communicating and sural nerves; the common peroneal nerve crosses the lateral head of the muscle, partly deep to biceps femoris. The *deep surface* is posterior to the oblique popliteal ligament, popliteus, soleus, plantaris, popliteal vessels and tibial nerve. A bursa, which sometimes communicates with the knee joint, is anterior to the tendon of the medial head. The tendon of

5.100 Muscles of the right calf; superficial layer. (From Quain's *Anatomy*, 11th edition.)

the lateral head sometimes contains a sesamoid fibrocartilage or bone where it plays over the lateral condyle; one is also occasionally present in the tendon of the medial head.

Nerve supply. The tibial nerve, S. 1 and 2.

The soleus (5.96, 98) is a broad flat muscle situated immediately deep or anterior to gastrocnemius. It arises from the back of the head and the upper fourth of the posterior surface of the fibula, from the soleal line and the middle third of the medial border of the tibia, and from a fibrous band between the tibia and fibula which arches over the popliteal vessels and tibial nerve. This origin is aponeurotic, most of the muscular fibres arising from its posterior surface and proceeding to the tendon of insertion, which is on the superficial surface. Some muscle fibres also arise from the deep surface of the aponeurosis; they are short, oblique and bipennate in arrangement, and converge on a narrow, central intramuscular tendon which merges distally with the principal tendon (5.96). The latter, gradually becoming thicker and narrower, joins with the tendon of gastrocnemius to form the *tendo calcaneus*.

Relations. Its *superficial surface* is close to gastrocnemius and plantaris, its *deep surface*, to the flexor digitorum longus, flexor hallucis longus, tibialis posterior, and posterior tibial vessels and tibial nerve, from all of which it is separated by the deep transverse fascia of the leg.

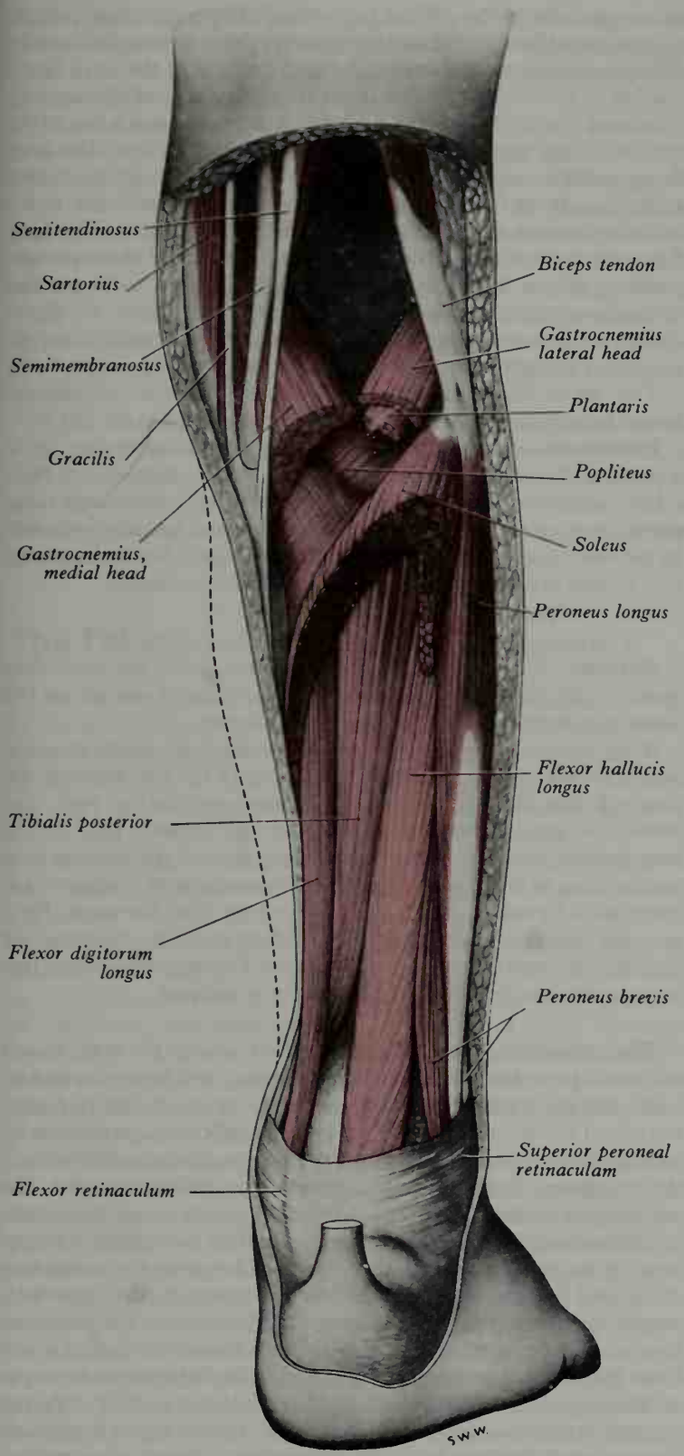
Nerve supply. Two branches from the tibial nerve, S. 1 and **2**. For the intramuscular distribution of the nerve supplies of gastrocnemius, soleus and plantaris consult Schumacher *et al.* (1973).

The gastrocnemius and soleus together form a tripartite muscular mass which shares the tendo calcaneus, and is hence sometimes termed the *triceps surae*.

The tendo calcaneus (5.100) is the thickest and strongest human tendon. It is about 15 cm long, and begins near the middle of the leg, but its anterior surface receives muscle fibres from soleus, almost to its lower end. It gradually becomes more rounded towards a level about 4 cm above the calcaneus; below this it expands and is attached to the posterior surface of the calcaneus at mid level, a bursa separating it from the upper part of this surface. The tendon fibres spiral through 90° in descending, so that, for example, the medial fibres become the most posterior (White 1943). This arrangement permits some degree of elongation and elastic recoil, and hence some storing of energy in the tendon, which can be released at an appropriate phase of locomotion. Alexander and Vernon (1975) have studied such elastic recoil (in kangaroos), and Alexander has supplied a detailed mathematical analysis of the contribution of elasticity in the tendo calcaneus to bipedal gait (Alexander 1976).

Actions. The muscles of the calf are the chief plantar flexors of the foot, and the gastrocnemius is a flexor of the knee; they possess considerable power, and are usually of large size.

Gastrocnemius provides propelling force in walking, running and leaping. Soleus is frequently said to be concerned with steadying the leg on the foot in the standing position and its postural function is emphasized more than its value as a prime mover; but such a rigid distinction between the two muscles is probably an over-simplification. Nevertheless, in standing the centre of gravity lies on a vertical line passing anterior to the talocrural joint (which in this position is loose-packed), and a strong brace is required behind the joint to maintain the posture. Electromyography has demonstrated that during symmetrical standing soleus consistently exhibits continuous activity, whereas the gastrocnemei are active only intermittently in most cases (Joseph *et al.* 1955; Joseph 1960). The phasic activity of the triceps surae in walking has not yet been satisfactorily analysed into the relative contributions from soleus and gastrocnemius.



The plantaris (5.100) arises from the lower part of the lateral supracondylar line and the oblique popliteal ligament. It has a small fusiform belly, from 7 to 10 cm long; this ends in a long slender tendon, which crosses obliquely between gastrocnemius and soleus and runs along the medial border of the tendo calcaneus to be inserted with it. This muscle is sometimes double, and at other times missing. Occasionally, its tendon merges with the flexor retinaculum (p. 611), or the fascia of the leg. Daseler and Anson (1943) found this muscle absent in 160 of 1,545 legs.

Nerve supply. The tibial nerve, S. 1 and 2.

Actions. The plantaris is the rudiment of a large muscle, the tendon of which is inserted into the plantar aponeurosis in some of the lower animals: in man it is accessory to gastrocnemius.

THE DEEP GROUP

The deep crural flexors (5.98, 101), include one, the popliteus, which acts on the knee joint, the rest, flexor hallucis longus, flexor digitorum longus and tibialis posterior, acting on the talocrural joint and other joints of the foot.

5.101 The right posterior crural muscles, deep group, in a child, aged 8 years.

The deep transverse fascia of the leg is a fibrous stratum between the superficial and deep posterior crural muscles, extending transversely from the medial margin of the tibia to the posterior border of the fibula. Above, where it is thick and dense, it is attached to the soleal ridge of the tibia and to the fibula, inferomedial to the attachment of soleus. Between these bony attachments it is continuous with the fascia covering popliteus and receives an expansion from the tendon of semimembranosus; it is thin at intermediate levels, but below, where it covers the tendons behind the malleoli, it is thick and continuous with the flexor and superior peroneal retinacula (p. 611).

The popliteus (**5**.101), flat and triangular, forms the deep boundary or floor of the lower part of the popliteal fossa. The lateral, larger part of the muscle arises by a strong tendon, about 2·5 cm long, from a depression at the anterior end of the groove on the lateral condyle of the femur, its medial fibres from the arcuate popliteal ligament (p. 485) where it blends with the fibrous capsule adjacent to the lateral meniscus; fibres also arise from the outer margin of the meniscus itself. The muscle is attached to the medial two-thirds of the triangular area above the soleal line on the posterior surface of the tibia, and into the tendinous expansion which covers its surface. An additional head may arise from the sesamoid in the lateral head of gastrocnemius.

Relations. The popliteal tendon is intracapsular and is overlapped by the fibular collateral ligament of the knee and the tendon of biceps femoris (**4**.76). Invested on its deep surface by synovial membrane, it grooves the posterior border of the lateral meniscus and the adjoining part of the tibia, and emerges inferior to the posterior band of the arcuate ligament (**4**.72). On the floor of the popliteal fossa it is covered by a strong layer of fascia derived mostly from the tendon of semimembranosus.

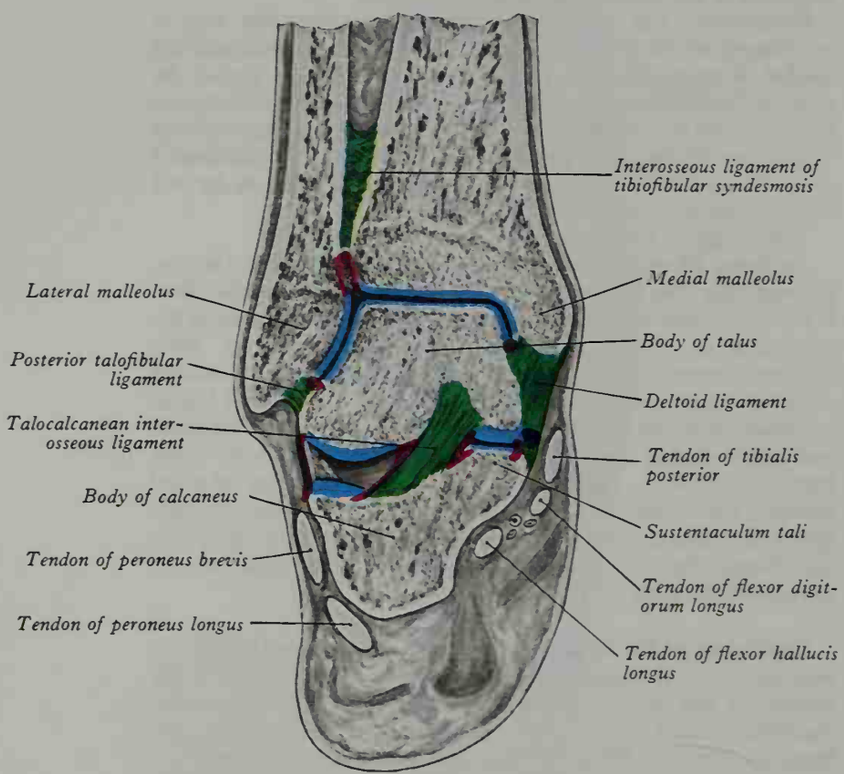
Nerve supply. The tibial nerve, L. 4 and 5 and S. 1.

Actions. The popliteus rotates the tibia medially on the femur, or, when the tibia is fixed, rotates the femur laterally on the tibia. It is usually regarded as the muscle which 'unlocks' the joint at the beginning of flexion of the fully extended knee (p. 488); electromyographic observations support this view. Its connexion with the arcuate popliteal ligaments, fibrous capsule and lateral meniscus, suggests that it may draw the posterior part of the latter backwards during lateral rotation of the femur and flexion of the knee joint and so protect the meniscus from being crushed between the femur and the tibia during these movements (Last 1950). The muscle shows marked activity in knee flexion during crouching; this may aid the posterior cruciate ligament in preventing forward dislocation of the femur.

The flexor hallucis longus (**5**.99, 101) arises from the inferior two-thirds of the posterior surface of the fibula (save for the lowest 2·5 cm or so), from the lower part of the interosseous membrane, from the posterior crural intermuscular septum, and from the fascia covering tibialis posterior, which it overlaps to a considerable extent. The fibres pass obliquely down to a tendon which occupies nearly the whole length of the posterior aspect of the muscle. This tendon grooves the posterior surface of the lower end of the tibia, the posterior surface of the talus, and the inferior surface of the sustentaculum tali of the calcaneus (**5**.102, 103). The grooves on the talus and calcaneus are converted by fibrous bands into a canal, lined by a synovial sheath. Distal to this it crosses the flexor digitorum longus from lateral to medial side, pursuing an obliquely curved course superior to it; at the crossing point the long digital flexor receives a fibrous slip from the flexor hallucis longus tendon. The latter then crosses the lateral portion of flexor hallucis brevis to reach the interval between the sesamoid bones under the head of the first metatarsal. It continues on the plantar aspect of the great toe running in an osseo-aponeurotic tunnel to be attached to the plantar aspect of the base of the distal phalanx. The tendon is retained in position over the lateral part of flexor hallucis brevis by the diverging stems of the distal band of the medial intermuscular septum. The connecting slip to flexor digitorum longus varies considerably in size; it usually continues into the tendons for the second and third toes, but is sometimes restricted to the second, or occasionally reaches the tendons of the second, third and fourth toes.

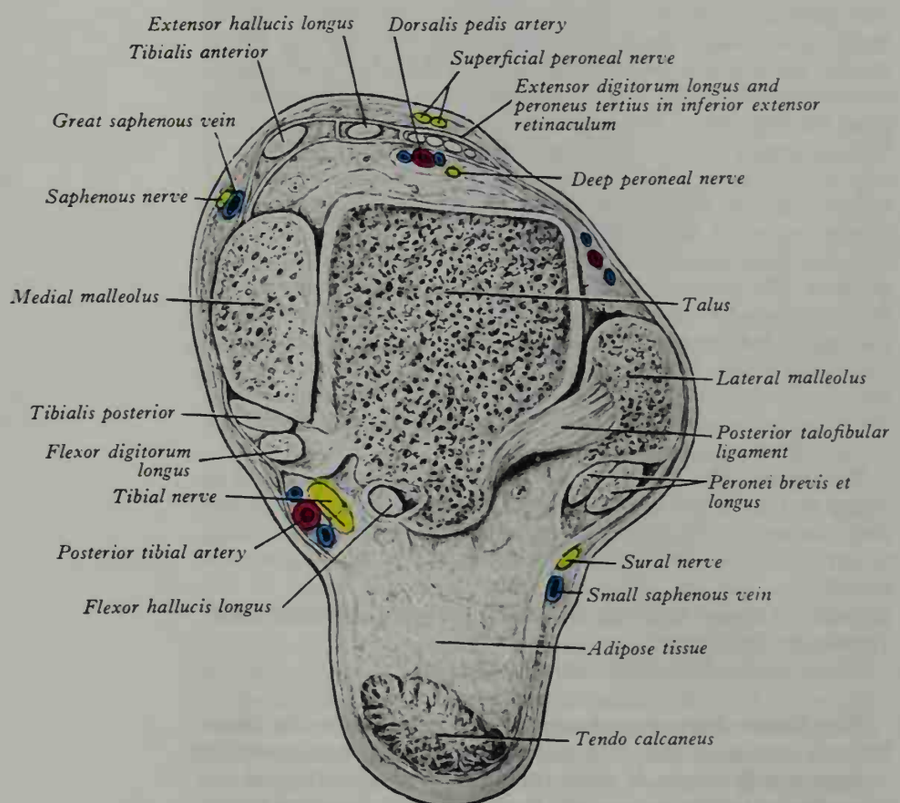
Relations. The *superficial surface* of the muscle is related to soleus and the tendo calcaneus, from which it is separated by the deep transverse fascia; its *deep surface* to the fibula, tibialis posterior, the peroneal vessels, the lower part of the interosseous membrane, and the talocrural joint; its *lateral border* to the peronei; its *medial border* to the tibialis posterior, posterior tibial vessels and tibial nerve.

Nerve supply. The tibial nerve, S. **2** and 3.



The flexor digitorum longus (**5**.101), medial to the flexor hallucis longus, is thin and pointed proximally, but gradually widens as it descends. It arises from the posterior surface of the tibia, medial to tibialis posterior, from just below the soleal line to within 7 or 8 cm of the lower extremity of the bone; it also arises from the fascia covering tibialis posterior. The muscle ends in a

tendon extended along almost the whole of its posterior surface which gradually crosses tibialis posterior and passes behind the medial malleolus, in a groove shared with tibialis posterior, but separated from the latter by a fibrous septum. Each tendon is in a separate compartment lined by a synovial sheath. It passes obliquely forwards and laterally, in contact with the medial side of the sustentaculum tali (**5**.102), deep to the flexor retinaculum, and enters the sole of the foot (**5**.109), where it crosses superficial to the tendon of flexor hallucis longus, receiving a strong slip from it. It continues across the sole to form the whole of the long flexor tendon of the fifth digit and contributes to those of the second, third and fourth digits. It may also occasionally send a slip to the tendon of the flexor hallucis longus in the great toe. The long flexor tendons of the second, third and fourth digits receive accessions from flexor accessorius and variably from the flexor hallucis through the connecting slip mentioned above. The long flexor tendons of the lateral four digits are attached to the plantar surfaces of the bases of their distal phalanges, each passing through an opening in the corresponding tendon of flexor digitorum brevis at the base of the proximal phalanx. (Compare with the arrangement in the hand, pp. 575, 576.)



The lateral head of flexor accessorius may be inserted into the lateral border of the flexor digitorum longus tendon (p. 615).

Relations. In the leg the muscle's *superficial surface* is in contact with the deep transverse fascia, which separates it from soleus, and, distally, from the posterior tibial vessels and tibial nerve; its *deep surface* is related to the tibia and tibialis posterior. In the foot it is covered by abductor hallucis and flexor digitorum brevis, and crosses superficial to flexor hallucis longus.

Nerve supply. The tibial nerve, S. **2** and 3.

5.102 A coronal section through the left talocrural, talocalcanean and subtalar joints. Ligaments are shown in green, articular cartilage in blue, and synovial membrane in red.

5.103 Transverse section through the inferior part of the talocrural joint.

Actions. *When the foot is off the ground*, both the preceding muscles flex the phalanges of the toes, acting primarily on the distal phalanges. They are also plantar flexors.

When the foot is on the ground and under load, these muscles, acting synergically with the small muscles of the foot and—in the case of the flexor digitorum longus—especially with the lumbricals and interossei (p. 617), maintain the pads of the toes in firm contact with the ground, enlarging the weight-bearing area and helping to stabilize the heads of the metatarsal bones, which form the fulcrum on which the body is propelled forwards. Both muscles show little activity in the standing position, contributing little to the longitudinal arch mechanism. During take-off and tip-toe movements, however, their activity is marked.

The tibialis posterior (**5**.96, 101) arises between flexor hallucis longus and flexor digitorum longus, and is overlapped by both, but especially by the former; it is the most deeply placed muscle of the flexor group. Two pointed processes, separated by an angular interval traversed by the anterior tibial vessels to reach the extensors, characterize the proximal end of the muscle. The medial part of the muscle arises from the posterior surface of the interosseous membrane, excepting its lowest part, from a lateral area on the posterior surface of the tibia between the soleal line above and the junction of the middle and lower thirds of the shaft below. The lateral part arises from a medial strip of the posterior fibular surface in its upper two-thirds. The muscle also arises from the deep transverse fascia, and from the intermuscular septa separating it from adjacent muscles. In the lower quarter of the leg its tendon passes anterior to (i.e. deep to) that of flexor digitorum longus and lies with it in a groove behind the medial malleolus, but enclosed in a separate synovial sheath; it next passes deep to the flexor retinaculum (p. 611) and superficial to the deltoid ligament (**5**.102) to enter the foot. In the foot it is first inferior to the plantar calcaneonavicular ligament, where it contains a sesamoid fibrocartilage. The tendon then divides into two. The more superficial and larger division, a direct continuation of the tendon, is attached to the tuberosity of the navicular, from which fibres are continued to the inferior surface of the medial cuneiform. A tendinous band also passes laterally and a little proximally to the tip and distal margin of the sustentaculum tali. The deeper, lateral division gives rise to the tendon of origin of the medial limb of flexor hallucis brevis, and then continues between this muscle, and the navicular and medial cuneiform bones, to end on the intermediate cuneiform and the bases of the second, third and fourth metatarsals. The slips to the metatarsals are variable in number, that to the fourth metatarsal being the strongest. Slips to the cuboid and lateral cuneiform have also been described (Lewis 1964; see also **3**.203).

Relations. The *superficial surface* of the muscle is in relation with soleus, from which it is separated by the deep transverse

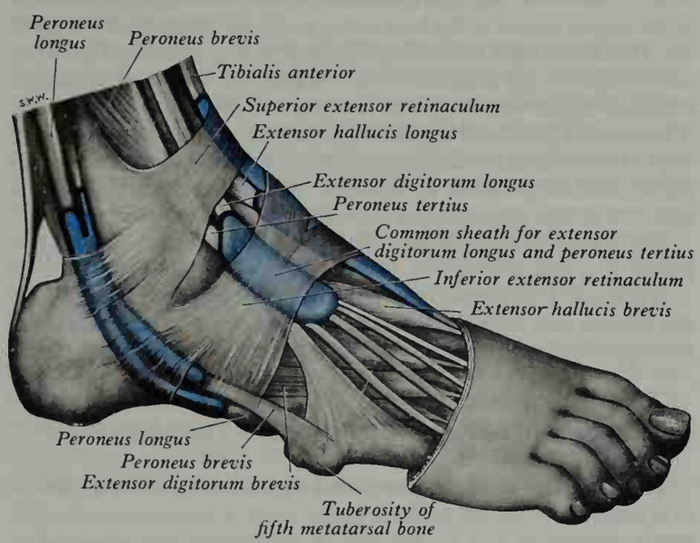
fascia, the flexor digitorum longus, the flexor hallucis longus, the posterior tibial vessels, tibial nerve, and the peroneal vessels; its *deep surface* is in contact with the interosseous membrane, tibia, fibula and talocrural joint.

Nerve supply. The tibial nerve, L. 4 and 5.

Actions. The tibialis posterior is the principal invertor of the foot and may assist powerful plantar flexion. Through its insertions into the cuneiform bones and the bases of the metatarsals it has long been considered to contribute to the elevation of the longitudinal arch of the foot. However, it is quiescent in standing but phasically active in walking, during which, in concert with the intrinsic foot musculature and the lateral calf muscles, it probably affects the degree of pronation of the foot, and the distribution of weight through the metatarsal heads.

It has been suggested that when the body is supported on one leg, the tibialis posterior, acting from below, assists in maintaining balance by resisting any tendency to overbalance to the lateral side. It must be remembered, however, that any act of balancing demands the cooperation of many muscles, particularly groups acting on the hip joint and vertebral column.

The Talocrural Fasciae and Retinacula



As the tendons of the muscles of the leg cross the talocrural joint to the foot, they are bound down by localized thickenings of the deep fascia which constitute retinacular bands, comparable, both in formation and function, with the retinacula of the wrist (pp. 583–584). They comprise superior and inferior extensor, flexor, and superior and inferior peroneal retinacula.

The superior extensor retinaculum (5.97, 104) binds down the tendons of tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius, as they descend immediately above the anterior aspect of the talocrural joint; the anterior tibial vessels and the deep peroneal nerve also pass deep to it. It is attached laterally to the lower end of the anterior border of the fibula, and medially to the anterior border of the tibia; above, it is continuous with the deep fascia of the leg and similar dense connective tissue connects its inferior border to the inferior extensor retinaculum. Only the tendon of tibialis anterior has a synovial sheath in this situation (5.104).

The inferior extensor retinaculum (5.97, 104) is a Y-shaped band anterior to the talocrural joint. Its stem is attached to the upper surface of the calcaneus, in front of the sulcus calcanei, and passes medially, forming a strong loop around the tendons of peroneus tertius and the extensor digitorum longus (5.103); from the deep aspect of the loop a band passes laterally behind the interosseous talocalcanean ligament and the cervical ligament to be attached to the sulcus calcanei (Smith 1896; Stamm 1931). From the medial extremity of this loop the two diverging bands pass further medially to complete the Y. The *upper* consists of two layers; the deep one passes deep to the tendons of extensor hallucis longus and tibialis anterior, but superficial to the anterior tibial vessels and deep peroneal nerve, to reach the tibial malleolus. The superficial layer crosses superficial to the tendon of extensor hallucis longus and is then firmly connected to the deep one; it may or may not be continued superficial to the tendon of tibialis anterior to reach the tibia. The *lower band* extends downwards and medially to be attached to the plantar aponeurosis; it is superficial to the tendons of extensor hallucis longus and tibialis anterior, the arteria dorsalis pedis and the terminal branches of the deep peroneal nerve.

The flexor retinaculum (5.98) is attached anteriorly to the tip of the medial malleolus, distal to which it is continuous with the deep fascia on the dorsum of the foot. Its posterior extremity is attached to the medial process of the calcaneus and to the plantar aponeurosis. Its upper border is not clearly demarcated from the deep fascia of the leg, especially the deep transverse layer. Its lower border is continuous with the plantar aponeurosis and many fibres of the abductor hallucis are attached to it. The flexor retinaculum converts the bony grooves in this situation into canals for the tendons and bridges over the posterior tibial vessels and tibial nerve as all these structures enter the sole. From medial to lateral these structures are: the tendon of tibialis posterior, the tendon of flexor digitorum longus, the posterior tibial vessels, tibial nerve and the tendon of flexor hallucis longus (5.103).

The peroneal retinacula are fibrous bands which retain the tendons of peroneus longus and brevis in position as they curve round the lateral side of the ankle. The *superior retinaculum* (5.101) extends from the back of the lateral malleolus to the deep transverse fascia of the leg and the lateral surface of the calcaneus. The *inferior retinaculum* is continuous in front with the inferior extensor retinaculum; behind it is attached to the lateral surface of the calcaneus; some of its fibres are fused with the periosteum on the peroneal trochlea of the calcaneus, forming a septum between the tendons of peroneus longus and brevis.

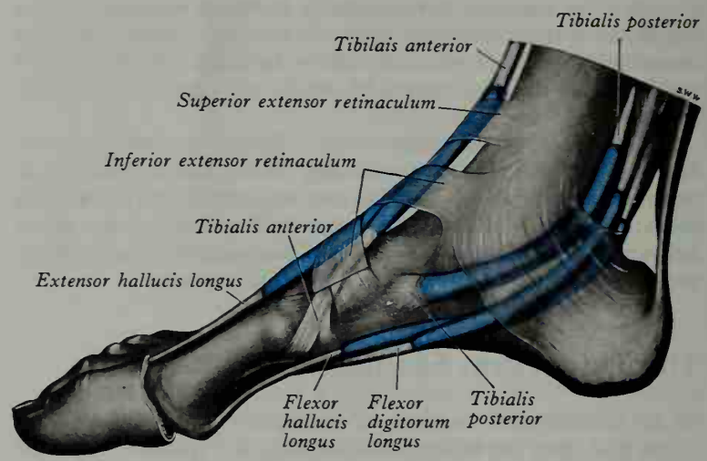
5.104 The synovial sheath of the tendons at the right ankle. Lateral aspect.

The synovial sheaths in the talocrural region. The tendons crossing the talocrural joint are all to some degree deflected from a straight course, and are hence held down by retinacula and enclosed in synovial sheaths.

Anteriorly the sheath for tibialis anterior extends from the proximal margin of the superior extensor retinaculum to the interval between the diverging limbs of the inferior retinaculum (5.105); the sheath for extensor digitorum longus and peroneus tertius and another for extensor hallucis longus start just above the level of the malleoli, the former reaching the higher. The sheath of extensor hallucis longus is prolonged to the base of the first metatarsal bone, while that of extensor digitorum longus reaches only to the level of the base of the fifth metatarsal bone. *Medial* to the ankle (5.105) the sheath for tibialis posterior extends for about 4 cm above the malleolus; below, it ends just proximal to the attachment of the tendon to the tuberosity of the navicular. The sheath for the flexor hallucis longus reaches the level of the malleolus, while that for flexor digitorum longus goes slightly higher; the former is continued to the base of the first metatarsal bone, the latter ends at the navicular. *Lateral* to the ankle (5.104) a sheath, which is proximally single but double below, encloses peroneus longus and brevis. It extends for about 4 cm proximal to the tip of the malleolus, and downwards and forwards for about the same distance.

IV. The Muscles of the Foot

The muscles which are *intrinsic* or confined to the foot follow the primitive limb pattern of dorsal extensors and plantar flexors. Topographically and functionally associated with these are the tendons of the *extrinsic* muscles, already considered. The intrinsic extensor musculature is most limited, but it should be noted that, as in the hand, certain of the intrinsic flexor muscles are also concerned in part with extensor activities.



1. The Dorsal Muscle of the Foot

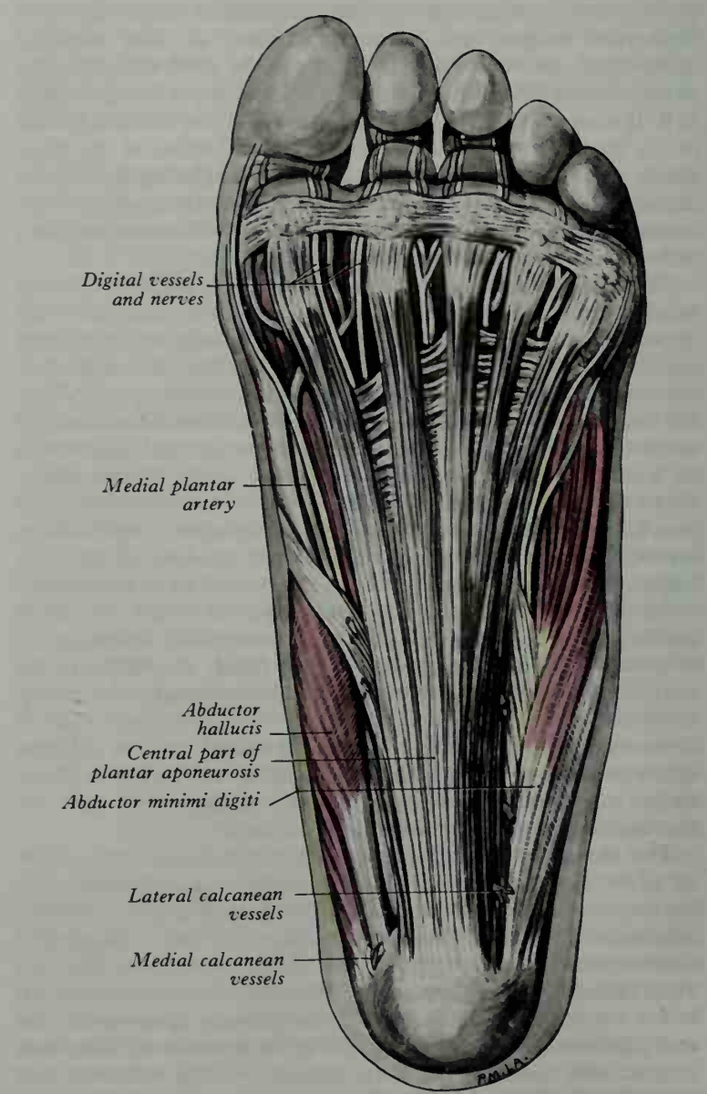
The deep fascia on the dorsum of the foot (*fascia dorsalis pedis*) is a thin layer, continuous above with the inferior extensor retinaculum; at the sides of the foot it blends with the plantar aponeurosis; anteriorly it ensheathes the dorsal tendons.

The extensor digitorum brevis (5.97, 104) is a thin muscle, arising from the anterior region of the superolateral surface of the calcaneus, in front of the groove for peroneus brevis, from the interosseous talocalcaneal ligament, and the stem of the inferior extensor retinaculum. It slants distally and medially across the dorsum of the foot, and ends in four tendons. The medial part of the muscle is usually a more or less distinct slip ending in a tendon which crosses the dorsalis pedis artery superficially to be attached to the dorsal aspect of the base of the proximal phalanx of the great toe; it is sometimes termed the *extensor hallucis brevis*. The other three tendons are attached to the lateral sides of the tendons of extensor digitorum longus of the second, third and fourth toes. This muscle is subject to much variation in the form of accessory slips (from the talus and navicular), extra tendons (to the fifth digit), and suppression of tendons. It may be connected to the adjacent dorsal interosseous muscles.

Nerve supply. The lateral terminal branch of the deep peroneal nerve, S. 1 and 2.

Actions. Through the tendons of extensor digitorum longus the muscle aids in extension of the phalanges of the middle three toes; but, in the hallux, it acts only on the first phalanx.

5.105 The synovial sheaths of the tendons at the right ankle. Medial aspect.



2. The Plantar Fasciae and Muscles

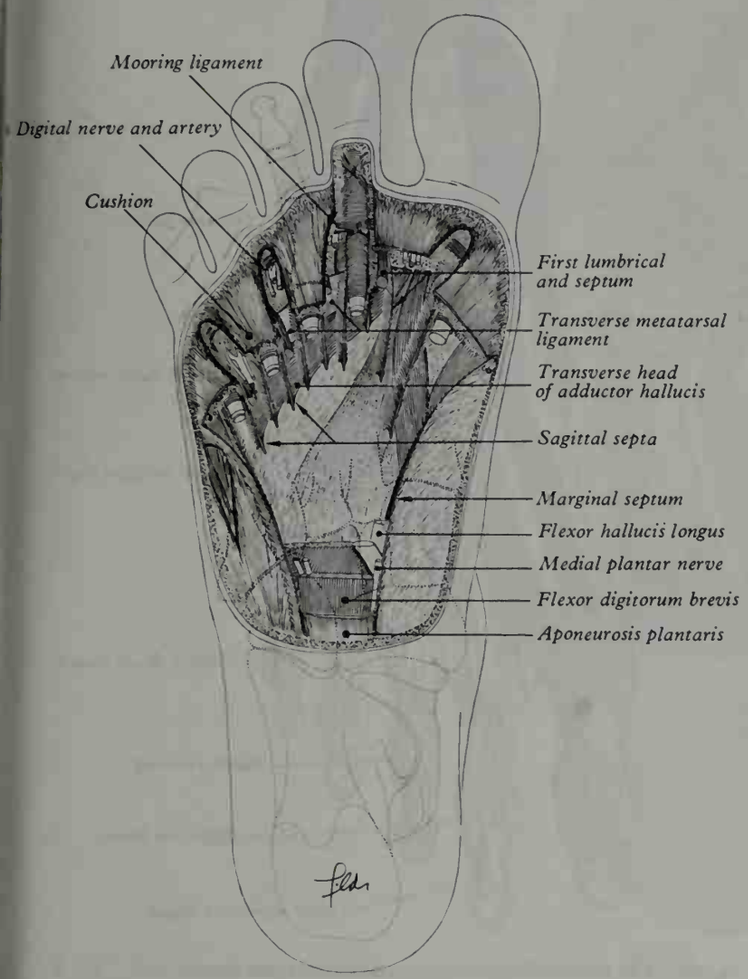
The plantar fasciae, deep and superficial, show a pattern of arrangement similar to those in the hand (5.106A–D), with some small differences due to absence of opposition and grasping in the foot. They are arranged to limit the mobility of the skin, to hold down muscles and especially tendons in the concavity of the foot and digits, to facilitate the excursions of these tendons, to prevent compression of the plantar and digital vessels and nerves, and perhaps to aid venous return. The plantar skin is repeatedly subjected to forcible shearing and impact stresses in locomotion, particularly in the areas of the posterior calcaneal tubercles, the metatarsal heads, and the pulps of the terminal segments of the toes. As in the hand, pads of adipose tissue occur in these regions, and these are diffusely pervaded by fine but collectively strong connective tissue strands, which tether the skin and limit displacement of the fat, thus augmenting rather than impeding its resilient cushioning effect. The direction of these strands, which extend from the deep fascia through the subcutaneous tissues to the dermis of the skin, is adapted to that of prevailing stresses, as has been clearly demonstrated in the sub-metatarsal region, the *'ball' of the foot*, by Bojsen-Møller and Flagstad (1976) (5.106D).

The parts of the deep fasciae on the inferior aspect of the plantar structures are usually named collectively the *plantar aponeurosis* (*vide infra*); but it is only the central part of this which is extensively aponeurotic, and some anatomists reserve the name for this part alone. The medial and lateral parts are aponeurotic only posteriorly, where they provide muscle attachments (*vide infra*).

The plantar aponeurosis, or fascia (5.106A), is composed of collagen fibres disposed chiefly in a longitudinal manner, but also transversely. It can be conveniently divided for description into medial and lateral parts which overlie the intrinsic muscles of the hallux and minimus, and a central part overlying the long and short digital flexors.

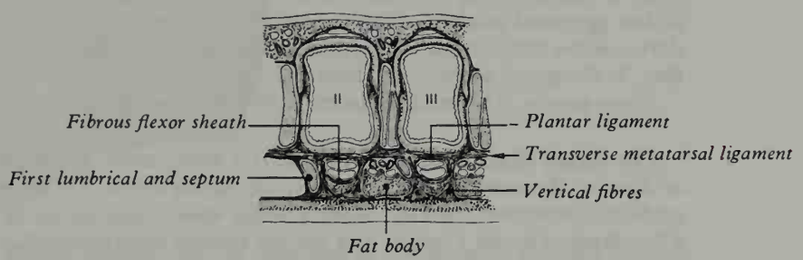
The central part is the strongest and thickest. Posteriorly narrow, where it is attached to the medial process of the calcaneal tuberosity, proximal to the flexor digitorum brevis, it becomes broader and somewhat thinner as it diverges towards the metatarsal heads. Just proximal to these it divides into five bands, corresponding with the toes. These five bands are united by transverse fibres where they begin to diverge (5.106A), below the metatarsal shafts. Proximal to the metatarsal heads the superficial stratum of each band is connected to the dermis by *skin ligaments* (*retinacula cutis*), which reach the skin of the ball of the foot proximal to the furrow separating toes from sole (5.106D). The deep stratum of each digital band of the aponeurosis divides into *two septa* which flank the digital flexor tendons, separating them from the lumbrical muscles and the digital vessels and nerves. These septa pass deeply to fuse with the interosseous fascia, the deep transverse metatarsal ligaments, the plantar ligaments of the

5.106A The plantar aponeurosis of the left foot.



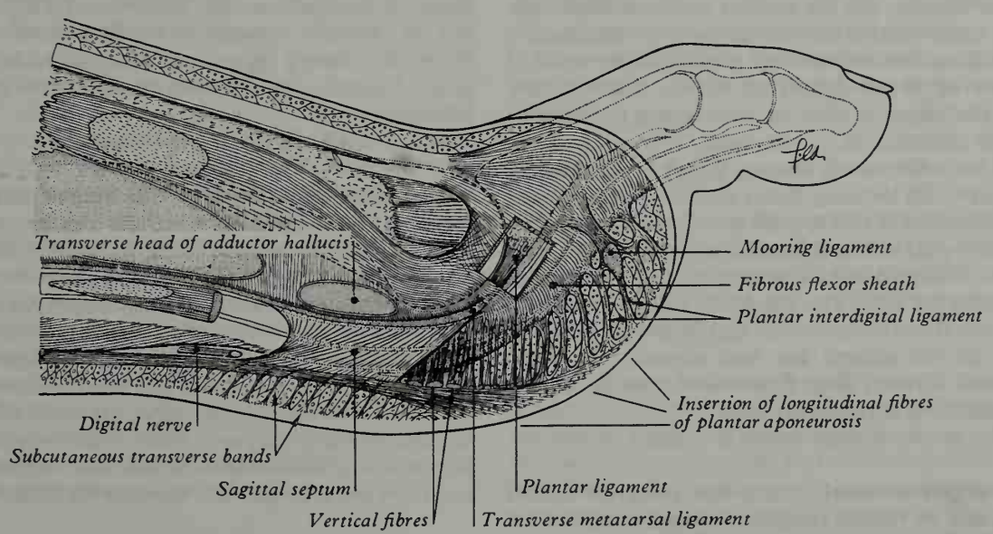
metatarsophalangeal joints, and the periosteum and fibrous flexor sheaths at the base of each proximal phalanx. In the webs between the metatarsal heads and the bases of the proximal phalanges pads of fat are developed, which cushion the digital nerves and vessels from adjoining tendinous structures and extraneous plantar pressures. These four fat pads are stabilized by vertical strands of collagen fibres, which extend from the fibrous flexor sheaths to the superficial stratum of the plantar aponeurosis and, through the latter, to the skin. Just distal to the metatarsal heads a *plantar interdigital ligament* (officially known as the superficial transverse metatarsal ligament) blends with the *deep* aspect of the superficial stratum of the plantar aponeurosis, where it extends into the toes (5.106C, D).

The central part of the plantar aponeurosis thus provides an intermediary between the skin and skeleton of the foot, through numerous *cutaneous retinacula* and *deep septa* extending anteriorly to the metatarsals and phalanges. It is also continuous with its medial and lateral parts, and at these junctions *two vertical intermuscular septa*, medial and lateral, extend deeply between the medial, intermediate and lateral groups of plantar muscles to reach bone (*vide infra*). Thinner *horizontal intermuscular septa*, passing between muscle layers, are derived from the vertical intermuscular septa.



The *lateral part* of the plantar aponeurosis is inferior to abductor digiti minimi; it is thin distally and thick proximally, where it forms a strong band, sometimes containing muscle fibres, between the lateral process of the calcanean tuberosity and the base of the fifth metatarsal bone; it is continuous medially with the central part, and with the fascia on the dorsum of the foot round its lateral border.

The *medial part* of the plantar aponeurosis is thin and inferior to abductor hallucis; it is continuous proximally with the flexor retinaculum, medially with the fascia dorsalis pedis, and laterally with the central part of the plantar aponeurosis.



The *lateral intermuscular septum* is incomplete, especially at its proximal end; distally its deep attachments are to the fibrous sheath of peroneus longus and to the fifth metatarsal bone. The *medial intermuscular septum* is also incomplete and divides into three bands, proximal, intermediate and distal, each of which displays lateral and medial divisions as it approaches its deep

5.106C A transverse section through the heads of the second and third metatarsal bones showing the course of the collagen fibre bundles in the submetatarsal cushions and around the joints. Fat covers the fibrous flexor sheath inside the cushion, and the digital nerves and vessels are lodged between the cushions.

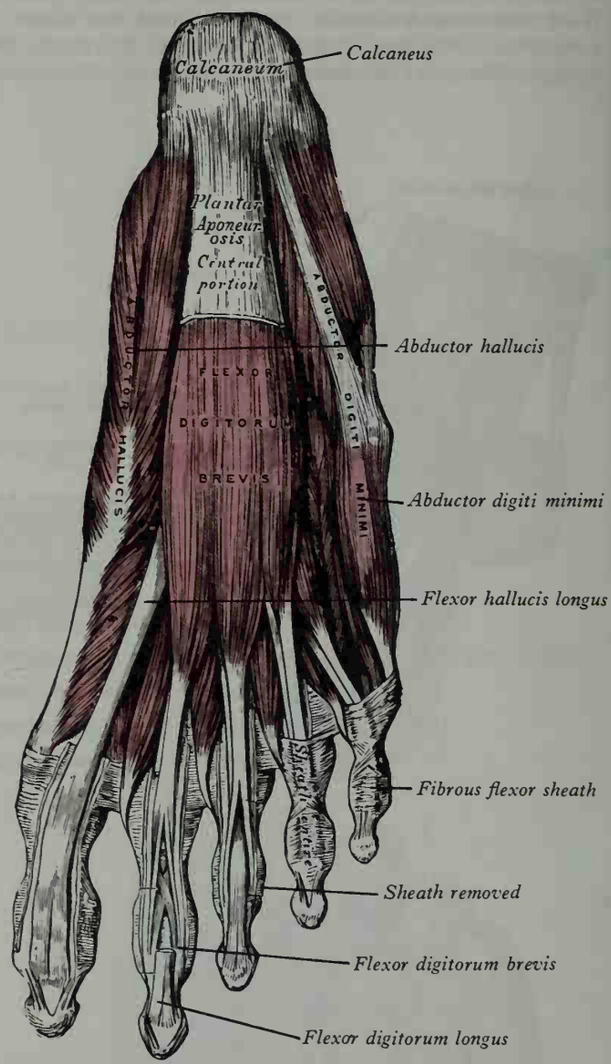
5.106D A sagittal section through the second interosseous cleft showing the internal architecture of the three major areas of the ball of the foot. The sagittal septum is attached to the proximal phalanx through the transverse metatarsal ligament and the plantar ligament of the joint. The vertical fibres and the lamellae of the plantar interdigital ligament are attached to the proximal phalanx through the fibrous flexor sheath. (From F. Bojsen-Møller and K. E. Flagstad 1976, by courtesy of the authors and the Cambridge University Press.)

attachment. The *proximal band* is attached laterally to the cuboid and blends medially with the tendon of tibialis posterior. The *middle band* is attached laterally to the cuboid and the long plantar ligament and medially to the medial cuneiform bone. The *distal band* divides to enclose the tendon of flexor hallucis longus and is attached to the fascia over flexor hallucis brevis.

The muscles in the plantar region of the foot may be divided into medial, lateral and intermediate groups, as in the hand. The medial and lateral groups comprise the intrinsic muscles of the hallux and fifth digit, while the central or intermediate group includes the lumbricals, interossei and short digital flexors. However, it is customary to group them in four layers, as met with in the course of dissection. These 'layers' can be over-emphasized, and in functional terms the former grouping will often be found more useful. Their actions are discussed together on p. 617.

THE FIRST LAYER

This, the superficial layer (**5**.107), includes the abductores hallucis et digiti minimi and the flexor digitorum brevis. All three extend from the calcanean tuberosity to the toes, and therefore, in this case, comprise a functional group capable of assisting in maintaining the concavity of the foot.



The abductor hallucis (**5**.107) lies along the medial border of the foot and covers the origins of the plantar vessels and nerves. It arises principally from the flexor retinaculum, but also from the medial process of the calcanean tuberosity, the plantar aponeurosis, and the intermuscular septum between it and flexor digitorum brevis. The fibres end in a tendon which is attached, together with the medial tendon of flexor hallucis brevis, to the medial side of the base of the proximal phalanx of the great toe. Some fibres are attached more proximally to the medial sesamoid bone of this toe. A separate tendinous slip may extend to the base of the proximal phalanx of the great toe; the muscle may also derive some fibres from the dermis of the medial border of the foot. It flexes and abducts the hallux.

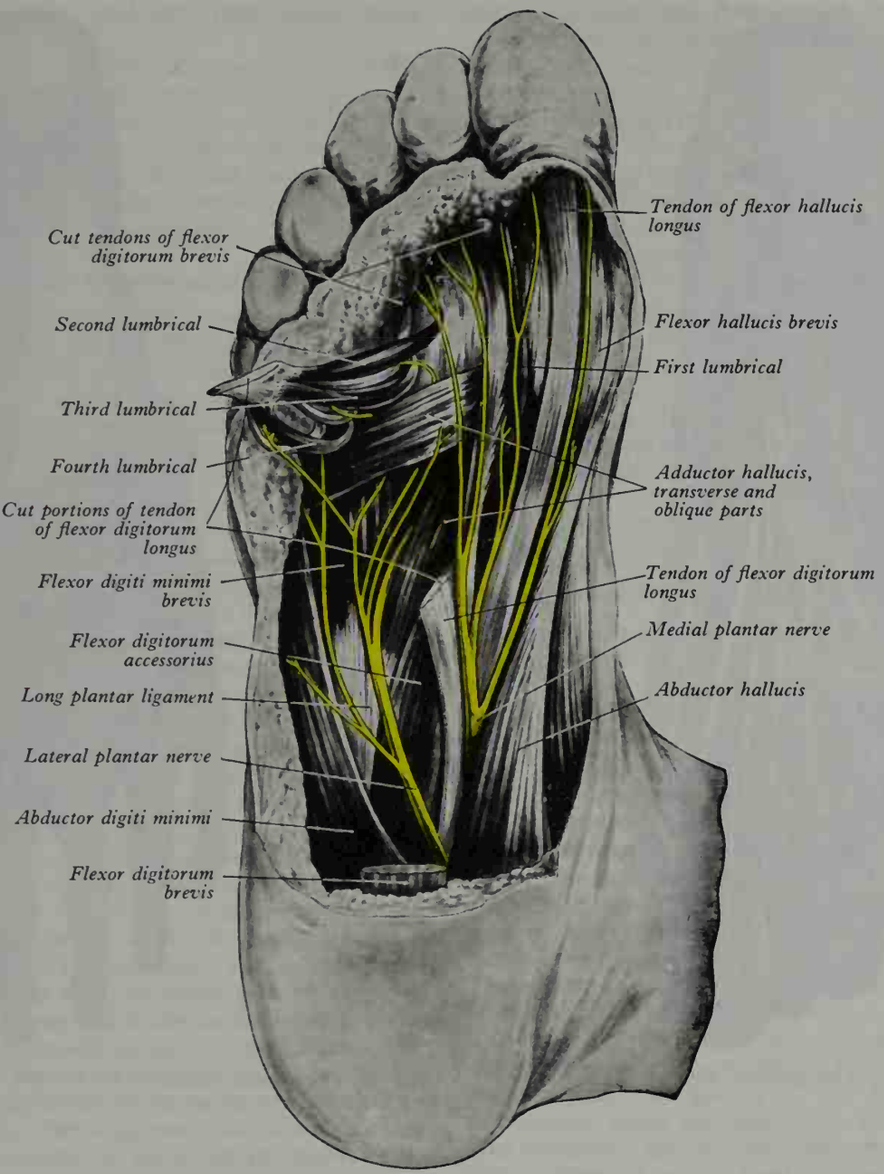
Nerve supply. The medial plantar nerve, S. 2 and **3**.

The flexor digitorum brevis (**5**.107) is immediately superior or deep to the central part of the plantar aponeurosis. Its deep surface is separated from the lateral plantar vessels and nerves by a thin layer of fascia. It arises by a narrow tendon from the medial process of the calcanean tuberosity, from the central part of the plantar aponeurosis, and from the intermuscular septa between it and adjacent muscles. It divides into four tendons, for the lateral four toes. At the bases of their proximal phalanges, each tendon divides into two slips, around the corresponding tendon of flexor digitorum longus; the two slips then reunite, partially decussate, and form a grooved channel for the tendon of flexor digitorum longus. The short flexor tendon divides again to be attached to both sides of the shaft of the intermediate phalanx. The mode of division of tendons of flexor digitorum brevis, and of their attachments to the phalanges, is identical with that of the tendons of flexor digitorum superficialis in the hand. The part of the muscle for the fifth toe is frequently absent. It may be replaced by a small muscular slip from the long flexor tendon or from flexor accessorius. The variations of this muscle have been surveyed by Nathan and Gloobe (1974) who combined previous findings with observations on 100 dissected feet. The frequency of variation in the latter group was 63 per cent. The slip to the fifth toe was most variable (63 per cent), those to the fourth and fifth less so (10 per cent), while that to the second toe was almost invariable. Variability extended, in each slip, from total absence to the occurrence of a second, supernumerary slip.

Nerve supply. The medial plantar nerve, S. 2 and **3**.

The abductor digiti minimi (**5**.107) lies along the lateral border of the foot, and its medial margin is related to the lateral plantar vessels and nerve. It arises from both processes of the calcanean tuberosity, from the plantar surface of the bone between them, from the plantar aponeurosis, and from the intermuscular septum between it and flexor digitorum brevis. Its

5.107 The superficial plantar muscles of the right foot.



tendon glides over a smooth groove on the plantar surface of the base of the fifth metatarsal bone and is attached with flexor digiti minimi brevis, to the lateral side of the base of the proximal phalanx of the fifth toe; hence it is more a *flexor* than an abductor. Some of the fibres arising from the lateral process usually reach the tip of the tuberosity of the fifth metatarsal (**3**.203). These fibres may form a separate muscle, *abductor ossis metatarsi digiti quinti*. An accessory slip from the base of the fifth metatarsal is not infrequent.

Nerve supply. The lateral plantar nerve, S. 2 and **3**.

The fibrous sheaths of the flexor tendons (**5**.107). The terminations of the tendons of the long and short flexor muscles are contained in osseo-aponeurotic canals similar to those in the fingers. These canals are bounded above by the phalanges, and below by fibrous bands, the *digital fibrous sheaths*, which arch across the tendons and are attached on each side to the margins of the phalanges. Along the proximal and intermediate phalanges the fibrous bands are strong, and the fibres are transverse (*annular part*); but opposite the joints they are much thinner, and the fibres decussate (*cruciform part*). Each canal contains a synovial sheath, which is reflected around the tendons; within this sheath *vincula tendinum* are arranged like those in the fingers (p. 577).

THE SECOND LAYER

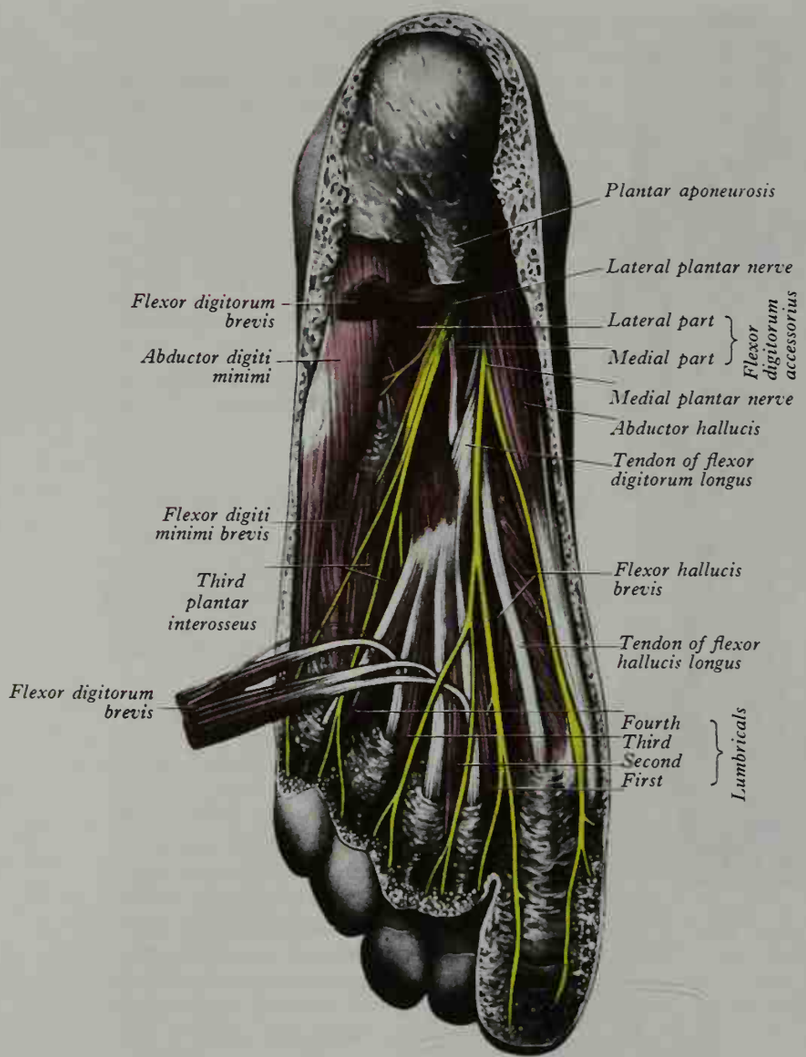
The muscles of this group are between those of the superficial layer, inferior to them, and those of the 'third layer', which are

5.108 The plantar muscles and their nerve supply. Most of the flexor digitorum brevis has been removed. The flexor digitorum longus has been divided partially, and its distal end has been turned forwards together with the second, third and fourth lumbricals.

superior. They include the flexor digitorum accessorius and four lumbrical muscles (**5**.108, 109).

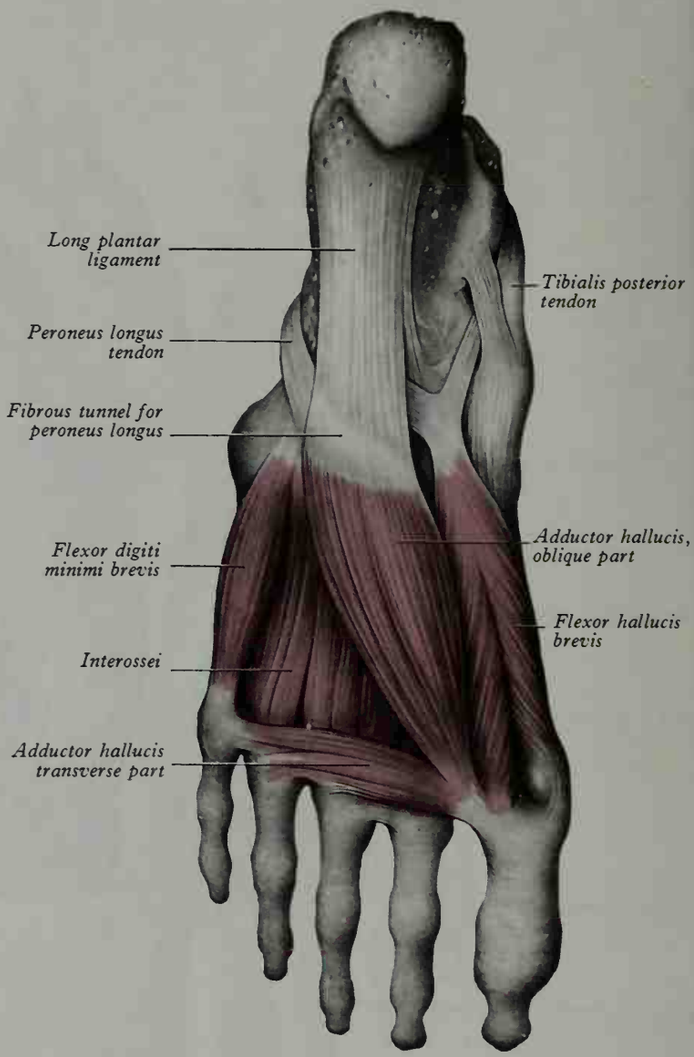
The flexor digitorum accessorius (**5**.109) arises by two heads separated by the long plantar ligament. The medial, and larger, is muscular, and attached to the medial concave surface of the calcaneus below the groove for the tendon of flexor hallucis longus; the lateral head, flat and tendinous, arises from the calcaneus in front of the lateral process of the tuberosity and from the long plantar ligament. The medial head may end in a fibrous lamina which passes deep to the tendon of flexor digitorum longus dividing into tendinous slips which join the long flexor tendons to the second, third and, sometimes, fourth digits, but about as often it joins the lateral border of the flexor digitorum longus tendon. The lateral head joins this fibrous lamina either on its superficial surface or lateral border, or it may terminate on the lateral border of the flexor digitorum longus tendon (Lewis 1962), thus perhaps 'correcting' the diagonal vector of this muscle. It is sometimes absent. It varies in the number of digits to which its slips proceed. The slip to the fourth is often absent; a slip to the fifth is not infrequent. For details see Novakova and Korbelář (1976).

Nerve supply. The lateral plantar nerve, S. 2 and **3**.



The lumbricals (**5**.109) are four small muscles, accessory to the tendons of flexor digitorum longus, and numbered from the medial side of the foot. They arise from these tendons, as far back as their angles of separation, and, with the exception of the first, which arises only from the medial border of the first tendon of flexor digitorum longus, each springs from two adjoining tendons. The muscles end in tendons which pass distally on the medial sides of the four lesser toes, to be attached to the dorsal digital expansions on the proximal phalanges.

Nerve supply. The first lumbrical is supplied by the medial plantar nerve and the rest by the deep branch of the lateral plantar nerve, S. 2 and **3**.



THE THIRD LAYER

This group comprises the shorter intrinsic muscles of the hallux and the fifth digit—flexor hallucis brevis, adductor hallucis and flexor digiti minimi brevis (**5**.108, 110). These are the most deeply situated muscles in the sole, except for the interossei, which are superior to them.

The flexor hallucis brevis (**5**.110) arises by a bifurcate tendon, the lateral limb of which is attached to the medial part of the plantar surface of the cuboid, posterior to the groove for the peroneus longus tendon, and to the adjacent part of the lateral cuneiform; the medial limb has a deep attachment directly continuous with the lateral division of the tendon of tibialis posterior (in the foot), and a more superficial one to the middle band of the medial intermuscular septum (Lewis 1964). The muscle divides into medial and lateral parts whose tendons are attached to the corresponding sides of the base of the proximal

5.109 The plantar muscles of the left foot. First and second layers.

5.110 The plantar muscles of the left foot. Third layer.

phalanx of the hallux, a sesamoid bone usually occurring in each at its attachment. The medial part is blended with abductor hallucis, the lateral with adductor hallucis, as they reach their terminations. Accessory slips from the calcaneus or long plantar ligament may occur, and a tendinous slip may reach the proximal phalanx of the second toe.

Nerve supply. The medial plantar nerve, S. 2 and **3**.

The adductor hallucis (**5**.110) arises by oblique and transverse heads. The *oblique head* springs from the bases of the second, third and fourth metatarsal bones, and from the sheath of the tendon of peroneus longus. The *transverse head*, a narrow, flat fasciculus, arises from the plantar metatarsophalangeal ligaments of the third, fourth and fifth toes (sometimes only from the third and fourth), and from the deep transverse metatarsal ligaments between them. The oblique head has medial and lateral parts; the medial blends with the lateral part of flexor hallucis brevis and is attached to the lateral sesamoid bone of the great toe; the lateral part joins the transverse head and is attached to the lateral sesamoid bone and the base of the first phalanx of the hallux. According to Cralley *et al.* (1976) the transverse part of this muscle is sometimes absent (3 out of 50 feet dissected). These observers failed to identify a phalangeal attachment for the transverse part; those fibres which did not reach the lateral sesamoid bone were attached with the oblique part of the muscle.

Part of the muscle may be attached to the first metatarsal, constituting an *opponens hallucis*. A slip may also pass to the proximal phalanx of the second toe.

Nerve supply. The deep branch of the lateral plantar nerve, S. 2 and **3**.

The flexor digiti minimi brevis (**5**.110) arises from the medial part of the plantar surface of the base of the fifth metatarsal bone, and from the sheath of peroneus longus; its tendon ends on the lateral side of the base of the proximal phalanx of the fifth toe. Occasionally some of its deeper fibres reach the lateral part of the distal half of the fifth metatarsal bone, sometimes described as a distinct muscle—the *opponens digiti minimi*.

Nerve supply. The superficial branch of the lateral plantar nerve, S. 2 and **3**.

THE FOURTH LAYER

This group comprises the plantar and dorsal **interossei**, which are similar to those in the hand, but they are arranged relative to the *second* and not the *third* digit, as in the hand, the second being the least mobile of the metatarsal bones.

The dorsal interossei (**5**.111A), are situated between the metatarsal bones. They are four bipennate muscles, each arising by two heads from the adjacent sides of two metatarsal bones; their tendons are attached to the bases of the proximal phalanges and to the dorsal digital expansions. The first reaches the medial side of the second toe; the other three pass to the lateral sides of the second, third and fourth toes. In the angular interval between the heads of each of the three lateral muscles one of the perforating arteries passes to the dorsum of the foot; through the space between the heads of the first muscle the terminal part of the dorsalis pedis artery enters the sole.

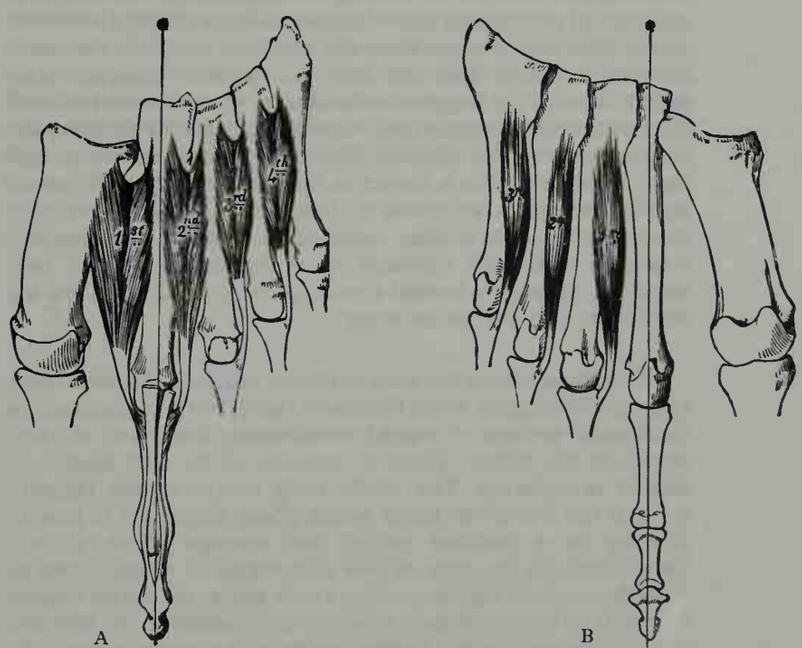
The plantar interossei (**5**.111B), three in number, are below rather than between the metatarsal bones, and each is connected with only one metatarsal bone. They arise from the bases and medial sides of the third, fourth and fifth metatarsal bones, and are attached to the medial sides of the bases of the proximal

phalanges of the same toes, and into their dorsal digital expansions.

Nerve supply. The dorsal and plantar interossei are supplied by the deep branch of the lateral plantar nerve (S. 2 and **3**), except those in the fourth interosseous space, which are supplied by the superficial branch of the same nerve. The first dorsal interosseous frequently receives an extra filament from the medial branch of the deep peroneal nerve on the dorsum of the foot, and the second a twig from the lateral branch of the same nerve.

The Actions of the Intrinsic Muscles of the Foot

As elsewhere in the body the actions of the muscles of the foot, or at least their potentialities, can be deduced from the mere geometry of their attachments, and the names applied to some of them indicate this. Such purely structural deductions must, of course, also take into consideration the modifying effects of contact with the ground, and they are in any case unlikely to provide more than suggestions regarding the actual roles of individual muscles in particular aspects of pedal activity. Direct observations of these muscles, either by eye or touch, is scarcely more informative; even with the aid of electromyography only the crudest of data are available, derived from a highly limited series of experiments. It must therefore be admitted that, despite some attractive speculation (p. 618), much uncertainty persists in these matters, as is attested by the volume of controversial literature on foot function.



There are two major conditions in which the musculature of the foot may be called upon to aid or modify the effects of muscular influences operating upon it from the leg; these are standing still and progression. In standing, with the feet flat on the ground, the feet are used as platforms for the distribution of weight, the centre of gravity of the body being maintained above them by suitable adjustment of tension and length in leg and trunk muscles. It is tempting to suppose that in these conditions the largely longitudinal intrinsic musculature of the sole would be active in sustaining the arched form of the foot against the flattening effect of body weight and this has been, of course, a canon of purely anatomical teaching for many years, despite increasing doubts amongst clinical and experimental workers. All the evidence from such sources, although limited in amount, indicates that the ligamentous ties of the foot, including the plantar aponeurosis, are largely sufficient. It is also often suggested that during standing, the intrinsic muscles, especially the abductors and short flexors, exert a 'tonic' effect in steadying the toe pads on the ground. Electromyographic evidence, admittedly scant, contradicts this and common observation shows that the toes can easily be extended out of contact with the ground with little adverse effect upon the efficiency of the feet in standing. Suzuki (1972), in a detailed electromyographic study of leg and foot muscles of normal and flat-footed individuals, observed that the intrinsic muscles of the foot were relatively inactive in the former individuals when standing, but were active in the flat-footed, as were long arch-supporting muscles such as peroneus longus.

When the heel is lifted from the ground in beginning to take a step, whether in walking or running, the whole of the weight and muscular thrust is transferred to the region of the metatarsal heads and the pads of the toes. This shifts the role of the foot from platform to lever and intensifies the forces acting on the fore part of the foot, especially in running and jumping. So much argument has been extended upon the nature and behaviour of the 'arches' of the foot and of the agents, muscular and ligamentous, which can or do act as 'tie-beams' or trusses across them, that the essential role of the foot as a lever is often overlooked. It is at first sight most ill-suited to act as a lever, being composed of a series of links, though its curvature or arched form has good mechanical precedents. In this situation it is clear that the concavity of the sole is accentuated, and the electromyographic evidence available indicates that the intrinsic muscles become strongly active. This would slacken the plantar aponeurosis, but the dorsiflexion of the toes which must occur tightens it up. The foot is also inverted and supinated, and the position of close-packing of the intertarsal joints is reached as the foot takes the full effects of leverage. In this position the foot loses all its pliancy (Inman 1969). The toes are held extended at the metatarsophalangeal and distal interphalangeal joints and flexed at the proximal interphalangeal including the interphalangeal joint of the hallux. This probably results from contraction of the flexor digitorum brevis and the long flexors of the toes, by drawing the terminal phalanges towards the sole and passively buckling the rest of the toes into the above position. The buckling is perhaps controlled by the action of lumbrical and interosseous muscles by opposing extension at the metatarsophalangeal joints and flexion at the proximal interphalangeal joints. The flexor hallucis brevis could prevent excessive extension at the metatarsophalangeal joint of the hallux. The abductors of the hallux and fifth toe both act as flexors, with probably little abductor effect, though their disposition varies in different feet. It must be emphasized that analyses such as the above are speculative, and in view of the difficulties which impede electromyographic examination of the active foot, the present uncertainties are likely to persist (see also p. 619). Various imbalances in the actions of toe muscles are invoked to explain certain dysfunctions and deformities, such as contracted toes. Actual studies are rare, but an evaluation of the weights of lumbrical muscles has shown no correlation with toe contractures (Challey *et al.* 1975).

Standing, Walking and Running

Although birds are in a sense bipeds, as are some reptiles and eutherian mammals, only man has evolved a completely upright posture as his habitual working position. Some mammals, particularly primates, may adopt such a position for considerable periods, but none displays the degree of specialization associated with human adaptation to continuous upright standing and locomotion. Human erect posture is often held to have been attained at the cost of such a painfully difficult evolution that it is a precarious habit, prone to all manner of drawbacks, breakdowns and pathology. This is probably due to the influence of medically orientated thinking. A completely upright posture was characteristic of most, if not all extinct hominids and has been foreshadowed in other primates for an even greater period of time. The disadvantages of quadrupedal habit do not appear to have attracted similar veterinary attention.

In his *posture* the human primate is singular, if not unique, in having straightened the trunk and lower limbs to such an extent that the centre of gravity of any segment of the body is substantially above the joints upon which its weight impinges; even the head is almost if not wholly balanced upon the cervical spinal column. A vertical from the centre of gravity of the whole

5.111 A and B The interossei of the left foot. A Dorsal interossei viewed from the dorsal aspect. B Plantar interossei viewed from the plantar aspect. The axis to which the movements of abduction and adduction are referred is as indicated.

body (a point about a centimetre posterior to the sacral promontory) falls anterior to the ankle joint. Strong plantar flexion, particularly due to increased tension in soleus, is hence necessary to prevent forward sway or actual falling. However, in most individuals when standing in an easy, symmetrical manner, the same vertical passes in such a relationship to the hips and knees that gravity tends to increase extension, which is in part limited by the rise of tension in ligamentous structures (associated with the near close-packed position of the joints—*see* p. 438) rather than by muscle activity. Thus, such a posture, often maintained for long periods, requires little muscular activity (Akerblom 1948; Joseph 1960), except for brief bursts in appropriate muscle groups whenever the body sways from this position. It is noticeable that the standing position is often changed, intermittently relieving stress upon ligaments and transferring it to muscles (Smith 1950), the commonest habit being to hyper-extend one knee and to flex the other slightly. Thus one leg after the other is made to take the major stress of body weight, the slightly flexed leg acting for the time being as a kind of outrigger or prop. Evans (1977) has emphasized the role of the iliotibial tract in achieving and sustaining the 'locked' hyper-extended (close-packed) posture of the weight-bearing leg in such asymmetrical standing. The line of gravity is related to the curvatures of the spine in such a way that they are, on the whole, exaggerated by gravity, but can be controlled by small muscular tensions, over the details of which considerable controversy still obtains. Any considerable swaying of the trunk above the pelvis entails not only responsive activity in leg muscles but also in those of the trunk, such as the psoas major when the body sways backwards.

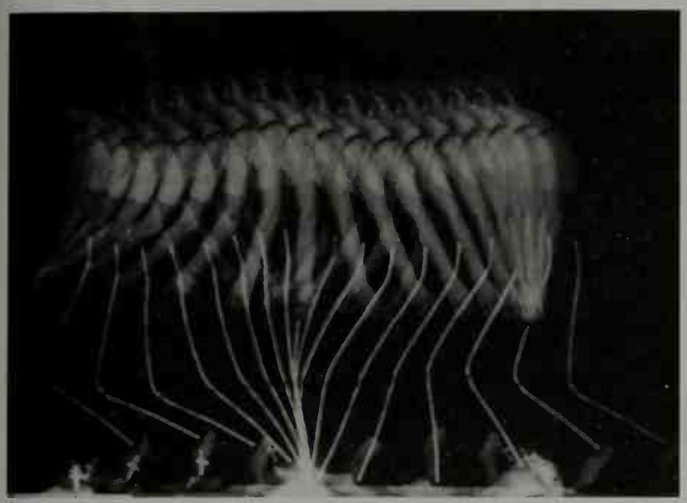
The energy-sparing principle of using gravity to hyperextend (or sometimes flex) joints is applied in some birds, such as the upright penguin, and passerine birds which roost in trees. It is, however, apparently unique in man, among mammals. It should be noted, however, that many quadrupeds also habitually stand for even more prolonged periods of time, apparently without great effort and with much less complaint than the human biped.

In *locomotion*, whether it be walking, running, jumping or climbing, there is an immediate departure from the economical pattern of standing. All muscles of the trunk, arms and legs may be at times involved, some as prime movers, others as fixators or stabilizers. The arms are swung as balancers and also as weighted pendulums to increase the impetus, especially in running and jumping; their use in climbing is obvious.

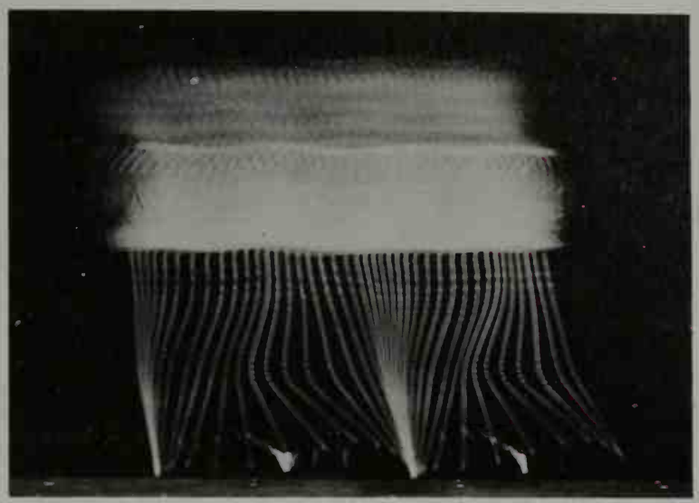
In studies of locomotion (*vide infra*) most attention has been focused upon analysis of walking movements and the temporal sequence of contraction and relaxation in some muscles involved. As the first step is taken from the standing position, the trunk inclines forwards and the feet are slightly inverted with accentuation of the longitudinal arches (p. 501). One heel is lifted from the ground, transferring the weight progressively along the lateral border of the opposite foot to the metatarsal heads, and then to the toes. This is known as the *stance phase*, which passes into the *swing phase* as soon as the foot leaves the ground, which it meets again in the reverse order—heel first and then again a repetition of the roll forwards on to the toes. From one heel impact to the next is termed a *walking cycle*, the cycle of one leg alternating with that of the other.

The **stance phase** has been variously analysed (Barnett 1956; Gray and Basmajian 1968; Elftmann 1966), but it is essentially a continuous process of weight transference from heel to toes, especially the hallux. These movements of the foot cannot be viewed in isolation. The whole body moves a little laterally towards the side of the leg in stance phase, the centre of gravity shifting to a variable extent (on average about 5 cm). Simultaneously the arm on this side begins to swing forwards with the opposite leg; the pelvis, which was at the outset rotated forwards on the stance side, now moves forwards on the opposite side (accompanying the forward swing of the opposite leg). The foot is, of course, fixed on the ground, and hence, as the knee extends and the ankle dorsiflexes, the tibia rotates medially to a small extent carrying the talus with it, and the femur undergoes an obligatory conjunct medial rotation at the knee joint (p. 488) and hence at the hip joint. The latter medial rotation of the femur relative to the acetabulum is accentuated by the rotation of the pelvis in the opposite direction mentioned above. This series of congruent medial rotations, combined with dorsiflexion and transient supination of the subtalar skeleton (p. 501) serves to bring all the articulations of the leg and foot near their close-packed positions. The resulting momentary rigidity coincides with the instant of maximum thrust imparted by the powerful plantar flexors of the foot. Thereafter, as the heel is raised from the ground, the foot passes into plantar flexion and pronation and the thrust is now transmitted through a loosely packed pliant lever (under muscular control) to the head of the first metatarsal and the dorsiflexing hallux, which finally leaves the ground to terminate the stance phase. (This brief description should be compared with an analysis of the various movements of the pedal skeleton—pp. 501–503.)

In the **swing phase** the toes leave the ground, as the opposite heel meets it, to transfer support. The leg, relieved of weight bearing, swings forwards with flexion at the hip and knee, dorsiflexion of the foot and lateral rotation of all those elements that had undergone congruent medial rotation during the stance phase. The leg swings forwards with a pendular action which, however, is under the influence of the hip flexors. As the limit of the stride is reached, the momentum of the limb is overcome by the hip extensors to bring the heel to the ground, and to begin another cycle.



These events occur far more rapidly than can be described, but the general analysis is fully supported by cinematographic evidence. The actual role of many of the muscles involved has been investigated at every stage, but the details are beyond the scope of this account and should be sought in original studies.

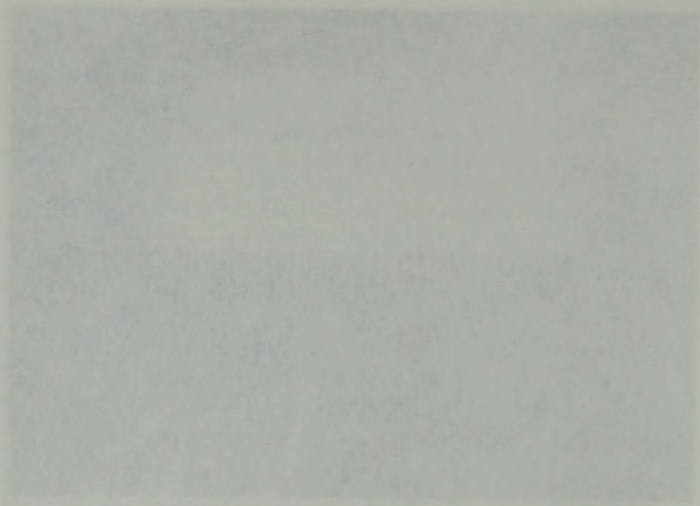


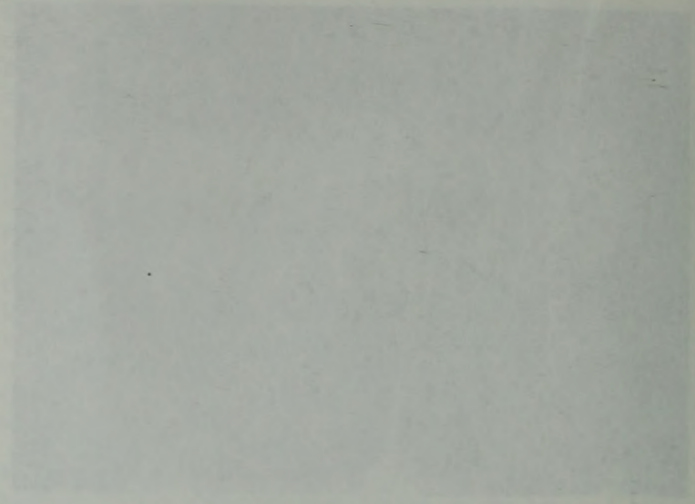
The speed of walking can, of course, be increased by augmenting the work done by the muscles involved, and by acceleration of their actions. In running, the movements are broadly similar, but the heels do not touch the ground, thrust being taken entirely by the forefoot. Moreover, the body is carried forwards by its momentum entirely unsupported for a brief period between take-off from one foot and descent upon the other. A similar unsupported phase characterizes hopping, whether on one foot or alternate feet. In jumping, take-off may be from one foot or two, either simultaneously or in quick succession; landing occurs in the same manner.

In all forms of progression the forces involved are gravitational, inertial and muscular. The latter may vary from minimal exertion, sustainable over long periods of time, to maximal effort for comparatively brief periods, although reliable estimates of the relative expenditures of energy are few.

Mechanical Analysis of Locomotion

Mathematical analysis of the mechanics and energetics of locomotion, studied in many animals, including invertebrates, has been advancing rapidly in recent years. (For an introduction to the literature in this field consult Alexander and Goldspink, 1977, and Pedley 1977.) Locomotion in many vertebrates has been analysed, and more particularly in mammalian quadrupeds. The basic data are usually cinephotographic and force platform recordings (Alexander *et al.* 1977), but X-ray cinephotography and electromyography (Wentink 1976) have also been used. The mechanics of bipedal locomotion have been studied in amphibia, marsupials, and primates, including mankind. One of the most interesting results of such studies is the recognition of the importance of the storage of recoil energy not only in muscle tissue but also in tendons (Alexander and Bennet-Clark 1977). Cinematic analysis of human walking and running has already contributed to phasic analysis of the movements involved, but the more recent mathematical studies go much further in accounting for the forces concerned. For example, it is possible to predict that there is a limiting optional velocity for walking, beyond which it becomes more economical, in terms of muscle energetics and oxygen consumption, to introduce a 'floating' phase by a change to running. The role of elastic recoil in human tendons and muscles has been studied by combined light and X-ray cinephotography, but reliable data are not yet available. Mathematical interpretation of locomotor mechanics has also





5.112A AND B Chronocyclograms of two individuals walking relatively fast. In A the support phase, with one foot on the ground, occurs at midpoint of the recording, which occupies one full cycle. In B two such support phases are apparent and the recording occupies somewhat less than two cycles. The bright lines are successive images of a stripe attached to the trousered leg proximal to the camera. Note the concentration of lines at the support phase and also the varying angulation at hip, knee, and ankle. (Photographs kindly supplied by Dr. D. W. Grieve, Department of Anatomy, Royal Free Hospital Medical School, London.)

stimulated a renewed interest in bodily proportions, especially in limbs, which provide necessary data for such analyses (McMahon 1977). Not only the dimensions of limb bones, relative to body size and weight, but also the proportions of their osseous segments and those of muscle masses, have become essential data in comparative mechanical studies of gait. The internal arrangements of fibres in muscles have also acquired a renewed significance in quantitative analysis (e.g. Alexander and Vernon 1975). Detailed coordination of all such data into even general concepts of either quadrupedal or bipedal locomotion is inevitably complex; but progress has been rapid in this field and highly interesting and valuable results are to be expected. For a discussion of optimal technique in bipedal walking consult Alexander and Jayes (1978).

The foregoing remarks largely concern analyses of electromyographic and cinematographic recordings in which the data have been considered qualitatively rather than quantitatively. Some workers in this field (e.g. Grieve and Cavanagh 1974) have claimed to be able to quantify electromyograms with considerably improved accuracy by computerized techniques. This has been coupled with an exacting method of measuring cinematic records obtained simultaneously in two or three cardinal planes. Since a temporal parameter is obviously involved, and is of course measurable from the recordings, a very detailed analysis of the angular displacements between the segments of the limbs involved in walking (and the speeds of movement of each segment) can be undertaken. The data obtained can be integrated by computer techniques, and they may also be expressed in graphic forms. Such integrated graphs of the cycle of movements, in space and time, are known as '*chronocyclograms*'. The so-called 'heel-strike' and 'toe-off' points of the cycle are commonly chosen as datum points. Such chronocyclography (*see* **5**.112) has already demonstrated changes in pattern with alternation of speed in walking, and comparisons can also be made between the events in 'normal' records with those obtained from patients afflicted with disturbances of locomotion. The latter developments facilitated and refined descriptions of abnormal gaits and thus it was hoped that they would also prove of applied value, but in its original form the technique was somewhat lengthy and tedious. However, the technique has been further improved by Grieve and his co-workers (1979). This depends upon computer evaluation of the cycle of angular changes in the thigh and foreleg segments, the angles being recorded by the impingement of a rotating beam of plane-polarized light upon suitable sensors attached to the limb segments. Since the signals produced by this polarized light goniometer (the Medelec Polygon equipment) are directly passed to a suitably programmed computer, a graphic recording is *immediately* available of the subject's angulation cycle, in stepping or walking. This development now renders the technique suitable for clinical application. (A stroboscopic method of recording has also been used, and the records shown in **5**.112A, B illustrate the cycle of angulation in walking.) The researchers quoted, and others, are currently promoting the collection and analysis of data on an international scale.

6

ANGIOLOGY

Introduction

The physico-chemical composition and properties of the fluid micro-environment of the cells comprising the various tissues of the body remain relatively constant, by the operation of an interlocking series of homeostatic control mechanisms, which depend for effectiveness upon adequate circulatory systems. The latter consist of cell-lined arrays of tubes and spaces which permeate or surround the tissues and through which a continuous flow of one of the body fluids occurs. The most extensive circulatory pathways comprise the *blood-vascular system*, consisting of the heart and blood vessels, through which the blood circulates, and the *lymphatic system*, consisting of lymph nodes and vessels which conduct the lymph—although such a restricted definition should perhaps be extended to include the isolated patches of lymphoid tissue, the spleen, thymus and the various pathways additionally involved in the wider concept of 'the *cirulation of the lymphocytes*' (p. 773). Other more restricted circulations are those of the cerebrospinal fluid, the perilymph, the various endocochlear fluids, the aqueous humour of the eye and the synovial fluid. The present section on *Angiology* is restricted to a consideration of the blood-vascular and lymphatic systems.

Repeated contraction of the heart, which consists of a *pair* of hollow, valved, muscular pumps, arranged in *series (vide infra)*, drives the blood through the blood-vascular system to reach all the tissues of the body. Leaving the heart, the blood is distributed through a series of large tubes, the *arteries*, which ramify and continually subdivide until minute vessels, the various grades of *arterioles*, are reached, which again subdivide to form close-meshed networks of microscopic vessels in intimate contact with the tissues. These vary in structure and are called either *capillaries* or *sinusoids* depending upon their particular structural and functional characteristics. From the latter the blood is collected via minute *venules* which repeatedly converge to form increasingly large tubes, the *veins*, which return the blood to the heart.

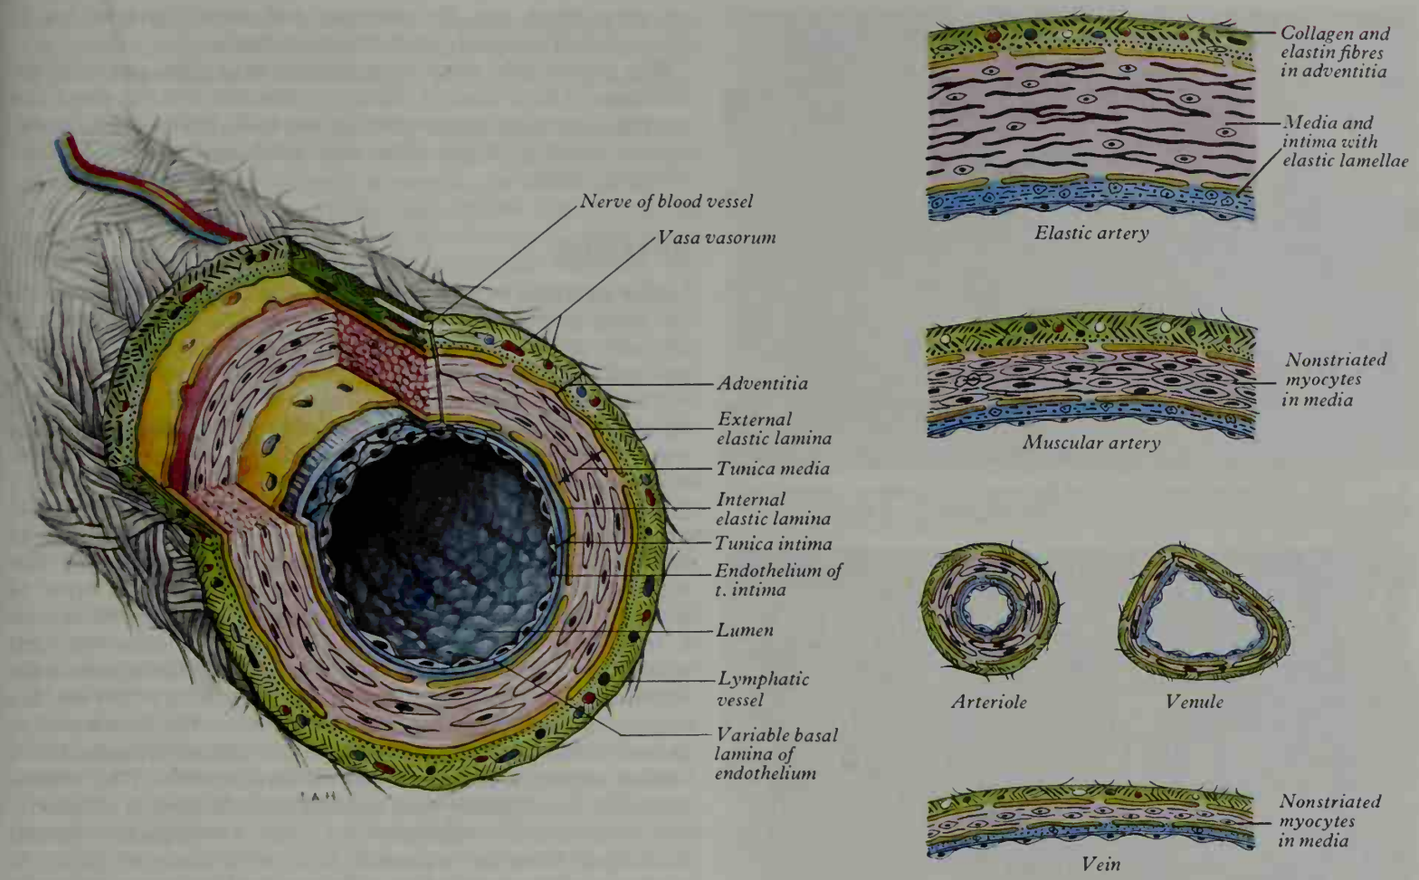
The terms artery, arteriole, capillary, venule and vein, are essentially *anatomical* names for vessels of particular dimensions, structural characteristics and topographical positions. Another useful *functional* classification groups the blood vessels into *distribution*, *resistance*, *exchange* and *capacitance* or *reservoir* vessels. Finally, varieties of *shunt* which provide bypass channels at a pre-capillary or pre-sinusoidal level must be considered.

The *distributing vessels* consist of the low-volume, high-pressure system of large arteries which leave the heart, and the branches of the arterial tree down to arteriolar levels. They show graded structural and functional characteristics with increasing subdivision and distance from the heart. The large vessels leaving the heart and their main branches contain much elastic tissue in their walls (*elastic arteries*), the repeated distension and elastic recoil of which converts the effects of the intermittent contractions of the heart into a more continuous although still pulsatile flow of blood throughout the arterial tree. The smaller arterial branches, while retaining a marked elastic component, contain an ever-increasing amount of non-striated muscle in their walls (*muscular arteries*), the differential contraction of which allows a controlled variation in the overall blood flow to the various large tissue masses, which corresponds to their fluctuating levels of physiological activity. It should also be noted, however, that some authorities prefer to use the term *conducting arteries* for the major outflow vessels, with much elastin in their walls, and *distributing arteries* for muscular arteries lying between these and the resistance vessels provided by the arteriolar channels (Simonescu and Simonescu 1977).

A more intimate control of the blood flow pattern through the microcirculatory units of the various tissues (*vide infra*) is provided by the muscular walls of the arterioles and precapillary sphincters (*resistance* vessels). These provide the principal source of the peripheral resistance to the flow of blood, which, together with the prevailing volume of cardiac output in unit time, determines the blood pressure levels in the arterial tree.

The capillaries, sinusoids and post-capillary venules are collectively termed *exchange vessels* because across their walls occurs the exchange between the blood and the tissue fluid bathing the cells, which constitutes the essential function of the blood circulatory system. This includes the transference of oxygen, carbon dioxide, nutrients, water and inorganic ions, vitamins, hormones, metabolic products, immune substances and finally, immunologically competent and phagocytic cells.

The larger venules and veins comprise an extensive, variable, large-volume, low-pressure system of *capacitance* or *reservoir vessels* through which the cardiac return occurs.



The mature heart has four chambers: through widespread usage these are termed the *right atrium, left atrium, right ventricle* and *left ventricle* (some discussion on the somewhat misleading nature of these names will be found on p. 639). Each atrium communicates freely with the corresponding ventricle, but the right and left chambers are separated from one another by partitions, called *septa*. The right and left heart in the adult thus comprise twin pumps *topographically combined* in a single organ but which are interposed *in series* at different points in the blood-vascular system and separate it into a *systemic* and a *pulmonary* circulation (constituting the so-called *double circulation* which characterizes birds and mammals—*vide infra* p. 636). The course of the blood from the left ventricle through the body generally to the right side of the heart constitutes the greater or *systemic circulation*, while its passage from the right ventricle through the lungs to the left side of the heart is termed the lesser or *pulmonary circulation*. The relatively short and restricted pulmonary system offers a much lower peripheral resistance than the systemic circulation and this is reflected in the considerably lower pressures in the pulmonary distribution vessels than in the aorta and in the relatively thin walls of the right ventricle (p. 637). Nevertheless, the average output volume of blood per unit time from the right and left heart must necessarily be the same.

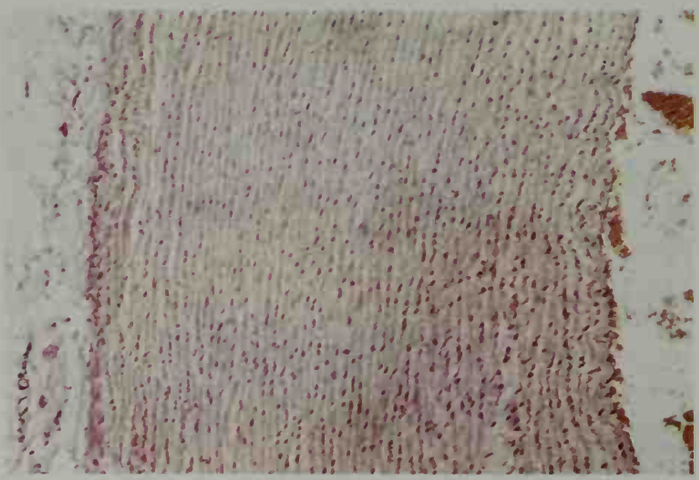
The superior and inferior venae cavae bring to the right atrium blood which has become deoxygenated, taken up carbon dioxide and been otherwise modified during its circulation through the tissues of the body. From the right atrium this venous blood passes into the right ventricle, which expels it into the pulmonary trunk to be conveyed to the lungs. As it circulates through the lung capillaries the blood is brought into close relationship with the inspired air and it gives off some of its carbon dioxide and acquires a fresh supply of oxygen. This oxygenated blood is returned by the pulmonary veins to the left atrium and thence passes into the left ventricle. With each beat of the heart the left ventricle pumps its contents into the *aorta* , which distributes the oxygenated blood through its numerous branches to the tissues and organs of the body.

The blood which circulates through the spleen, pancreas, stomach and the intestines is not returned directly from these organs to the heart, but is conveyed by the *portal vein* to the liver. In the liver this vein divides like an artery and ultimately ends in the hepatic blood sinusoids from which the rootlets of the *hepatic veins* arise; the hepatic veins carry the blood into the inferior vena cava, which conveys it to the right atrium. This constitutes the *portal circulation* and it will be understood that the blood supplied to the above-named viscera passes through two sets of minute vessels before reaching the inferior vena cava: (1) the capillaries in the spleen, pancreas, stomach, etc., draining into the portal vein; and (2) the sinusoids in the liver, draining into the hepatic veins. The passage through two sets of capillaries enables the blood to take up products of digestion from the alimentary canal and to convey them to the liver cells. A second venous portal circulation connects the median eminence and infundibulum of the hypothalamus with the pars distalis of the adenohypophysis (p. 1444).

The Structure of the Blood Vessels

Blood is ejected from the left ventricle during systole into the aorta, a single tube of about 2·5 cm diameter in the adult (Wright 1969) and with a wall thickness of about 1·5 mm. After traversing numerous generations of branches from this parent trunk the blood eventually enters the capillary bed in the tissues which, by contrast, consists of many millions of tubes about 8 μm in

6.1 A diagram showing the principal architectural features of the larger blood vessels. On the *left* the major layers and associated structures are depicted. On the *right* the particular features of an elastic artery, muscular artery, arteriole, venule and vein are shown.

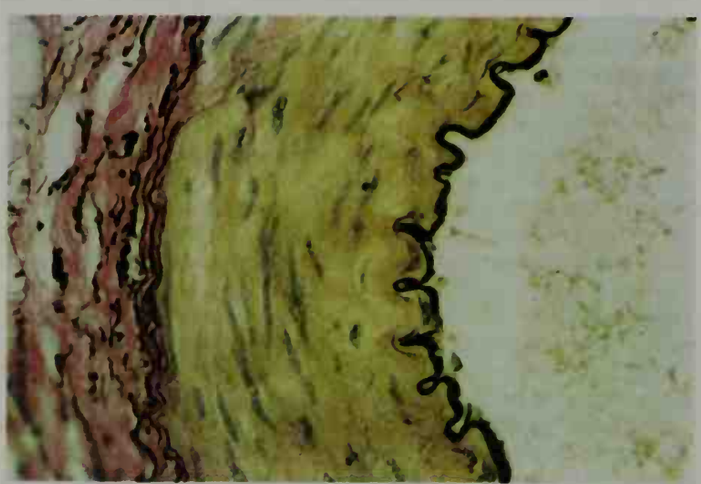


diameter with a wall thickness in places of less then an 0·2 μm and a total estimated length in the adult which approaches 60,000 miles (Zweifach 1961). It is often affirmed that the systemic *arterial tree* progressively divides into a larger and larger cross-sectional area. However, the evidence for this in man is by no means clear, particularly in the arterial pathways proximal to the arteriolar level. However, the change in the structural and functional attributes of the arteries is progressive with increasing branching and distance from the heart. There is both a geometric taper of lumen cross-section and an increase in stiffness of the vessel wall. During *arteriolar* and *capillary* branching the total cross-sectional area of the vessels increases greatly and this is accompanied by a progressive reduction in the flow-rate, systolic pressure and pulse pressure of the contained blood. The structural and functional attributes of these vessels change therefore, even more dramatically, with increasing branching and distance from the heart (**6**.1–8). However, the whole blood-vascular system, from the finest vessels up to and including the heart, have one structural component in common, namely, a smooth lining throughout of a single layer of endothelial cells. Even these cells show dimensional and other ultra-structural differences in different parts of the system and particularly in the capillary and sinusoidal networks. Vessels of larger calibre than capillaries or sinusoids possess organized tissue zones which surround the endothelial lining. These zones contain varying amounts of fibrous tissue (reticulin, collagen and elastin) together with fibroblasts and non-striated myocytes. Despite the fact that the radial organization of these components in a vessel wall varies greatly with vessel size and type, closely reflecting the functional roles of the vessel, most classical histologists have attempted to define three analogous zones (coats or tunics) in the walls of all vessels down to arteriolar and venular level (Cliff 1976). These are named from within outwards the *tunica intima*, *tunica media* and *tunica adventitia*, and because of common usage these terms will be retained in this account. Too strict an adherence to such an arbitrary classification should not obscure the overall functional organization of each vessel type. This includes the provision of a low-friction lining, structural elements which balance the longitudinal and circumferential stresses generated by the prevailing pressures of the contained blood, elastic recoil which progressively modifies the pulsatile nature of the pressure and flow variations in the arterial tree, and the ability to control calibre changes, by muscular action, with varying functional demands.

In general, the *tunica intima* consists of a single layer of endothelial cells supported externally by a delicate layer of subendothelial connective tissue with a predominantly longitudinal organization. The fibro-muscular *tunica media* extends from the internal to the external elastic lamina (*elastica interna* to *elastica externa*) and has a circumferential organization. The *tunica adventitia* which surrounds the external elastic lamina is a connective tissue coat with again a largely longitudinal organization and this blends externally with the surrounding fibro-areolar tissue.

Nutrient blood vessels, the *vasa vasorum*, and lymphatics run in the adventitia, and a few in the outer regions of the tunica media; nerve fibres may also supply all three major layers of the vessel wall (*vide infra*). The arteries are enclosed in a thin fibrous connective tissue *sheath*, artery and sheath being connected by delicate areolar tissue. The sheath usually encloses any accompanying veins and perivascular nerves, and sometimes major nerve trunks.

The thickness of vessel walls



The precise form and composition of blood vessel walls varies largely with the blood pressure and, in arteries, the nature of the pressure wave within. Thus, arteries are proportionately much thicker than veins, and both arteries and veins inferior to the heart are in general thicker than their counterparts superior to it, in accordance with the higher hydrostatic pressure of the blood in the lower parts of the body when in the erect posture. Arteries of

6.2A Part of a transverse section of the aorta of a monkey, stained with haematoxylin and eosin, showing the distribution of cell nuclei.

6.2B Part of a transverse section of a young human aorta stained with Verhoeff's stain for elastin. Note the density of the concentric fenestrated elastic laminae. (Kindly supplied by Dr. R. O. Weller, Department of Pathology, Guy's Hospital Medical School.)

6.2C An oblique section of a medium-sized muscular artery, stained with Verhoeff's stain for elastin (black), and van Gieson's stain for collagen (red). Note the characteristic folded, prominent internal elastic lamina.

the systemic circulation have thicker walls than ones of corresponding diameter in the pulmonary circuit, reflecting their marked differences in pressure. Arteries within the 'closed box' pressure system of the cranium and vertebral canal have very thin walls in relation to their diameter, the external and middle coats being reduced in thickness; similar considerations apply to the vessels within the medullary cavities of the long bones. In contrast, some vessels are exceptionally muscular, particularly where considerable external pressures or other mechanical forces act upon them, e.g. the coronary and carotid arteries are in possession of especially thick muscular media.

As a general rule, elastic arteries have walls about one tenth the thickness of their interior diameter, muscular arteries about one quarter, arterioles approximately one half, whilst veins, again, have a mural thickness about one tenth that of their luminal diameter, or less.

ARTERIES

Large arteries of the elastic type (6.1, 2, B). These include the aorta and its main branches of distribution, the brachiocephalic, common carotid, subclavian and common iliac arteries, and also the pulmonary arteries and their principal branches.

The *tunica intima* consists of a layer of endothelial cells resting on a basal lamina and a layer of subendothelial connective tissue, together being about 100 μm thick in young adults. The endothelial cells are flattened and polygonal, and are joined by intercellular junctions which include zonulae occludentes and maculae communicantes. The general cytological features of endothelial cells will be considered with capillary structure. The subendothelial connective tissue comprises, first, a layer of interlacing mainly longitudinal collagenous and elastin fibres with a few fibroblasts and occasional nonstriated myocytes, and macrophages. This is succeeded by a fenestrated elastic membrane which corresponds to the internal elastic lamina of the smaller arteries, but is not sharply demarcated from the tunica media, because the latter, in these larger arteries, contains a succession of similar elastic membranes (*see* Dobrin 1978). The intimal thickness varies greatly with age and other factors: in children it may be an almost insignificant layer, but in young adults intimal thickening becomes noticeable due, it is thought, partly to migration and proliferation of nonstriated myocytes from the media, and to a greater or lesser extent to the deposition of lipid material which often forms irregular fatty streaks. In normal young adults the intima is about one sixth of the total wall thickness, but after middle age, lipid deposits may grossly expand this layer.

The *tunica media* consists almost entirely of concentric, circularly disposed, fenestrated elastic lamellae, up to forty layers thick in normal aortae, separated from one another by fibrous tissue containing a basophilic matrix, permeated by bundles of collagen and elastin fibres which surround circularly disposed non-striated myocytes (Somlyo and Somlyo 1968). For the most part these myocytes are unexceptional, but those adjoining the intima often assume highly branched bizarre shapes (Keech 1960), and interconnect adjacent lamellae. There appears to be a good correlation between the internal pressure of elastic arteries and the number of elastic lamellae which, together with their associated nonstriated myocytes, form '*lamellar units*' (Wolinsky and Glagov 1967a). The nonstriated myocytes are responsible for the laying down of the lamellae, and also the collagen and glycoprotein components between them (Ross and Klebanoff 1971), an ability also shown to a much smaller degree by non-striated myocytes elsewhere in the body. The numbers of lamellae increase greatly during postnatal development, the aorta of the newborn being almost devoid of them, and therefore, of the muscular type. They also increase in number in hypertension under the influence of the extra mechanical stress (*see* Cliff 1976).

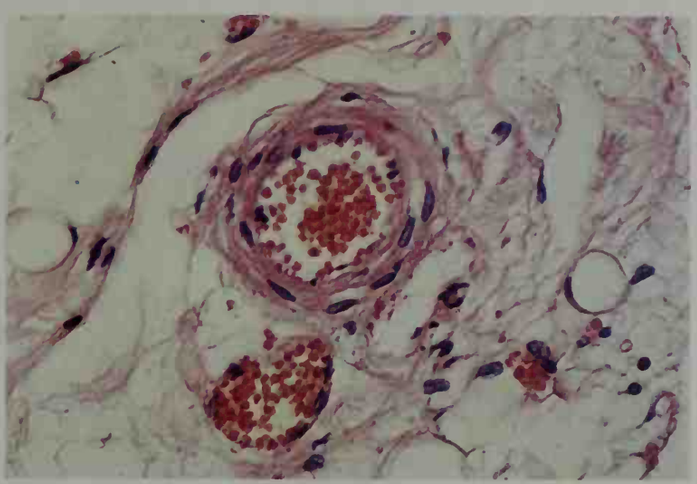
The disposition of the myocytes varies with their overall position in the vascular system. In the elastic arteries nearest the heart, the myocytes interconnect radially adjacent lamellae ('*Spannmuskeln*'), whereas more distally they are orientated in a more circular direction ('*Ringmuskeln*'), being arranged end to end (Benninghof 1927; Wolinsky and Glagov 1964); in both cases they display a slight helical arrangement.

The *tunica adventitia* is composed of fibrous tissue containing a few elastic fibres. It is relatively thin and merges into the surrounding connective tissue.

From middle age onwards, various structural alterations are found in elastic (and other) arteries, in addition to the intimal changes already mentioned; this is particularly true of the aorta, and arteries of the heart and brain. The amount of elastin and collagen increases, muscle decreases, and there is a lower water

content leading to an increase in general stiffness. Other associated changes include the desposition of calcium salts and lipid in the media, and the splitting of the internal elastic lamina.

Medium and small arteries of the muscular type (6.1, 2C, 3). The *tunica intima* consists of a single layer of elongate endothelial cells, longitudinally arranged, the outer surfaces of which are covered with a typical basal lamina closely abutting upon the *internal elastic lamina*. The latter is a fenestrated elastic sheet appearing in transverse sections as a bright refractile zone which, because of agonal contraction of the muscular media, is thrown into characteristic wavy folds. As there is less elastic tissue in the media than there is in the larger vessels, the internal elastic lamina stands out in sharp contrast. Here, and in the large arteries, the fenestrations in the elastic layers are considered to act as diffusion paths for metabolites between the various layers of the vessel wall.



In the coronary arteries the internal elastic lamina is bounded by a specialized thick layer of longitudinal muscle and fibrous tissue, which presumably enables the vessels to accommodate to the marked changes in length occurring throughout the cardiac cycle.

The *tunica media* consists mostly of non-striated myocytes with scattered elastic membranes and a few collagen fibres. The myocytes are generally disposed in low-pitched helices except in the smaller vessels where they are circumferential. The myocytes are similar to those elsewhere (p. 518), but are claimed to contain fewer micropinocytotic vesicles and more rough-walled endoplasmic reticulum and ribosomes; the Golgi apparatus is small. Adjacent non-striated myocytes are interconnected with communicating junctions which act to coordinate the activity of the muscle layer, under neural or neuro-humoral control. Longitudinal myocytes exist in both the intima and media of arteries subject to repeated bending, e.g. the carotid, axillary, uterine, cervico-occipital, and palmar arteries. In the umbilical arteries, longitudinal muscle occurs in the inner region, and circular in the outer zone of the tunica media.

The *tunica adventitia* consists of collagenous and elastin fibres which run predominantly in a longitudinal direction. The outer portion is somewhat loosely arranged, merging into the surrounding areolar tissue, and so allows considerable movement between the artery and the neighbouring structures. Immediately adjacent to the smooth muscle of the tunica media the adventitia contains much elastic tissue which here includes the fenestrated *external elastic lamina*.

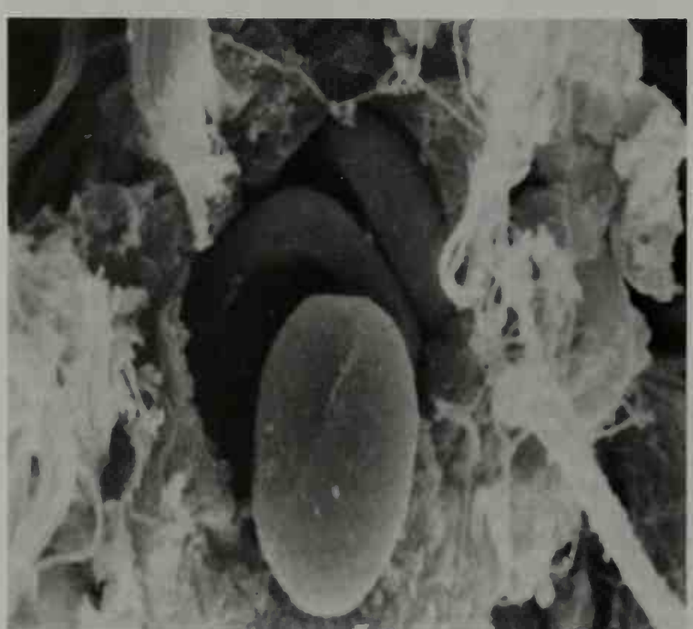
ARTERIOLES, TERMINAL ARTERIOLES, METARTERIOLES, AND PRECAPILLARY SPHINCTERS (6.4, 5A–E)

The terminal branches of the smallest arteries open into *muscular arterioles* of between 100 and 50 μm in diameter, which in turn branch into *terminal arterioles* of less than 50 μm in diameter and with but one or two layers of non-striated myocytes in their walls (Rhodin 1971). The side branches from the terminal arterioles are 10–15 μm in diameter at their origins, but may decrease over a distance of 50–100 μm to as little as 5 μm at their narrowest point. At their mouth they are surrounded by a prominent layer of circular non-striated myocytes. These vessels are sometimes termed *metarterioles*, and their surrounding muscle rings, *precapillary sphincters*. They open directly into the capillary bed, and act as a final control of nutritive blood flow. In several instances, precapillary sphincters have been seen to undergo periodic opening and closing, each cycle of activity lasting 2–8 seconds.

Both the larger and terminal arterioles are lined by a single layer of flattened endothelial cells which are greatly elongated in the long axis of the vessel. They rest on a basal lamina, separated in places from the lamina of the non-striated myocytes of the media by patches of elastic tissue, homologous with the internal elastic lamina of larger vessels. This elastic tissue becomes scantier and finally disappears in the finest terminal arterioles. The media of the larger arterioles consists of a few layers of non-striated myocytes circularly disposed, but with the outermost layer often forming a low-pitched helix. The single layer of myocytes in a terminal arteriole has a similar spiralized form and, as in the larger arterioles and metarterioles, they form intercellular (myo-endothelial) junctions with the overlying endothelium, at those points where the elastic lamina is lacking.

The adventitial coats of arterioles consist of a fine feltwork of collagen fibres and a few associated fibroblasts.

Arterial Nutrient Supply



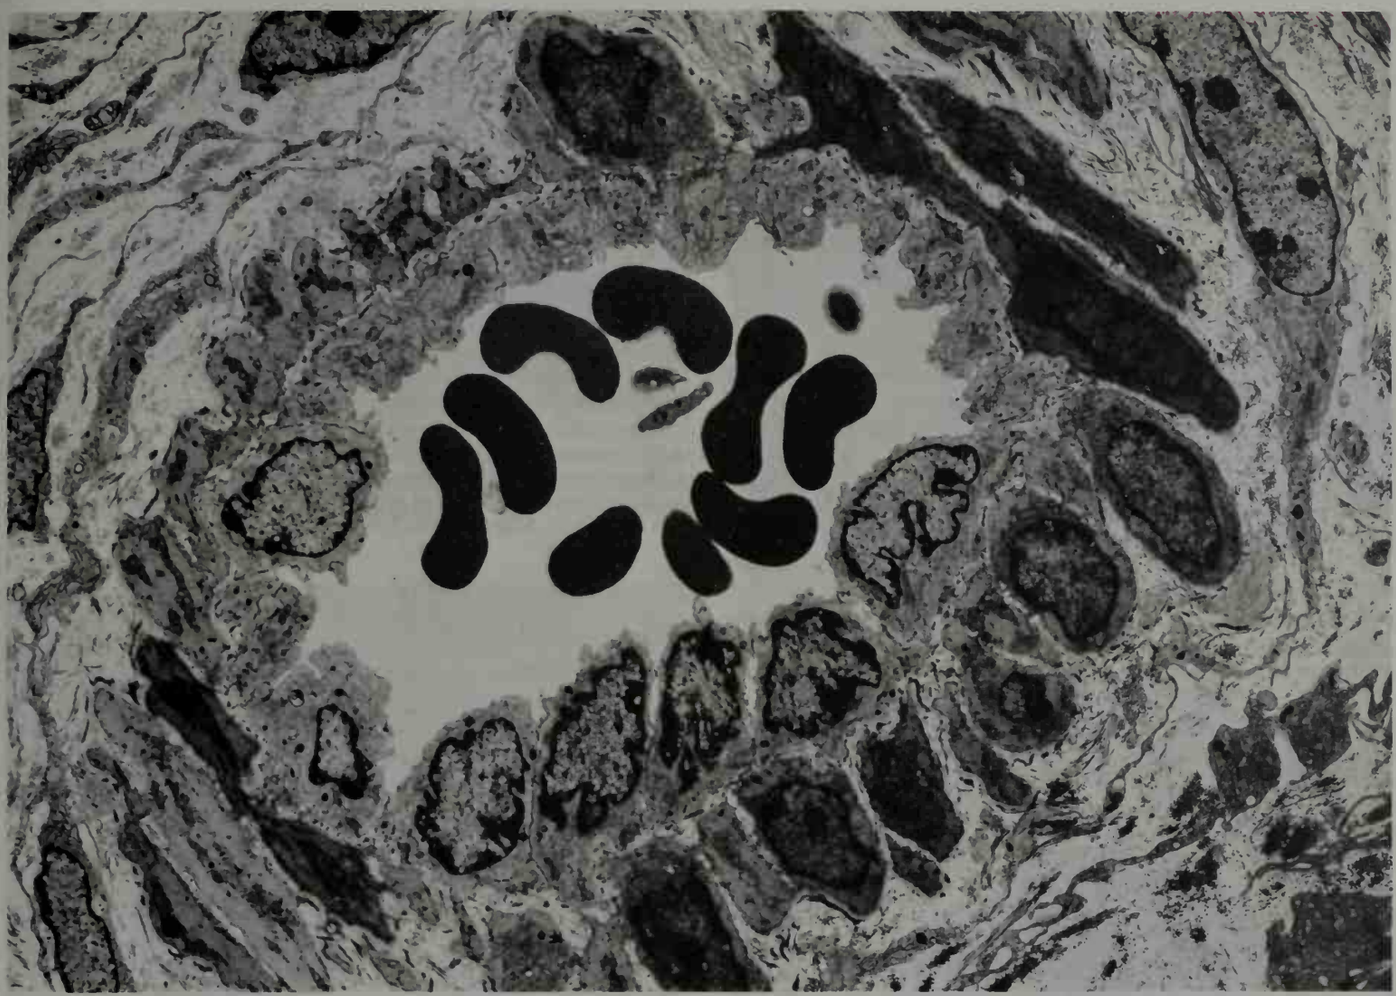
The larger arteries are supplied with blood vessels. These nutrient vessels, called the *vasa vasorum*, arise from branches of the artery itself, or of a neighbouring vessel, at some considerable distance from the points at which they are distributed; they ramify in the loose areolar tissue connecting the artery with its sheath, and, after forming a dense capillary network in the adventitia, supply the outer part of the media. The nutritional requirements for the remainder of the vessel wall are obtained by diffusion from the blood in the lumen of the vessel, and it is assumed that the fenestrations in the elastic laminae are important in this regard. Minute veins return the blood from these vessels; they empty themselves into the vein or veins accompanying the artery. Lymph vessels are also present in the outer coat.

Arterial Nerve Supply

Arteries are also supplied with nerves; the majority are non-myelinated, but some are myelinated. The non-myelinated fibres are mostly efferent and constitute the vasomotor nerves to the vessels, along which passes the continuous flow of impulses responsible for the variable 'vasomotor tone' of the vessels. The

light microscopical evidence of pericellular nerve nets in the media has not been confirmed by electron microscopy, which has emphasized the paucity or absence of nerves within the media. The nerve fibres ramify in the adventitia and then approach the outer layer of medial non-striated muscle cells through the fenestrations in the external elastic lamina. The terminal area of a non-myelinated nerve fibre is extensive; in this area the axon is partly or wholly denuded of Schwann cell processes and contains clusters of mitochondria and numerous vesicles of 30–100 nm in diameter, many of which, in the middle diameter range, are dense-cored and typical of adrenergic synapses. This terminal is separated from the muscle cells by a distance of 60–400 nm, an interval which is considerably larger than that found at the synaptic junctions between non-myelinated fibres and non-striated muscle cells elsewhere, and the still narrower gap at the neuromuscular junctions in striated muscle. One terminal area may be related to several non-striated muscle cells and one smooth muscle cell may be innervated by more than one axon terminal (Appenzeller 1964; Lever 1965, 1968; Burnstock *et al.* 1970). It is assumed that the transmitter substance can diffuse through the basal lamina material which surrounds much of the smooth muscle cell surfaces, and that further spread of the excitatory process into the depths of the media occurs via the low-resistance communicating ('gap') junctions between adjacent muscle cells. The myelinated fibres are believed to be afferent and are distributed to the outer and inner coats where they terminate in expanded and varicose endings.

The significance of afferent nerve fibres in the general systemic arterial tree is uncertain, but some may mediate pain impulses under certain pathological and traumatic states. In some specific sites the afferent nerve fibre terminals are specialized as baroreceptors (pressoreceptors) which monitor the systemic blood pressure levels (e.g. in the carotid sinus and aortic arch), or as chemoreceptors which respond to increases in hydrogen ion and carbon dioxide concentration, or decreases in oxygen tension in the circulating blood (carotid and aortic bodies). Lamellated corpuscles (Pacinian corpuscles), which are mechanoreceptors, are occasionally found in the outer coat of the aorta.



The majority of blood vessels do not receive a vasodilator innervation and, in these, neurogenic vasodilation follows a reduction of sympathetic vasoconstrictor tone. However, nerve-mediated vasodilator action is seen: (1) in skeletal muscle vessels which receive a cholinergic sympathetic innervation (2) in various exocrine glands following secretomotor activity with the secondary release of the vasodilator bradykinin; (3) in the skin following afferent nerve stimulation, the collaterals of which ramify on neighbouring blood vessels and form the structural basis for the so-called 'axon reflex'.

The largest arterial trunks receive branches direct from the sympathetic ganglia, but for the smaller arteries (brachial, femoral, etc.) the supply is carried in the peripheral nerves and diverges in a series of small branches (pp. 1125, 1129). In the splanchnic arteries perivascular plexuses extend along the whole extent of the vessels.

CAPILLARIES AND SINUSOIDS

In many tissues (e.g. muscle, skin, lung, alimentary tract, brain, etc.) the side branches of the terminal arterioles beyond the

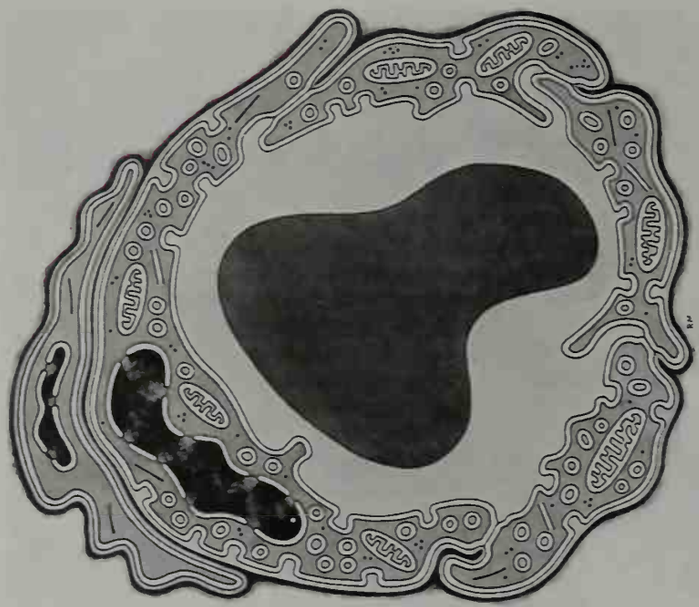
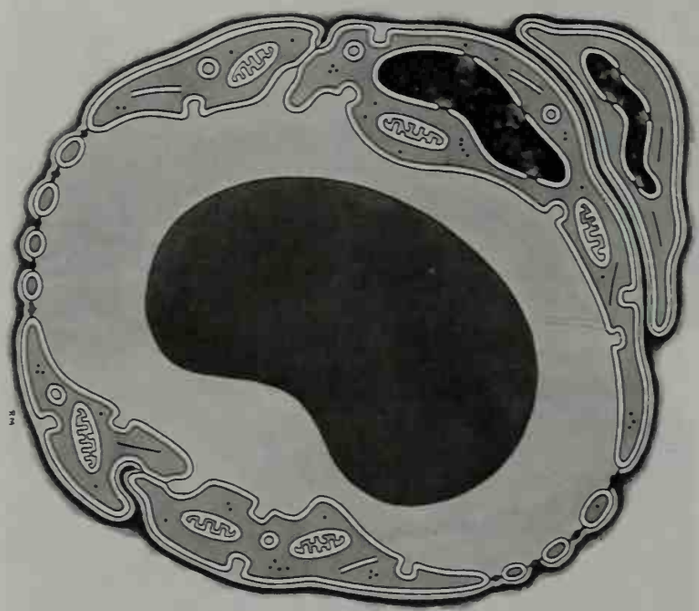
A Low-power view of a group of vessels showing a small artery (mid-right) with an accompanying vein (mid-left) in transverse section. An obliquely sectioned vein is also visible (extreme right) and a lymphatic vessel is present on the upper left; the extravascular tissue consists mainly of irregular dense connective tissue. Magnification × 320.
B Medium-power view of a transversely sectioned small artery, showing the thick muscular wall and the longitudinally ridged intima with erythrocytes adhering to the endothelial surface. The adventitia blends with the surrounding dense fibrous tissue. Magnification × 1,000.
C High-power micrograph of the cut end of a capillary with three erythrocytes visible. Note the extreme thinness of the endothelial wall (left) and the collagen fibres in the extravascular tissue. Magnification × 6,000 (Preparations by Michael Crowder, Guy's Hospital Medical School.)

6.5D Transmission electron micrograph of a partially contracted small arteriole in transverse section, showing an outer zone of non-striated myocytes and an inner lining of endothelial cells. Erythrocytes are visible within the lumen. The specimen is from the uterus of a rat. Magnification × 4,000.

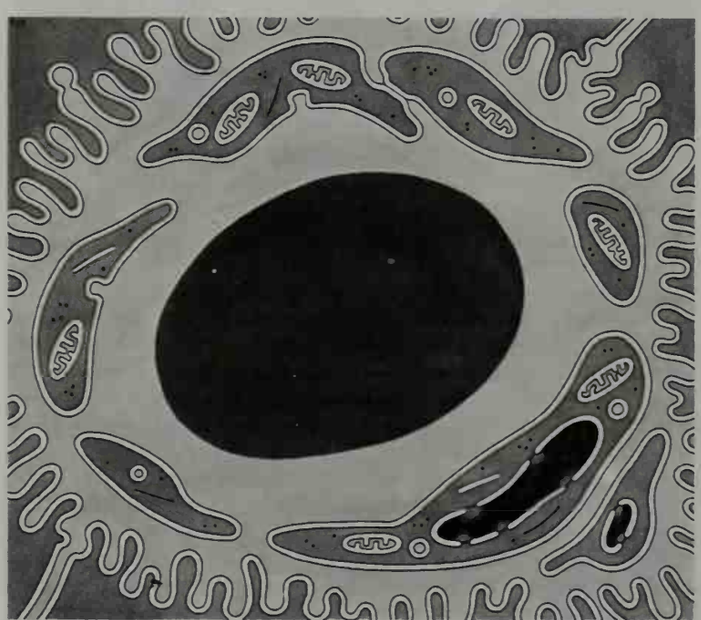


precapillary sphincters, pass through a short transition zone of 50–100 μm where a few isolated, spiralling smooth muscle cells persist external to the endothelium and which then continue as true *capillaries* of fairly uniform diameter. These intercommunicate to form a capillary network, the organization of which varies with the tissue concerned (*vide infra*). In other tissues (e.g. red bone marrow, spleen, liver, suprarenal and parathyroid glands, carotid and coccygeal bodies) the smallest blood vessels differ from true capillaries. They are wider, with an irregular lumen and a very thin wall; little, if any, connective tissue separates the endothelial wall from the neighbouring cells of the organ in which they lie. They are called *sinusoids* and among their lining endothelial cells there may be many actively phagocytic cells of the macrophage type.

Until recent times our knowledge of capillary and sinusoid structure was severely restricted by the relatively low resolution of the light microscope, but electron microscopy has revealed marked variation in the fine structure of these minute vessels in the various tissues (Bennett *et al.* 1957; Rhodin 1962 a & b; Fawcett 1963; Florey 1966; Wisse 1970). In general, capillaries consist of a tube lined by a single layer of polygonal or lanceolate endothelial cells which show variations in their fine structure and intercellular junctions. Surrounding the endothelial tube is usually a typical glycoprotein basal lamina which, at isolated points over the capillary, splits to enclose flattened or branching perivascular cells or *pericytes*. The basal lamina usually merges into an adventitial layer of fine reticular tissue, with occasional fibroblasts and mast cells, which border the extravascular tissue-fluid spaces. Variations in all these features have formed the basis for a variety of classifications, but broadly, a capillary may be considered as either *continuous* or *fenestrated*.



6.5E Transmission electron micrograph of a metarteriole fully contracted. The endothelial cells almost totally occlude the lumen. The dark cells around the periphery are pericytes. A biopsy specimen of human synovial membrane. Magnification × 6,000.



Continuous capillaries (**6**.6A, 7, 8) are found in many tissues including the skin, connective tissues, striated and smooth muscle, lung and brain. The cytoplasm of each cell is fairly thick opposite its oval nucleus but becomes attenuated elsewhere and presents a smooth luminal surface with occasional filopodia. The cytoplasm has the usual cell organelles but these are few in number. It contains fine filaments of about 4–7 nm diameter and a small amount of endoplasmic reticulum with attached and free ribosomes; the Golgi apparatus is small. The filaments may represent skeletal or possibly contractile elements. On the luminal and basal surfaces the plasma membrane is the site of numerous flask-shaped invaginations or *caveolae*, and the underlying cytoplasm contains many vesicles of 50–70 nm diameter. These are considered to form on one surface, to detach, cross the

cytoplasm and fuse with the opposite wall, thus discharging their contents. The cytoplasm around the invaginations is also rich in phosphatases. At the junctions of the endothelial cells the plasma membrane may be simple, or imbricated and interdigitated; the cells frequently overlap. In most regions a gap of about 20 nm containing electron-dense material separates the plasma membranes, but in other sites, the opposed plasma membranes either approach each other closely, or fuse to form tight junctions (*see* p. 7). True desmosomes are infrequent in man.

Fenestrated capillaries (**6.6B**) are found in the renal glomeruli, the intestinal villi, endocrine glands and the pancreas. Here, the cytoplasm on each side of the nuclear region is extremely thin, often approaching 40–60 nm and is apparently perforated at intervals by a system of 'pores' which vary greatly in number and size (their diameters may range from 30 to 100 nm). Each pore, however, appears 'closed' by a thin electron-dense diaphragm which often appears to be a condensation of basal lamina material. However, the molecular status of the diaphragm and the permeability of the pores remains uncertain. Whilst the use of electron-dense tracers (e.g. ferritin) and electron microscopy has added to our knowledge, many aspects of the structural basis of variations in capillary permeability are unresolved and under active investigation (*vide infra*). Another unresolved question concerns the mechanism of variations in

capillary diameter and blood flow. Many workers believe that flow variations are exclusively determined by the state of contraction of the arterioles and precapillary sphincters, whilst others claim that the endothelial cells themselves, and some types of pericyte, possess poorly developed cytoplasmic contractile systems (Epling 1966).

The sinusoids (**6**.6C) also show regional variations in structure. Their calibre is larger and more irregular than that of capillaries. They are lined by a variety of cell types and they may be grouped as either *discontinuous, closed* or *fenestrated*. The fenestrated sinusoids are typical of the endocrine glands and possess many of the fine structural features seen in the fenestrated capillaries, including a diaphragm and a delicate, complete basal lamina. Intercellular gaps are absent and the lining cells are not prominently phagocytic. In contrast the discontinuous sinusoids of the liver are lined by flattened, often branched cells, some of them highly phagocytic; large intercellular gaps occur at many points. Further details of these sinusoids and the other specialized types found in the bone marrow and spleen will be considered under the individual organs.

VENULES

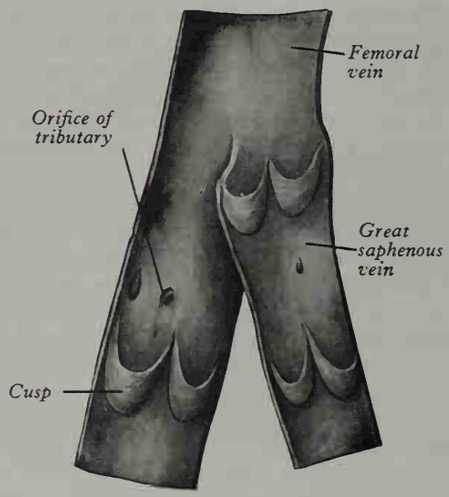
With the confluence of a number of capillaries, a *venule*, some 20–30 μm in diameter is formed, consisting essentially of a tube of flattened, oval or polygonal endothelial cells supported by a basal lamina, and a delicate adventitial coat of longitudinal fibres with interspersed fibroblasts (Rhodin 1968). Some authorities (e.g. Simonescu and Simonescu 1977) distinguish between the initial postcapillary venules which are surrounded by pericytes (*pericytic venules*) and the somewhat larger vessels partially enclosed in a muscular tunica media (*muscular venules*). Venules in the immediate postcapillary position are important sites of fluid exchange and leucocyte migration; in the lymphoid tissue of the gut and bronchial walls, lymph nodes and thymus, the endothelial cells of the postcapillary venules are cuboidal in form, and have incomplete intercellular junctions, permitting the ready passage of lymphocytes to and from the blood (*vide supra*, p. 773). In other tissues these vessels are believed to be a major site of transendothelial migration into the extravascular spaces, for neutrophils and other motile cells, as well as a region in which neutrophils can temporarily attach to the endothelium as a *marginated pool* of cells.

The intercellular junctions of venules are particularly sensitive to inflammatory agents which promote the leakiness of these vessels to fluids and defensive cells in the inflammatory response (*see* e.g. Marchesi 1961, 1962).

PERMEABILITY OF CAPILLARIES AND VENULES

The capillary bed, together with the postcapillary venules, forms an enormous area for the *exchange* of nutrients, gases, metabolites and water, between the blood and surrounding tissues, and also constitutes the chief route of leucocyte migration from the vascular system to the extravascular spaces. These capacities are reflected in the capillary bed density, which varies with the general metabolic level of the tissues they supply. Thus, it has been calculated that in the highly demanding myocardium there are about 2,000 capillaries per cubic millimetre of tissue, about 1,000 in skeletal muscle, but only some 50 in the connective tissue component of the skin (*see* Simonescu and Simonescu 1977). The total surface area of such capillaries may be relatively large, up to 2·4 metres^2 per 100 cm^3 in skeletal muscle, and about 4 metres^2 per 100 cm^3 in lung, giving a value of about 60 metres^2 for the capillaries of the systemic circulation and 40 metres^2 for the pulmonary circulation (*see* Krogh 1959; Intaglietta and Zweifach 1971).

The permeability of capillaries and venules has been extensively studied with various methods, ranging from physiological measurements of fluid composition, to structural investigations with tracers, e.g. Evans' blue, horseradish peroxidase, and ferritin, introduced into the bloodstream or extravascular spaces (Karnovsky 1967, 1968, 1970). These techniques have demonstrated that although, in general, the endothelium of blood vessels is a semi-permeable barrier acting as a dialysing membrane, i.e. allowing water, gases, and ions to pass across the wall by diffusion whilst preventing the passage of large molecules, there is also some movement of colloids and even quite large water-soluble molecules both into and out of the bloodstream across the endothelial cells. Physiological measurements of rates of large molecules, e.g. dextrans, have indicated the existence of two distinct categories of diffusion, corresponding to hypothetical '*large pore*' and '*small pore*' channels (Grotte 1956; Landis and Pappenheimer 1963), although the precise structural basis of these diffusion routes is not certain. Tracer studies have shown that large molecules, or molecular aggregates, can be taken across endothelia in the numerous pinocytotic (endocytic) vesicles, and indeed in some cases vesicles from both sides may fuse to form continuous channels (Bruns and Palade 1968). The vesicular transport system probably corresponds to the 'large pore' channels. 'Small pore' diffusion, it has been suggested, might represent leakage through intercellular junctions, and (where they are present) perhaps through fenestrae and their associated septa, as in the renal glomeruli (*see* Maul 1971).



However, the permeability of capillaries and postcapillary venules varies greatly in different tissues, and this can, to some extent, be correlated with the organization of the endothelium in those regions. In tissues where ready exchange of large molecules occurs, e.g. the alimentary tract, endocrine glands, fenestrated or incomplete endothelia, with numerous endocytic vesicles are present, and intercellular junctions are either incomplete or of the 'leaky' variety (Simonescu *et al.* 1972, 1973, 1975). In other areas, where known physiological barriers to large molecule diffusion occur, e.g. the brain, thymic cortex, testis and exocrine pancreas, endothelia are complete and non-fenestrated, with complete and efficient zonulae occludentes between cells, and there are relatively few endocytic vesicles. Most tissues, however, e.g. skeletal muscle, occupy intermediate positions between these two extremes.

VEINS

The walls of the veins, like those of the arteries, are composed of three coats, the internal being endothelial, the middle muscular, and the external of connective tissue (**6**.1).

The main difference between the veins and the arteries is in the comparative weakness of the middle coat in the former; its much smaller content of muscle and elastic fibres is related to the much lower venous blood pressure.

In the smallest veins the three coats are difficult to distinguish. The endothelium is supported on a membrane separable into two layers, the outer of which is the thicker, and consists of a delicate membrane of collagen fibres and fibroblasts, while the inner is composed of a network of longitudinal elastic fibres. In the veins next above these in size (0·4 mm in diameter) a layer of white fibres with a few non-striated muscular cells circularly disposed forms the middle coat, while the elastic and connective tissue elements of the outer coat are more distinct. In the middle-sized veins, the endothelium is of the same character as in the arteries, but its cells are shorter and broader. It is supported by a connective tissue layer, consisting of a delicate network of branched fibroblasts, and external to this there is a layer of elastic fibres disposed in the form of a network in place of the definite fenestrated membrane seen in arteries. This constitutes the *tunica intima*. The *tunica media* is composed of a thick layer of connective tissue with elastic fibres, intermixed in some veins with non-striated muscular fibres arranged circularly. The white fibres predominate, and the elastic fibres are in much smaller proportion than in the arteries. The *tunica adventitia* consists, as in the arteries, of areolar tissue with longitudinal elastic fibres. In the largest veins it is very much thicker than the tunica media, and contains many longitudinal muscular fibres. These are most distinct in the inferior vena cava, especially at the termination of this vein in the heart, in the trunks of the hepatic veins, in all the large trunks of the portal vein, and in the external iliac, renal and azygos veins. In the inferior vena cava, renal and portal veins they extend through the whole thickness of the outer coat, but in the

6.9 The upper portions of the femoral and great saphenous veins laid open to show valves. About two-thirds of natural size.

other veins mentioned a layer of connective and elastic tissue is found external to the muscular fibres. The white connective tissue fibres in the tunica adventitia of the inferior vena cava are disposed in bundles which form a network of right- and left-hand spirals, and this arrangement, together with the elastic fibres, facilitates the lengthening and shortening of the vessel which occurs with ascent and descent of the diaphragm (Franklin 1937). The large veins which open into the heart are covered for a short distance with a layer of cardiac muscle continued on to them from the heart and in the case of the coronary sinus the covering is complete (Coakley and King 1959). Muscular tissue is absent: (1) in the veins of the maternal part of the placenta; (2) in the venous sinuses of the dura mater and the veins of the pia mater; (3) in the veins of the retina; (4) in the veins of the spongy substance of bones; (5) in the venous spaces of the corpora cavernosa and corpus spongiosum. These veins consist of an endothelial lining supported by connective tissue.

Most veins are provided with *valves* which serve to prevent the reflux of the blood (**6**.9). Each valve is formed by a reduplication of the intima, strengthened by connective tissue and elastic fibres, and is covered on both surfaces by endothelium, the arrangement of which differs on the two surfaces. On the surface of the valve next the wall of the vein, the cells are arranged transversely; while on the other surface, over which the current of blood flows, the cells are arranged longitudinally in the direction of the current. Most commonly two such valves are found opposite one another, more especially in the smaller veins or in the larger trunks at the point where they are joined by smaller branches; occasionally there are three, and sometimes only one. The valves are semilunar and they are attached by their convex edges to the wall of the vein; the concave margins are free, directed in the course of the venous current, and lie in close apposition with the wall of the vein as long as the current of blood is centripetal; if, however, regurgitation takes place, the valves become distended, their opposed edges are brought into contact, and the backflow is interrupted. The wall of the vein on the cardiac side of the attachment of each valve is expanded into a pouch or *sinus*, which gives to the vessel, when injected or distended with blood, a knotted appearance. The valves are very numerous in the veins of the extremities, especially in the veins of the lower extremities, these vessels having to conduct the blood against the force of gravity in addition to being subjected to intermittent pressure due to muscular contractions. They are absent in the very small veins and very large veins and are absent or few in number in many other tissues. Particular features will be noted with the description of the individual veins.

The return of blood along the veins is under the influence of a number of factors. The smaller veins are filled by the blood overflowing into them from the capillary bed. The deep veins of the limbs are subjected to pressure due to contractions of the surrounding muscles, and the venae comitantes are affected in a similar way by arterial pulsations. This squeezing of the veins would tend to drive the blood in both directions along the vessels, but the valves prevent flow towards the periphery and so the blood must flow towards the heart so long as the valves are competent. The force of gravity in the veins of the head and neck and the suction due to negative intrathoracic pressure in the veins near the heart are also important factors in venous return.

The rate of flow of the blood in veins being slower than in the arteries, veins are larger and more numerous than the corresponding arteries so that the blood delivered to tissues can be adequately returned to the heart.

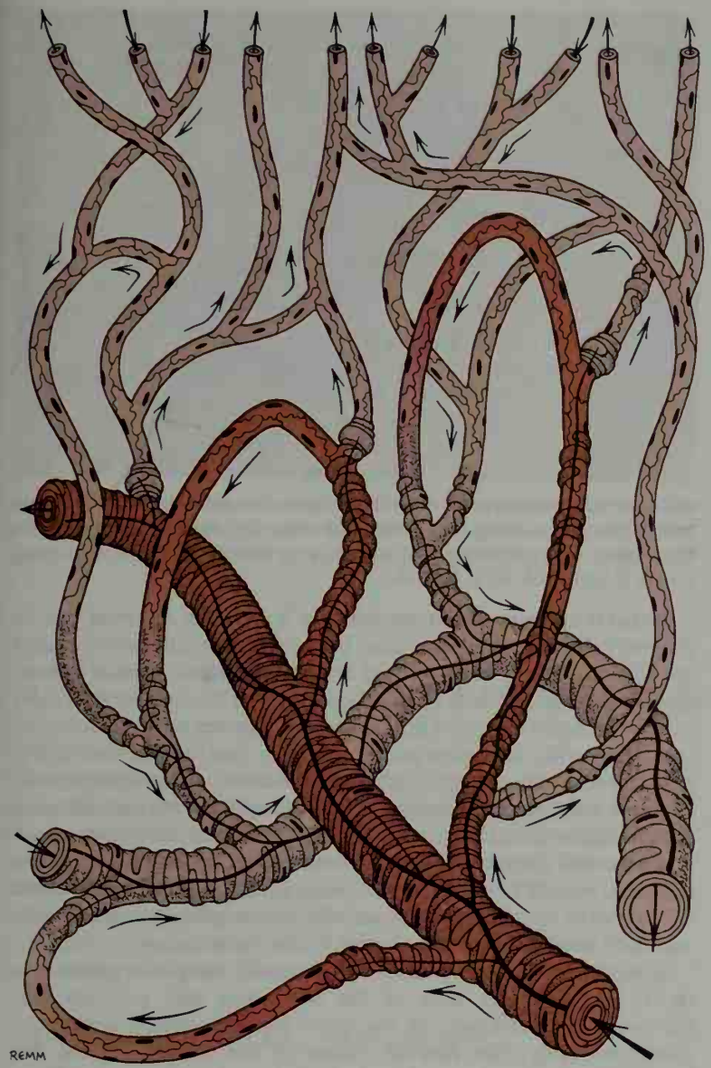
The walls of the larger veins, like the arteries, are supplied with nutrient vessels, termed *vasa vasorum*. Unlike those in the arteries these vessels may penetrate as far as the intima probably reflecting the low venous blood pressure and oxygen tension. Nerves (post-ganglionic sympathetic efferent, and primary afferent) also are distributed to the veins in the same manner as to the arteries, but in much lesser numbers.

ASSOCIATIONS BETWEEN ARTERIES AND VEINS

Arteries and veins usually, though not invariably, run in close relationship to each other within fascial planes, the pedicles of viscera, and neurovascular bundles to muscles and other structures. The vein may be single, but often an artery is accompanied by a pair of veins, one lying on each side, having numerous cross-connexions, and both contained within a connective tissue sheath: these are termed *venae comitantes*.

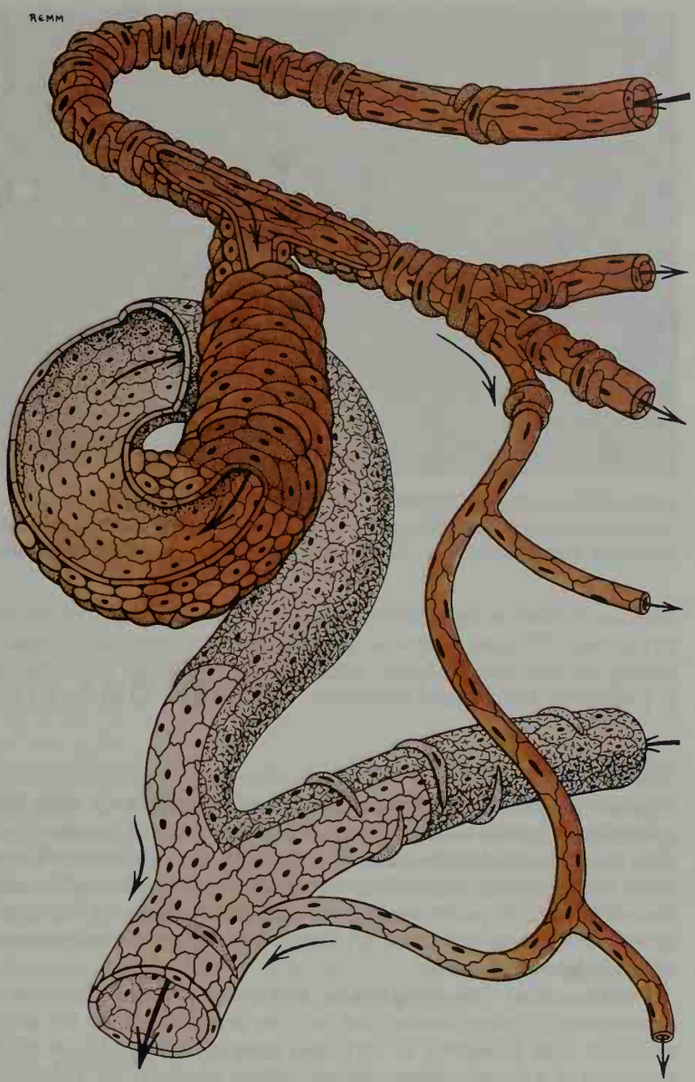
As noted above, intimate apposition of artery and vein is probably an important determinant aiding the return of venous blood towards the heart, due to the interplay of the arterial pulsations and the valved interior of the veins. In some cases such close associations between vessels are also important in the *countercurrent exchange* of heat or ions from the incoming to the outgoing blood. An excellent example is in the blood supply of the testis where the branches converging to form the testicular vein comprise a complex pampiniform plexus surrounding the testicular artery, which arrangement promotes heat transfer from the arterial to the venous blood, thus permitting the testis to remain at a lower temperature than that of the general abdominal viscera (*see* Evans 1949; Grant and Payling Wright 1971; also p. 1415). An analogous arrangement of arterial and venous sinusoids exists in the vasa recta of the renal medulla; in this situation countercurrent exchange ensures that sodium ions are retained at a high concentration within the medulla (p. 1395) as efferent venous blood gives up its sodium ions to the afferent arterial supply.

Vascular Patterns



The distribution of the systemic arteries is like a highly branched tree, the common trunk of which, formed by the aorta, commences at the left ventricle, while the smallest ramifications extend to the viscera and to the peripheral parts of the body.

There is considerable variation in the mode of division of the arteries: occasionally a short trunk subdivides into several branches at the same point, as in the coeliac and thyrocervical trunks; more usually the vessel gives off several branches in succession, and still continues as the main trunk, as in the arteries of the limbs and those of the head and neck.

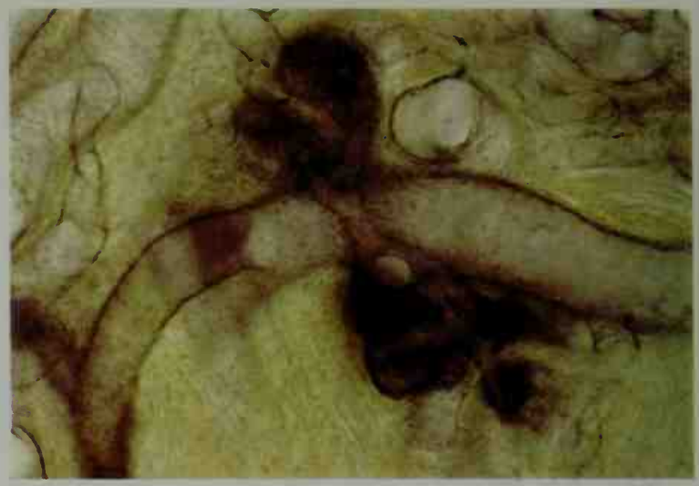


A branch of an artery is smaller than the trunk from which it arises; but if an artery divides into two branches, the combined sectional area of the two vessels is, in nearly every instance, somewhat greater than that of the trunk, and the combined sectional area of all the arterial branches greatly exceeds that of the aorta.

ANASTOMOSES

Arteries do not always end in arterioles and capillaries; in many cases they unite with one another, forming what are called *anastomoses*. Anastomosis between trunks of nearly equal size is found in the brain, where the two vertebral arteries unite to form the basilar artery, and the two anterior cerebral arteries are

6.10 Diagram of a microcirculatory unit based upon descriptions in Zweifach (1937, 1959, 1961) and Reynolds and Zweifach (1959). Note the terminal arteriole, thoroughfare channels, true capillaries and the collecting venule. The distribution of nonstriated muscle cells and precapillary sphincters is shown. See text for further description.



6.11 Diagram of an arteriovenous anastomosis. Note the thick wall of the anastomotic channel composed of many layers of characteristically modified 'epithelioid' nonstriated muscle cells. See text for further description.

connected by the anterior communicating artery, and in the abdomen, where the intestinal arteries have free anastomoses between their larger branches. In the limbs, the anastomoses are largest and most numerous around the joints; the branches arising from an artery above a joint unite with branches from the vessels below it, and lateral anastomoses complete peri-epiphysial circles (p. 259). Arterial anastomoses increase in frequency with the remoteness of the vessels from the heart and the smaller branches of the arteries anastomose more frequently than the larger; between the smallest twigs these anastomoses may be so numerous that they constitute a close network. Anastomoses allow of an equalization of pressures over the territories which they connect and provide alternative channels of supply to a particular area; hence their frequency around joints where the circulation may be temporarily impeded during movement. If the arteries join end to end (e.g. the palmar and plantar arches, intercostal arteries, arteries of the stomach and intestine), cutting the anastomosis results in bleeding from both ends. An anastomotic channel may be so enlarged as to replace the normal and constitute an aberrant supply to a part (e.g. 721). From the clinical point of view anastomoses provide, by their enlargement, the basis for a *collateral circulation* when a vessel is interrupted by accident, disease or by ligation. The collateral circulation often develops rapidly and if the increased flow through and pressure within the collateral channels are maintained, the vessels enlarge, often become tortuous and structural changes appropriate to the function occur in the walls and new blood vessels may develop. The resulting collateral circulation is, however, never in excess of the functional needs of the part. Sudden occlusion of a vessel may be followed in some situations by death of the part supplied, whilst gradual occlusion may allow time for the dilatation of the anastomosing channels and adequate nourishment of the tissue. The collateral circulation develops more rapidly in the young. The mechanisms involved in the dilatation of the collateral channels are not fully understood; haemodynamic changes consequent on the fall of the peripheral resistance, anoxia, nervous factors and the effects of accumulating metabolites have all been implicated.

END-ARTERIES

In certain regions of the body there are arteries which have no anastomoses with their neighbours and are therefore called *end-arteries*. If an artery of this type be occluded, serious nutritional disturbances resulting in death (necrosis) will occur in the tissues supplied by the vessel. The central artery of the retina is the best example of an end-artery, and its occlusion is followed by permanent blindness. Whilst the large arteries at the base of the brain form effective anastomoses, the central arteries which enter the brain substance communicate with each other only through the capillary bed, and, from a practical point of view, are end-arteries. The same applies to the arteries of the spleen, kidneys, lungs and the metaphyses of long bones. The branches of the coronary arteries do in fact anastomose to some extent, but all too

6.12A and B Human digital arteriovenous anastomoses prepared by intravascular perfusion of haematoxylin and subsequent clearing, of a full thickness specimen of skin. The heavily stained, thick-walled, tortuous, anastomotic channels contrast with the central arterial stem and the thin-walled venous outflow channels. See text for further details. (The specimens were prepared and kindly provided by Dr. R. T. Grant, Guy's Hospital Medical School.)

frequently this is insufficient to provide an adequate collateral circulation. Occlusive arterial disease in these important organs having an end-arterial blood supply is thus of great importance in pathology and clinical medicine.

VASCULAR SHUNTS

In many tissues there exist vessels of communication between the arterial and venous sides of the circulation which, when open, by-pass the nutritive tissue circulation through the capillaries. They may be classified according to their dimensions, site and complexity as: (1) preferential thoroughfare channels; (2) 'simple' arteriovenous anastomoses; (3) highly specialized arteriovenous anastomoses or *glomera*.

Preferential 'thoroughfare channels'. It has been demonstrated in many tissues that the true capillaries arise not only as direct side branches of terminal arterioles, but also as side branches of a thoroughfare channel which connects the terminal arteriole and the venule (Zweifach 1937, 1959, 1961; Reynolds and Zweifach 1959; Maggio 1965; Grant and Payling Wright 1968, 1970). This *thoroughfare channel* has a larger calibre than the true capillaries, and a fine structure which closely resembles typical continuous capillaries, but with occasional, widely spaced, smooth muscle cells spiralled around the endothelial lining. Each capillary side branch is surrounded at its origin by a precapillary sphincter. It is considered that a thoroughfare channel and its associated true capillaries form a functional *microcirculatory unit* (**6.10**). In times of low functional demand the blood flow is largely limited to the by-pass channel with the majority of the precapillary sphincters closed. Periodic opening and closing of different sphincters irrigates different parts of the capillary net. With increasing functional demand, the nutritive blood flow to the tissues may increase greatly following the opening of many sphincters. The size of the microcirculatory unit varies greatly with the particular tissue, e.g. in striated muscle each channel may give rise to 20–30 true capillaries, whereas in some glandular tissues only to 1–2. However, detailed investigations of the cremaster muscle and biceps femoris tendon of the rat (Grant and Payling Wright 1968, 1970) have emphasized that in these situations the thoroughfare channels are confined to the perimuscular and peritendinous connective tissues and are absent from striated muscle itself. The form of the capillary net also varies with the tissue, the meshes being either round or elongated. Round or angular meshes are most common and prevail where there is a dense network, as in the lungs, mucous membranes and in the skin. Elongated meshes occur in muscles and nerves, the long axis of the mesh running parallel with that of the muscle or nerve fibres. Sometimes the capillaries have a looped arrangement as in the papillae of the skin and tongue. The number of the capillaries and the size of the meshes determine the degree of vascularity of a part; the smallest meshes are found in the lungs and in the choroid coat of the eye.

Arteriovenous anastomoses. In a number of situations in the body direct connexions exist between the smaller arteries and the corresponding veins termed *arteriovenous anastomoses* (Grant and Bland 1931, Popoff 1934, Clark 1938). The connecting vessel may be straight or coiled and it often possesses a thick muscular coat of peculiar structure and a relatively fine lumen, measuring 10–30 μm on the average. Under the influence of the sympathetic nervous system, which gives a rich supply of non-myelinated fibres to the wall of the vessel, it is capable of complete closure and in that event circulation passes through the capillary bed in the ordinary way. When patent, the vessel carries blood directly from the artery to the vein and so partially or completely excludes the capillary bed from the circulation for the time being.

Arteriovenous anastomoses of relatively simple organization (**6.11**) occur in the skin of the nose, lips and external ear; the mucous membrane of the nose and alimentary canal; the coccygeal body; the erectile tissue of the sexual organs; the tongue; the thyroid gland and the sympathetic ganglia. They probably occur also in other situations.

In the skin of the hands and feet (especially the digital pads and nail beds), the anastomoses exhibit a special arrangement and form a large number of small units which have been termed '*glomera*'. They are situated in the deeper layer of the corium and each '*glomus*' has one or more afferent arteries. These vessels arise from branches of the cutaneous arteries which run towards the skin surface (**6.12**). The afferent arteries come off at right angles from their parent vessels, which thereafter are continued into the papillary layer of the corium, where they end in a capillary plexus. A short distance from its origin the afferent artery of a glomus gives off a number of fine 'periglomeral' branches and at once becomes considerably enlarged. It makes an S-shaped curve and then narrows down to become continuous with a short funnel-shaped vein which opens, at right angles, into a collecting vein. This vein commences on the deep aspect of the glomus, and curves round its outer surface. Having gained the superficial aspect of the glomus the collecting vein retraces its course, receiving venules from the papillary layer of the skin as it does so. Finally, it joins one of the deeper cutaneous veins.

In the child at birth arteriovenous anastomoses are few in number and poorly differentiated; they develop rapidly in the early years of life. In old age they undergo atrophy and sclerosis and are reduced in number.

Structurally the vessels immediately concerned in the digital arteriovenous anastomoses are unusual. At the point where it enlarges into the connecting vessel, the afferent artery presents a number of small endothelio-muscular elevations which project into its lumen, but proximal to this point its structure is typical. The connecting vessel has a lining of endothelium, supported by some fine collagenous fibres, but is devoid of an internal elastic lamina. An inner longitudinal and an outer circular muscle coat are not sharply differentiated from one another. The muscular wall is thick and on section the muscle fibres appear pale and

swollen, with centrally situated nuclei, so that they have been described as 'epithelioid'. The emerging vein has a thin wall, the muscular coat being entirely wanting. Numerous elastic fibrils are present and are continued into the tunica adventitia of the collecting vein.

Arteriovenous anastomoses regulate the regional blood flow and their functional state varies. They are capable of contraction, but the mechanism is uncertain. Where circular muscle tissue is present in the walls, the epithelial cells may act as cushions which narrow the lumen. Where such muscle is absent, closure of the lumen may result from swelling of the epithelioid cells. Cutaneous arteriovenous anastomoses play an important part in regulating body temperature both generally and locally. When the local temperature of the rabbit's ear is raised above 40 °C the connecting vessel relaxes and an increased flow of blood at body temperature results, with a consequent cooling effect. When the local temperature is lowered below 15 °C the connecting vessel again relaxes. In this case the increased flow of blood at body temperature will help to raise the local temperature unless the process of artificial cooling is intensified. Again, when the body temperature of a rabbit is raised artificially there is a general opening up of all the subcutaneous arteriovenous anastomoses, a considerable increase in heat radiation and a consequent drop in the body temperature (Grant 1930). The cooling effect of panting in the dog is associated with the opening up of the arteriovenous anastomoses in its tongue. The paucity and underdeveloped character of arteriovenous anastomoses in the newborn, and the marked reduction in number of the subcutaneous arteriovenous anastomoses with advancing age, may be associated with less efficient temperature regulation.

The arteriovenous anatomoses present in the mucous membrane of the alimentary canal fulfil a different function (Spanner 1931). In man the arteriole to a villus has a direct connexion with its corresponding venule and, during periods when absorption is not occurring, the connexion becomes patent and serves to raise the pressure in the portal vein. On the other hand, during absorption the connexion is closed and the circulation passes through the capillary plexus at the apex of the villus.

Other suggested functions of arteriovenous anastomoses include the regulation of the blood pressure, secretion by the epithelioid cells and pressor reception.

THE THORACIC CAVITY AND HEART

The skeletal walls of the thorax are described on pp. 291–292. Its capacity does not correspond with the osseous thorax, because the lower part of the region enclosed by the ribs is encroached upon by the diaphragm and the upper abdominal viscera. The capacity varies with the phase of respiration, which also affects to some extent the positions and relations of the thoracic viscera. Its arbitrary upper limit is usually taken as the plane of the thoracic inlet, but the apices of the lungs extend above this into the neck.

THE THORACIC INLET (**6**.62, 63, 118)

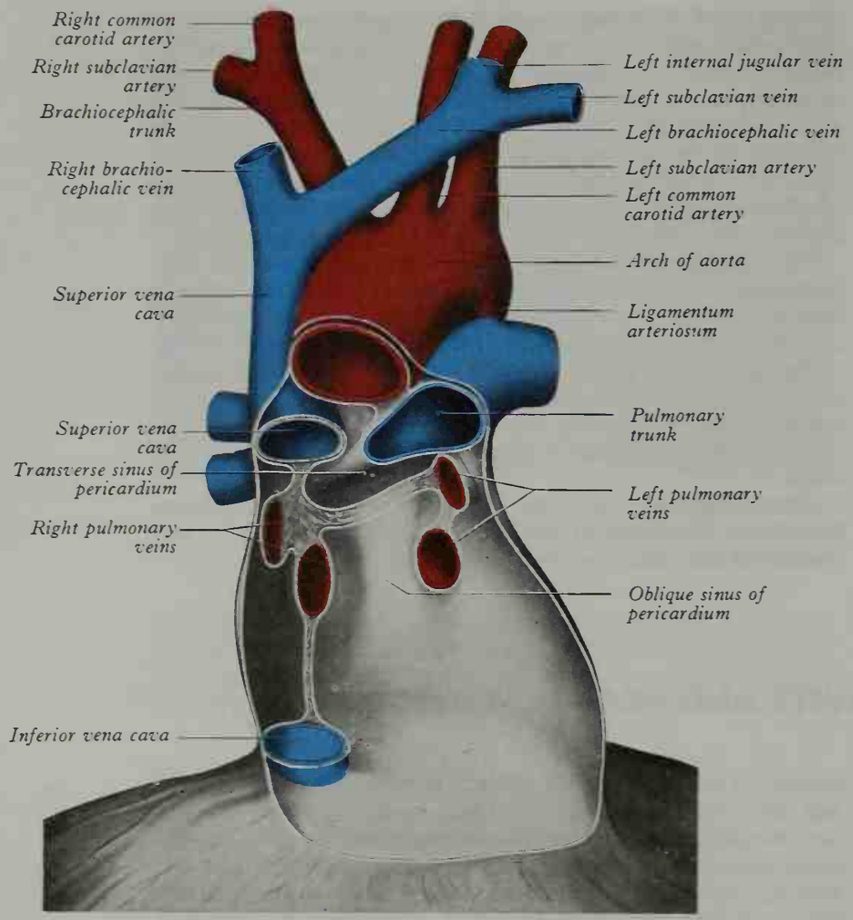
The bony boundaries of the inlet are described on p. 291, **3**. 60. The structures which pass through the upper opening of the thorax fall naturally into two groups, viz.: those in or near the median plane and those placed more laterally on each side in close relationship with the cervical parts of the pleurae and lungs.

In or near the median plane, behind the manubrium, the lowest parts of the sternohyoid muscles just enter the thorax. Immediately behind these are the sternothyroid muscles, the remains of the thymus and the inferior thyroid veins on their way to their termination in the brachiocephalic vein. In the child, in particular, the left brachiocephalic vein itself may be so highly placed as to cross over to the right actually in the thoracic inlet. More posteriorly, the trachea and the oesophagus, together with the recurrent laryngeal nerves, occupy the median region and, behind the left margin of the oesophagus, the thoracic duct enters the neck. Just in front of the vertebral column are the longus colli muscles and the anterior longitudinal ligament.

On each side the upper part of the pleura and the apex of the lung occupy the thoracic inlet. Between the pleura and the neck of the first rib, from medial to laterial side, lie the sympathetic trunk, superior intercostal artery and most of the ventral ramus of the first thoracic nerve passing obliquely upwards and laterally to join the lowest trunk of the brachial plexus. Anteriorly, between the pleura and the first costal cartilage the internal thoracic artery enters the thorax.

On the right side (**6**.62), the brachiocephalic artery leaves the chest between the trachea and the pleura. The vagus nerve, having passed at a higher level between the subclavian artery and vein, lies at the thoracic inlet between the pleura and the brachiocephalic artery. The right brachiocephalic vein enters the thorax anterolateral to the brachiocephalic artery and the right phrenic nerve crosses the internal thoracic artery and comes to lie lateral to the brachiocephalic vein as these vessels pass behind the first costal cartilage.

On the left side (**6**.63), the left common carotid and subclavian arteries leave the thorax between the pleura laterally and the trachea medially; the left vagus nerve is running downwards lateral to the interval between the two vessels. Anterolateral to this is the left brachiocephalic vein. The left phrenic nerve crosses the internal thoracic artery at a higher level than it does on the right side so that, at the thoracic inlet, it is running in the interval between the left brachiocephalic vein anterolaterally and the subclavian and common carotid arteries posteromedially,



THE THORACIC OUTLET

This is wider transversely than from before backwards. It slopes obliquely downwards and backwards, so that the thoracic cavity is much longer behind than in front. The diaphragm (p. 549) closes the opening and forms a convex floor for the thorax. The floor is flatter at the centre than at the periphery, and higher on the right side than on the left; in the dead body the right side of the floor reaches the level of the upper border of the fifth costal cartilage, while the left extends only to the corresponding part of the sixth costal cartilage. From the highest point on each side the floor slopes suddenly downwards to the costal and vertebral attachments of the diaphragm; this slope is more marked and longer behind than in front, so that only a narrow space is left between the diaphragm and the posterior wall of the thorax.

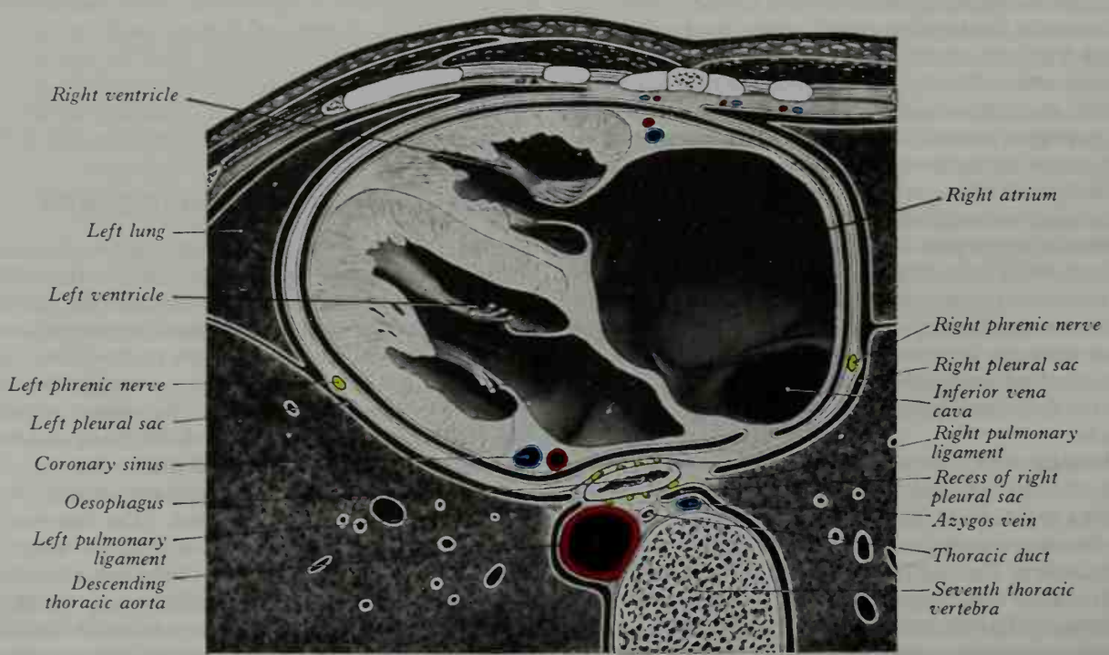
DIVISIONS OF THE THORACIC CAVITY

The thoracic cavity is divided by the *mediastinum*, the region between the lungs which extends from the back of the sternum to the vertebral column, and descends from the thoracic inlet above to the diaphragm below. The heart lies in the mediastinum, enclosed within a fibroserous sac, the *pericardium*; the lungs occupy the right and left parts of the thoracic cavity. Each lung is covered with a serous membrane, called the *pleura*, which also lines the walls of the corresponding half of the chest, and forms the lateral boundary of the mediastinum (**6**.13B).

For the purposes of description the mediastinum is divided into a superior and an inferior part. The *superior part* extends downwards from the thoracic inlet as far as an oblique plane passing through the lower edge of the manubrium sterni in front and the lower border of the fourth thoracic vertebra behind. The *inferior part*, below this plane, is subdivided into three portions, viz. an *anterior* in front of the pericardium, a *posterior* behind the pericardium and diaphragm, and a *middle*, which contains the pericardium, the heart and the large vessels entering or leaving

6.13A The interior of the pericardial sac after removal of the heart, ventral aspect.

the latter (**6.13B**). Details of the different component parts of the mediastinum are given with the description of the respiratory organs.



The Pericardium

The pericardium (**6.13A, B**) contains the heart and the roots of the great vessels. It is placed in the mediastinum behind the body of the sternum and the cartilages of the ribs from the second to the sixth inclusive, and in front of the thoracic vertebrae, from the fifth to the eighth inclusive. It is essentially composed of two opposed layers of serous membrane, separated by a mere film of fluid, which nevertheless provides a complete cleavage between the heart and its surroundings, allowing it freedom of movement within the pericardium.

The pericardium consists of an outer sac, known as the *fibrous pericardium*, consisting of fibrous tissue and an inner, double-layered sac, the *serous pericardium*, a delicate membrane which lines the fibrous sac and covers the heart. The heart invaginates the wall of the serous sac from above and behind, and practically obliterates its cavity, the space being a potential one.

The *fibrous pericardium* is a cone-shaped bag, the apex of which is considered to end where it is continuous with the external coats of the great vessels, while its base is attached to the central tendon and to a small part of the muscular substance of the left half of the diaphragm. In some of the lower mammals the base is either completely separated from the diaphragm or joined to it by some loose fibrous tissue; in man much of its diaphragmatic attachment consists of loose fibro-aerolar tissue which can be readily broken down, but over a small area the central tendon of the diaphragm and the pericardium are fused. Above, the fibrous pericardium not only blends with the external coats of the great vessels, but is continuous with the pretracheal fascia (p. 537). The fibrous pericardium is also attached to the posterior surface of the sternum by *superior* and *inferior sternopericardial ligaments*, the superior passing to the upper end of its body, and the inferior to its lower end. (It should be noted that in the experience of modern thoracic surgeons, the development of these 'ligaments' is extremely variable; in particular the superior one is often indetectible.) By means of all these connexions it is securely anchored within the thoracic cavity and therefore maintains the general position of the heart within the chest. Some have also assumed that it prevents 'over-distension' of the heart, but recognizing the great range of variation that occurs in cardiac dimensions accompanying various pathologies, such a view is entirely speculative.

Anteriorly, the fibrous pericardium is separated from the front wall of the thorax, in the greater part of its extent, by the lungs and pleurae; but a small area, usually corresponding with the left half of the lower part of the body of the sternum and the sternal ends of the cartilages of the fourth and fifth ribs of the left side, is in direct relationship with the chest wall. Until it retrogresses at puberty or adolescence, the lower end of the thymus is in contact with the front of the upper part of the pericardium. *Posteriorly*, the fibrous pericardium rests upon the principal bronchi, the oesophagus, the

6.13B A transverse section through the mediastinum at the level of the body of the seventh thoracic vertebra, viewed from above.

oesophageal plexus of nerves, the descending thoracic aorta and the posterior part of the mediastinal surface of each lung. *Laterally*, it is separated by the pleura, from the mediastinal surfaces of the lungs; the phrenic nerve, with its accompanying vessels, descends between the fibrous pericardium and the mediastinal pleura on each side. *Inferiorly*, it is separated from the liver and the fundus of the stomach by the diaphragm.

The vessels receiving prolongations from the fibrous pericardium are: the aorta, the superior vena cava, the right and left pulmonary arteries, and the four pulmonary veins. The inferior vena cava, which enters the pericardium through the central tendon of the diaphragm, receives no covering from the fibrous layer.

The *serous pericardium* is a closed sac which lines the fibrous pericardium and is invaginated by the heart; it therefore consists of a *visceral* and a *parietal* layer. The visceral layer, or *epicardium*, covers the heart and the great vessels, and from the latter it is reflected to form the parietal layer, which lines the fibrous pericardium. The extension which covers the vessels is arranged in the form of two tubes. The aorta and pulmonary trunk are enclosed in one tube; the superior and inferior venae cavae and the four pulmonary veins are enclosed in a second tube, the attachment of which to the parietal layer is ⌐-shaped (**6**.13A). The cul-de-sac within the curve of the ⌐ lies behind the left atrium and is known as the *oblique sinus*, while the passage between the aorta and pulmonary trunk, in front, and the atria, behind, is named he *transverse sinus* (**6**.19B, 37). The sinus lies between the two pericardial tubes described above. The upper boundary of the transverse sinus is shown in **6**.13A.

A small triangular fold of the serous pericardium is reflected from the left pulmonary artery to the subjacent upper left pulmonary vein; it is known as the *fold of the left vena cava*. It contains a fibrous strand, called the *ligament* of the left vena cava, which is a remnant of the obliterated *left common cardinal vein* (or left duct of Cuvier, p. 183) and which extends downwards in front of the root of the left lung from the upper part of the left superior intercostal vein to the back of the left atrium, where it is continuous with the oblique vein of the left atrium (p. 184). The fold often forms the anterior wall of a small blind recess, the mouth of which is directed to the left. In some cases the left, instead of the right, common cardinal vein persists and forms a left superior vena cava which runs downwards, in front of the root of the left lung and on the back of the left atrium, to enter the right atrium, replacing in the lower part of its course both the oblique vein of the left atrium and the coronary sinus. Sometimes both common cardinal veins persist to form a right and a left superior vena cava, and the transverse anastomosis between the common cardinal veins, which normally forms the left brachiocephalic vein, may be small or absent. When the left common cardinal vein persists it is joined by the left superior intercostal vein.

Vessels and nerves. The *arteries* of the pericardium are derived from the internal thoracic arteries and their musculophrenic branches, and from the descending thoracic aorta; its *veins* are tributaries of the azygos system. Its nerve supply is derived from the vagus and phrenic nerves, and the sympathetic trunks.

Structure. The fibrous pericardium consists of a compacted network of a collagenous fibrous tissue. The serous pericardium consists of a single layer of flattened cells resting on a layer of subserous aerolar tissue which, in the case of the parietal layer, blends with the fibrous pericardium. The areolar tissue under the visceral layer is continuous with the interstitial tissue of the myocardium and contains fat which is greatest in amount along the ventricular border of the coronary sulcus, along the inferior border of the heart and in the interventricular grooves. The main trunks of the coronary vessels and their larger branches are embedded in this fat, the amount of which is related to that of the general body fat and gradually increases as age advances.

Applied Anatomy. Paracentesis of the pericardium (i.e. draining of fluid accumulating in the pericardial cavity due to disease, by means of a hollow needle) may be performed in the fifth or sixth left intercostal space near the sternum, with care to avoid wounding the internal thoracic artery. Alternatively, the exploring needle may be entered at the left costoxiphoid angle, and passed upwards and backwards into the pericardial sac.

It should be remembered, in relation to aortic surgery, that the serous pericardium, which clothes the pulmonary trunk on the wall of the transverse sinus, extends as far as the ligamentum arteriosum (p. 666).

THE HEART

General Introduction

All triploblastic organisms, invertebrate or chordates, possess some form of circulatory system to overcome impractically long diffusion distances by circulating a fluid from regions of high oxygen tension and high concentrations of nutrient substances to the immediate surroundings of mesodermal and other cells remote from the external environment. The constitution of the fluid and the methods by which it is circulated vary much, especially in the many different phyla of the invertebrates. The majority of these are, however, coelomates and hence contain a closed system of blood vessels and some localized means of propelling 'blood' through them in a true circulation. (There are exceptions to this: some very small annelid worms lack a blood-vascular system, and in some acoelomates, e.g. nematode worms, a body cavity (regarded as a *pseudocoel*) does occur, though it has no endothelial lining and merely permits the to and fro movements of the contained fluid under the influence of bodily movements. One nematode, *Ascaris*, possesses a haemoglobin in this fluid.)

In some coelomates, e.g. annelid worms, pulsatile sections of the vascular tubes, usually multiple, occur in many parts of the body, and the larger of such 'hearts' may be valved and may respond to neurogenic 'pacemakers'. In arthropods the heart is usually singular and dorsal in position and the circulation is 'open', i.e. the efferent vessels from the heart open into wide 'haemocoels' which surround most organs. (Some small arthropods, e.g. mites, have no circulatory organs.) Aquatic arthropods, such as the class *Crustacea*, respire through various forms of gill-like structures, the blood acting as the intermediary; but in the class *Insecta*, most of the species of which are emancipated from water, respiration is served by intercellular networks of tubes, independent of the circulation. If one takes into account other invertebrate phyla, such as the *Mollusca*, *Brachiopoda*, and *Echinodermata*, an even wider variety of circulatory pattern is apparent. But these facts are mentioned briefly as a contrast to the phylum *Chordata*, which displays a much more uniform circulatory pattern. Even in the most 'primitive' of the phylum, the *Hemichordata* (acorn worms) and the *Urochordata* (tunicates) the heart is single, and in the *Cephalochordata* (represented by the familiar *Amphioxus*) there is a ventral tubular 'heart' and a circulatory system basically vertebrate in type. The main, midventral pulsatile tube is assisted by pulsatile vessels in other parts of the circulation.

The *vertebrate* heart is ventral to the gut—to the pharynx in fishes and the embryos of land tetrapods, to the oesophagus in adult forms of the latter. Being developed from a tube, in terms of phylogeny, it is a single pump in earlier forms. However, from the beginning (as evidenced by the simpler extant forms) it shows a specialization into a succession of three or four enlarged segments of the tube—a collecting reservoir for the principal veins, the *sinus venosus*, a pulsatile but relatively thin-walled antechamber, the *atrium*, a thick-walled, highly muscular pumping chamber, the *ventricle*, and a fourth, the *bulbus cordis* which may be muscular or elastic and is absent in some forms. From the conical end of the ventricle (*conus arteriosus*), or from the bulbus cordis, when

present, the major arteries commence. Valves, usually consisting of several flaps or leaves (sometimes serially repeated), are interposed between successive cavities. The heart possesses its own *coronary* circulation (except in *Agnatha*), and is contained in a pericardial coelom, which is a separated part of the general 'body cavity'. The pulsatile rhythm of the vertebrate heart is basically *myogenic*, but is coordinated with other systemic demands by a regulating nerve supply. With an increasing degree of specialization from fishes to birds and mammals, particular parts and tracts of the cardiac muscle differentiate to form foci of initiation of muscular contraction and rapidly conducting pathways for dissemination of these cyclic stimuli. In almost all vertebrates the heart tube outgrows the cranio-caudal dimensions of the pericardial sac, developing a sinuous bend. Because of this the 'venous end' (the sinus venosus and atrium) becomes dorsal to the 'arterial end' (ventricle and conus); moreover, the S-shaped heart tends to take up an asymmetric position associated with a transition from symmetrical cardinal venous systems to asymmetric caval veins. The pericardial cavity is semi-rigid in some fish (e.g. elasmobranchs), due to its position dorsal to the pectoral girdle, and the resultant constancy of its volume aids the filling of the atrium by suction as the ventricle empties; in terrestrial and aerial vertebrates this effect is largely lost, because of the caudal 'migration' of the heart.

In discussing the phylogeny of the heart, and especially in deriving the mammalian organ from the cardiac patterns of earlier forms, it is to be emphasized that no direct palaeontological data are available. Comparison of the arrangements at different grades of vertebrate development as they exist in extant creatures provides the only source of information. This comparison can be misleading unless allowance is made for several factors which complicate considerations. Firstly, hearts must function at a very early stage of embryonic life, and they must continue to do so throughout development and into the usually greatly changed environment after birth. Moreover, the environmental demands upon the adult creature vary greatly; and if these demands are less in the case of a more recent (and presumably 'more highly evolved' group), actual retrogression of cardiac structure may occur. For example, in the *Dipnoi*, or lungfish (and also in crossopterygians, if the extant coelacanth fish, *Latimeria*, is representative) the atrium is almost completely divided and the ventricle partly so, whereas in the *Amphibia* the ventricle is uniformly single and the atrium fully divided only in the anuran amphibians. The incomplete division of the atrium in urodele amphibians is considered a retrogression in structural terms, but it must be of physiological advantage to this, the more active of these two sub-classes. Although it is orthodox, and indeed almost inescapable, to derive the mammals from the reptiles, there is not an extant representative of the latter from which the mammalian heart can be directly derived. Although some reptiles (e.g. the order *Crocodilia*) show complete division of the heart, the relation of the major arteries, pulmonary and systemic, to the ventricles precludes such a derivation. The reptiles ancestral to the mammals must have possessed different arrangements. (It is interesting to note, however, that the avian heart and its outflow vessels are much closer in these arrangements to those of extant reptiles.)

It is obvious that a completely satisfactory phylogenetic history is not possible in the case of the vertebrate heart, and for this reason alone an elaborate comparison will not be attempted here. But some particular trends of evolution must be mentioned.

The sinus venosus, typically symmetrical in fishes, already displays asymmetry in the *Cyclostomata*: its right duct alone persists in lampreys, the left in the hagfish. In the *Dipnoi* the sinus opens into the right half of a partly divided atrium. This condition persists in subsequent vertebrate classes; in *Anura*, many *Reptilia* and all *Mammalia* this asymmetry is coupled with some retrogression of the sinus and absorption of its vestiges into the right atrium. With the complete separation of the atria a right-hand systemic venous return is thus established.

The arterial 'end' of the heart, represented by a *bulbus cordis* in vertebrate embryos (and some adult forms) or by a contractile chamber, the *conus arteriosus*, in adult elasmobranch fishes, commonly exhibits valve flaps, often arranged serially in rows. Probably derived from the latter are the spiral valves of the *Dipnoi*, and these become more elaborate and efficient in the *Amphibia*. This development is closely associated with what must be regarded as the greatest era of transformation in the evolution of the heart—the long series of adaptive changes which accompanied and made possible the spread of vertebrate life from the aquatic to the terrestrial habitat. This transformation is accepted as occurring in the Devonian Period of the Palaeozoic Era, a period of 50 to 60 million years, approximately 300 million years ago. At the beginning of this transformation were dipnoan fish, chiefly dependent upon branchial respiration but also able to use, for aerial breathing, a pharyngeal diverticulum, the so-called 'swim bladder' (p. 1228); at the end of the transformation were amphibians, mainly dependent on pulmonary respiration, with lungs developed from some form of pharyngeal air sac, but also able to respire through a wet skin. These changes of respiratory habit, inseparably associated, of course, with cardiac and circulatory modifications, also demanded locomotor changes, the evolution of limbs, adapted from aquatic fins to terrestrial progression. (It is for such reasons that the *Amphibia* are regarded as a development from crossopterygians related to the extant *Dipnoi*.)

At the time of this great transformation, which may have occupied many millions of years, there already existed an inherent duality in the circulation, both the dipnoan and the amphibian possessing a *systemic* 'portal', arterial circulation, through gills in one case and subcutaneous networks in the other, and in addition a parallel *pulmonary* 'portal' circulation through the walls of either an air sac or true lungs. These separate circuits already return their blood to separate atria in the dipnoan; and although the ventricle is only partly divided, mixing of the two atrial inputs is probably diminished by the highly trabecular internal surface of the ventricle. Of course, the dipnoan ventricular output, though also largely separated into two streams by spiral valves in the large conus arteriosus, is conducted entirely to the gills; but the blood returning to the right atrium is conducted by a separate, dorsal division of the ventral aorta to the more caudal gill clefts and hence largely to the air sacs or 'lungs'.

In the amphibian circulation, with the disappearance of gill structures, the capillary beds of the systemic vessels supplying them disappear, and the main weight of respiratory function is pulmonary. The undivided ventricle (and partial division only of the atrium in some forms) may, however, permit some degree of mixture of the systemic and pulmonary flows through the heart; and presumably this is an advantage when the animal returns to water for breeding, cutaneous respiration then becoming predominant. There is thus no sudden change, in structure or function, during the slow cardiac adaptation from an aquatic to a terrestrial mode of life, but rather a change of emphasis between two, co-existent methods of respiration. The separation of the two flow routes through the heart is carried further in *Reptilia*. Despite the fact that some forms have returned to aquatic existence, respiration is now entirely pulmonary. This is coupled with a complete interatrial septum and at least a partial division of the ventricle, which is actually complete in *Crocodilia*. The latter are unusual in having a triple arterial outflow from the heart—a pulmonary artery from the right ventricle and also right *and* left aortic (systemic) arches, each arising from the contralateral ventricle. Because of this curious arrangement, the aortic arteries cross each other and communicate at this point. In the cayman this allows an almost complete shunt of blood into the left aorta, thus foreshadowing the mammalian condition.

In mammals, including mankind, the division of the heart (into atrium, ventricle, bulbus and conus) is complete and need not be described here. In the embryo, however, a series of stages occurs (p. 181) which closely resemble the final arrangements in earlier classes of vertebrate, and an arrest of development at various stages leads to a congenital defect which may resemble conditions in an earlier vertebrate form. However, the resemblance is modified by the fact that the heart must actually function at all but its earliest stages of development. The foramen ovale is a feature of mammalian pre-natal development, a necessary shunt mechanism rather than an atavistic indication of incomplete atrial septation in earlier forms. Hence, a persistently

patent foramen ovale is a manifestation of disturbed *mammalian* rather than *vertebrate* development. Similarly, many other cardiac abnormalities may be tentatively 'explained' as divergencies from ontogenetic development rather than by reference to an earlier vertebrate state.

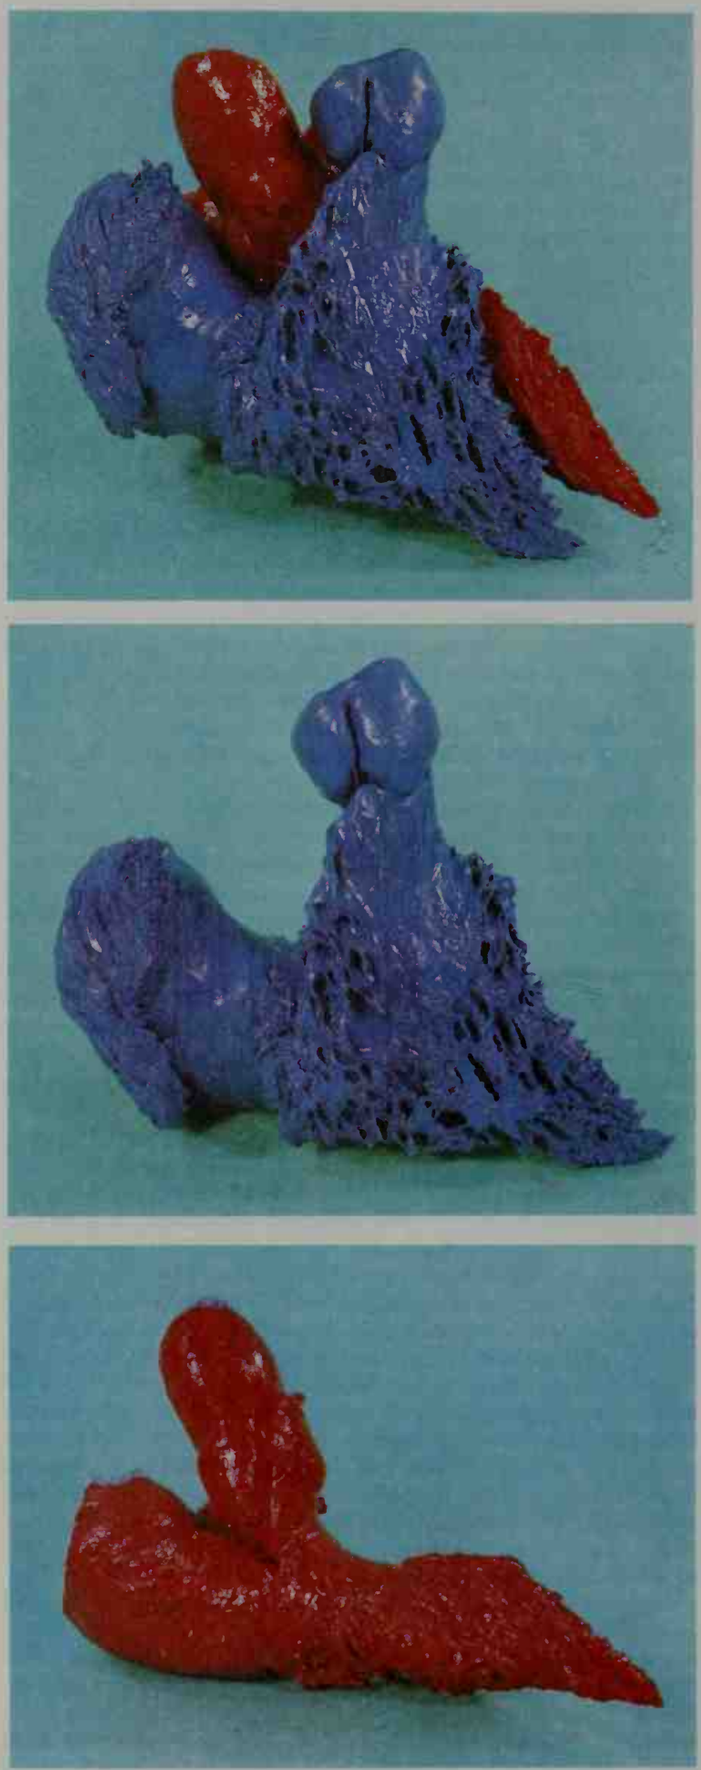
The fact that every vertebrate heart must function within its particular circulation from a very early stage of development, and long before either has reached its final arrangement, accords with the continuous picture of cardiac phylogeny which appears in retrospect. Although a relatively simple heart of single chambers, serially arranged, has finally led to a fully septated double heart consisting of two muscular pumps arranged 'in parallel', but in fact pumping in series, the transitional stages have been smooth and at no stage dramatic. This has been achieved despite the great change from purely aquatic respiration through gills to a state of exclusively pulmonary respiration. The smooth changeover may be ascribed to the existence of *both* methods of respiration in a long series of dipnoan and amphibian species over a long period of time. The double circulation, systemic through gills and pulmonary through lungs, has gradually evolved from a condition of *parallel* supply by incompletely septated hearts to one of *serial* supply on completion of septation. In this gradual change, between two highly different circulations, evolutionary changes in the vessels served by the heart have, of course, occurred in a harmonious succession of adaptations. For some details of these changes, from the ontogenetic point of view, consult the section on *Embryology* in this volume. The literature of cardiac evolution is large; extensive bibliographies exist in the works of Bolk *et al.* (1931–9); Grassé (1954); Foxon (1955); Robb (1965); Romer (1970); and Foxon and Bannister (1974).

In the following pages it will become evident that there is no entirely satisfactory and logical progression to be adopted in a description of the heart—whatever standpoint is approached first it necessarily assumes some knowledge contained in more detail in later sections. Nevertheless, it is hoped that the sequence presented represents a good compromise. An account of the general organization of the heart precedes considerations of its external features, surface anatomy and radiological appearances; thereafter the chambers are described sequentially in terms of their internal features, flow tracts, valve architecture, with brief functional allusions; finally the fine structure of the myocardium, the 'fibrous skeleton', and both the well-accepted and more controversial aspects of the specialized conducting tissues are combined with an overall illustration of the coordinated cycle of cardiac contraction and relaxation.

General Cardiac Organization

As noted above, the mammalian, including the human, heart consists of a pair of valved muscular pumps topographically combined in a single organ, and whilst their fibromuscular framework and conducting tissues are inextricably interwoven in a single complex functionally interdependent unit, each pump (the so-called 'right' and 'left' hearts) is physiologically *separate*, being interposed *in series* at different points in the double circulation. Thus, despite this *functional* 'in series' disposition (*vide infra*) it is often stated (*v. supra*) that the two pumps are *topographically* 'in parallel': however, as we shall see, even the latter comment is an over-simplification since the two pumps have completely contrasting haemodynamic roles, and their outflow channels exhibit a *mutual spiral* of almost 180° as they discharge towards their primary destinations.

The chambers of the heart are the right and left atria and right and left ventricles, the atria providing the receiving reservoirs for venous blood and a relatively weak contractile system which effects final filling of the ventricles, whilst the ventricles provide the much more powerful expulsive contraction forcing the blood into the main arterial trunks.



The 'right heart' of clinical parlance consists of the *right atrium* which receives the superior and inferior caval and main coronary inflows of venous blood from the systemic circulation: this is passed through the right *atrioventricular orifice*, guarded by the *tricuspid valve*, into the *inflow tract* of the *right ventricle*. Contraction of the latter causes final closure of the tricuspid valve and, with increasing pressure within the ventricle, a level is reached when ejection of blood through the right ventricular *outflow tract* (the *infundibulum or conus arteriosus* and the *pulmonary valve*) is achieved, ejection obviously necessitating temporary opening of the valve. (The pressure profiles, time relationships, and sequences of valve opening and closure, are treated more fully below.) It should be noted here, however, that the right ventricular outflow tract discharges into the pulmonary trunk, arteries, and thereafter is restricted to perfusion of the *relatively* low-resistance pulmonary arteriolar and capillary vascular bed, and many of the structural features of the 'right heart' including the overall geometry of its chambers, the vectors of its inflow and outflow tracts, its myocardial architecture (in particular the thickness of its ventricular walls), and the construction and relative strengths of the tricuspid and mitral valves, accord with such a role, involving comparatively low and leisurely pressure fluctuations.

The 'left heart', in complete contrast, consists of the *left atrium* which receives the pulmonary (plus a little coronary) venous inflow, and by its contraction completes the filling of the *left ventricle* through the *left atrioventricular orifice*, guarded by the *mitral valve*. The latter provides the portal of entry to the inflow tract of the left ventricle, contraction of which raises its luminal pressure rapidly, causing closure of the mitral valve (*vide infra*) followed, with minimal delay, by opening of the aortic valve and ejection of blood through the left ventricular *outflow tract* via the aortic orifice into the aortic sinuses, ascending aorta, and thence throughout the whole of the non-pulmonary systemic arterial, arteriolar and capillary tree, including the coronary vessels themselves. This vast vascular bed provides a relatively high peripheral resistance, and this, together with the metabolic demands of the tissues, in particular the high and persistent requirements of the cerebral tissues, is the clue to an understanding of the structural organization of the 'left heart' including again, the geometry of its cavities, flow vectors, planes and strengths of the mitral and aortic valves, and the thickness of the left ventricular myocardium. Thus, the ejection phase of the left ventricle is of shorter duration than that of the right ventricle, but its pressure fluctuations are very much greater (**6**.35).

Because of the prolonged and complex phylogenetic history (outlined above), ontogenetic history (p. 181), and contrasting functional demands, the human heart is far from being a simple pair of parallel pumps, topographically combined, despite the obvious fact that (on average) the right and left ventricles deliver the same volume of blood with each heart beat. The heart, in fact, presents a complicated, spiralized, three-dimensional arrangement which is not obviously related directly to the cardinal planes of the body, and hence terms such as 'left' and 'right', 'apex' and 'base', 'surface', 'aspect' and 'border' may prove misleading to those embarking on a study of cardiac anatomy. Another source of confusion is the common practice of studying isolated specimens of whole or dissected hearts with subsequent difficulty in relating the observations to the heart *in situ*. The following few paragraphs are included to highlight some of these difficulties and, it is hoped, circumvent certain misconceptions before proceeding to a more detailed description of individual chambers.

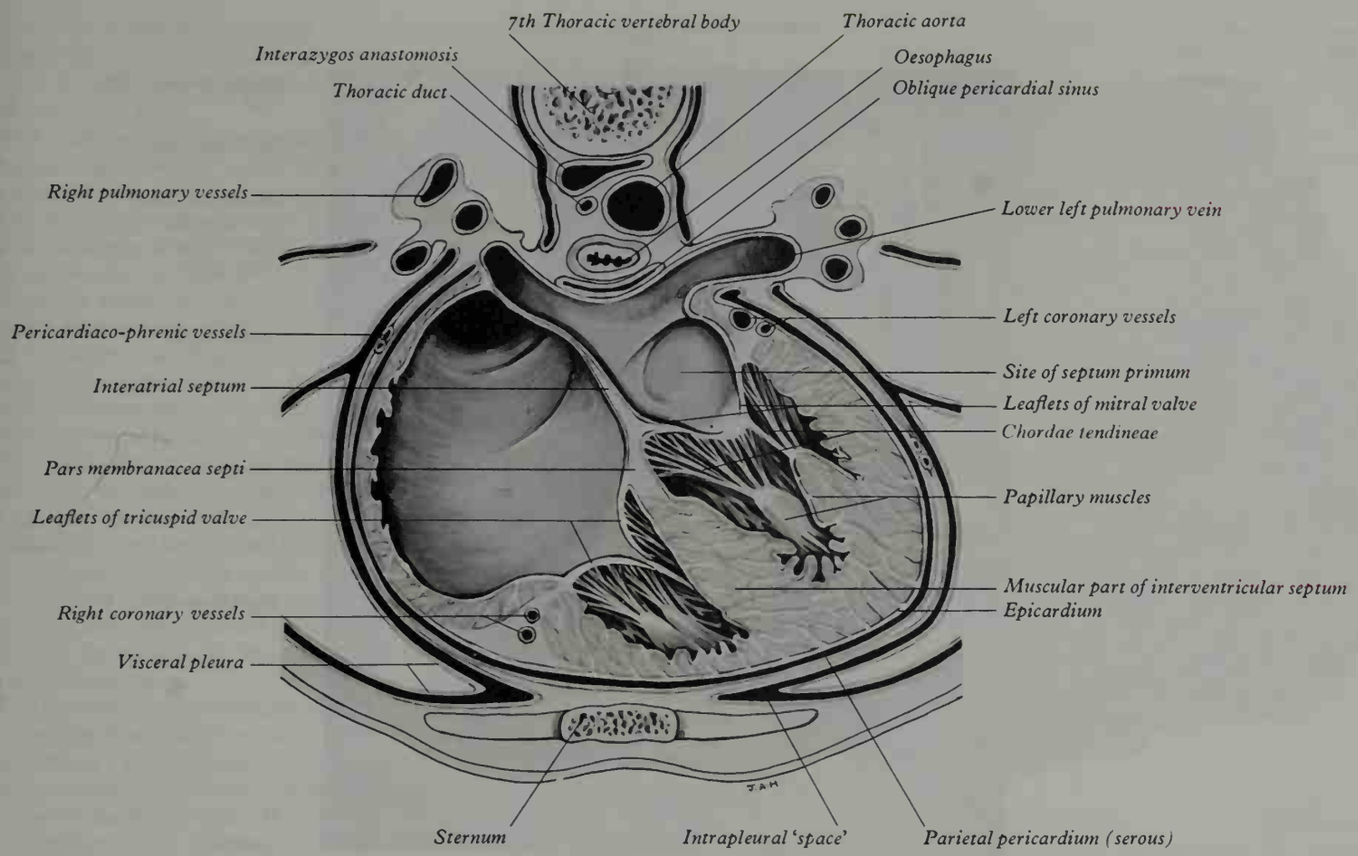
Some of the principal features of cardiac anatomy can, as an introduction, be helped by a consideration of corrosion casts of a normal heart in which the left heart and right heart have been filled with resins of contrasting colours (**6**.14A, B, C), and by a survey of a horizontal section through the mediastinum, including the heart, at the level of the seventh thoracic vertebra (**6**.15).

In illustrations **6**.14A, B, C the left heart (red) and the right heart (blue) are viewed from the *ventral aspect* in their normal mutual relationship (**6**.14A), followed by the right heart (**6**.14B) and left heart (**6**.14C) in isolation (*see* caption for further details). It is seen immediately that the general form of the two is in complete contrast and that the unmodified terms 'right' and 'left' are singularly inappropriate. The right heart, whilst forming the right aspect or border of the heart, then follows a gentle wide-open curve (almost 'stomach-like' in form) and covers most of the

6.14A–C Coloured polyester resin luminal casts of a human heart; right atrium, ventricle, infundibulum, pulmonary root and valvular sinuses—*blue*; left atrium, ventricle, aortic vestibule, root and sinuses—*red*. A Sternocostal surface with right and left hearts *in situ*; B isolated cast of right heart; C isolated cast of left heart. Note the impressions made by the musculi pectinati, trabeculae carneae (spiralized in the left ventricle), the smooth areas related to the atrioventricular valve leaflets, and the dilated sinuses in the walls of the aortic and pulmonary roots. (Casts prepared by Dr. M. C. E. Hutchinson, photography by Mr. Kevin Fitzpatrick, Department of Anatomy, Guy's Hospital Medical School.)

anterior aspect of the left heart (with the exception of a left-sided strip including the apex). Thus, much of the so-called right heart in fact forms a great part of the *ventral surface* of the heart, its outflow tract proceeding upwards and to the left until it even terminates on the *left* side of the outflow tract of the left ventricle. The impressions of the leaflets of the tricuspid valve and those of the sinuses and cusps of the pulmonary valve are *widely separated*, occupying completely different planes, and the flattened cavity of the right ventricle (which is crescentic in section—*vide infra*) is splayed out between them. Conversely, the so-called left heart (except for the narrow left-sided strip and apex mentioned above) is largely *posterior* in position and, as seen in **6**.14A, when viewed from the ventral aspect, is virtually obscured by the chambers of the right heart. It should also be noted at this stage that the left ventricular inflow orifice of the mitral valve is *very closely related* to its outflow orifice (i.e. the aortic valve), the two being embraced by the wide divarication of the 'right' inflow and outflow orifices. The planes of the left ventricular orifices, even though somewhat inclined to each other, are much more nearly coplanar than those of the right; the left ventricular cavity also shows marked differences—it is narrow, conical, and the spiral nature of its trabeculated interior is obvious. The tip of the left ventricular cone occupies the cardiac *apex*, whilst most of the *anatomical base* of the heart is provided by the left atrium.

Clearly, the heart as a whole is placed *obliquely* in the thorax (*see* further below) and this is easily confirmed by reference to the horizontal section shown in illustration **6**.15. Note particularly that the interatrial septum and interventricular septum are virtually in line but are inclined *forwards and to the left* at an angle of about 45° to the sagittal plane, whilst the planes of the mitral and tricuspid valves, although not precisely coplanar and vertical, are broadly in a plane at right angles to the septal plane. In brief, therefore, the right atrium lies not only to the right but extends *anterior* and *inferior* to the left atrium (and also, to a small extent, anterior to part of the left ventricle, the *atrioventricular septum* intervening). The right ventricle forms most of the *anterior aspect* of the ventricular part of the heart; only its right inferior extremity lies to the *right* of the left ventricle, whilst its upper left extremity (outflow orifice) lies to the *left* and superior to the aortic valve. The left atrium forms most of the *posterior aspect* of the heart, supplemented by a small part of the right atrium, whilst the left ventricle is only prominent *inferiorly*, along the left margin, and at the cardiac apex. The atria are essentially to the right and posterior to their respective ventricles.



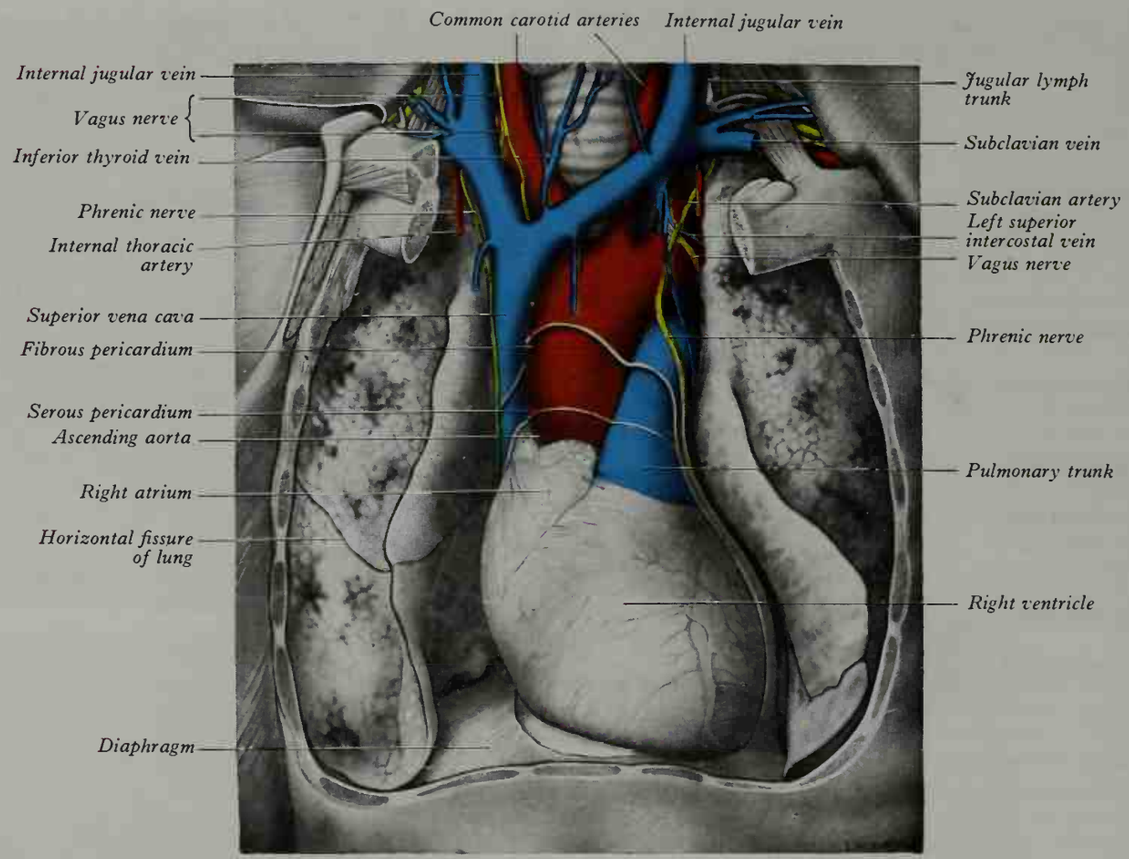
Despite some inevitable repetition, it is hoped that the foregoing remarks will assist an elementary understanding of the heart before pursuing a more detailed appraisal of its size, position, shape and parts. Additionally, such general dispositions as these are of the greatest importance when planning or interpreting radiographs, angiocardiograms, and echocardiograms.

Cardiac Size, Shape and External Features

The heart is a compact, hollow, fibromuscular organ of a somewhat conical or pyramidal form possessing, therefore, a base, apex, and a series of surfaces and 'borders' (**6**.14, 16, 17); it occupies the middle mediastinum between the lungs and pleurae (**6**.15, 16, 17), and is enclosed in the pericardium (p. 634). It is placed *obliquely* in the chest behind the body of the sternum and adjoining costal cartilages and (left) ribs; approximately one-third lies to the right of the median plane and two-thirds to the left.

An average adult heart measures about 12 cm from base to apex, 8 to 9 cm transversely at its broadest part, and 6 cm anteroposteriorly. Its weight, in the male, varies from 280 to 340 gm (average 300 gm), while in the female, from 230 to 280 gm (average 250 gm). It is held that cardiac weight is about 0·45 per cent of body weight in the male and 0·40 per cent in the female (Hudson 1965); adult weight is achieved between 17 and 20 years.

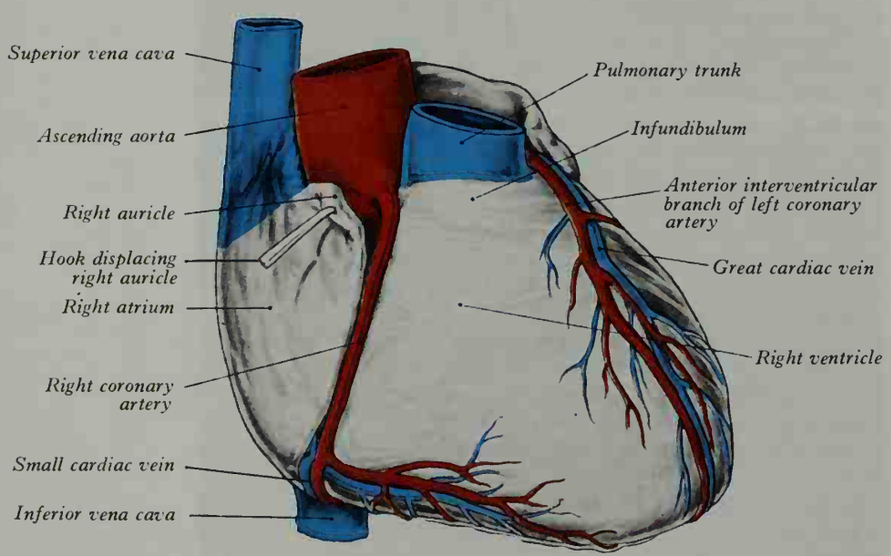
The oblique disposition of the heart has been mentioned in the previous section and may be emphasized by continuing the analogy of a rather deformed pyramid the base of which faces



6.15A Transverse section through the heart, pericardium and related structures at the level of the lower border of the body of the seventh thoracic vertebra to show the principal dispositions of the cardiac chambers and septa, and surrounding structures, viewed from below.

posteriorly and to the right, the apex pointing anteriorly and to the left. Thus a line joining the apex and approximate centre of the base, if projected anterolaterally would pass through the ventral chest wall near the left mid clavicular line; projected posterolaterally it would emerge in the neighbourhood of the right midscapular line. Some aspects of the cardiac 'pyramid' are flattened, others presenting a gentle or more pronounced convexity, these various aspects often merging into each other along rather ill-defined boundaries. Clearly, such dispositions render the precise definition of the extent of named surfaces and intervening 'borders' difficult: in the following pages account will be taken not only of the official nomenclature (*Nomina Anatomica* 1977) but in many instances, terms stemming from widespread clinical practice will be given as alternatives. The heart is described as possessing an (anatomical) base and apex; its *surfaces* are designated—sternocostal (anterior), diaphragmatic (inferior), right, and left (pulmonary); its *borders* are termed—upper, inferior (the 'acute' margin or border), and the left (the 'obtuse' margin or border). (It may be noted here that some authorities persist in naming the right surface as a 'border', despite its extensive nature; furthermore, the right surface is unquestionably as 'pulmonary' as the left surface. A further avoidable source of confusion is the use of the term 'posterior' surface for the unambiguous terms diaphragmatic or inferior surface; if posterior is to be used to denote a cardiac surface it should be reserved for its anatomical base. Finally, as will be discussed more fully below, there are a number of different usages of the term 'cardiac base' by different authorities.)

CARDIAC SURFACE GROOVES AND SULCI



The division of the heart into its principal four chambers, i.e. the right and left atria and the right and left ventricles, is indicated externally by a series of grooves or sulci; some of these are deep and obvious, lodging other prominent structures; others are less distinct and sometimes barely perceptible, whilst some of the grooves or sulci are completely obscured from surface view in part of their extent by major structures which cross them.

The atria are separated from the ventricles by the *coronary (atrioventricular) sulcus* (**6**.16A, B, 17, 27, 28, 39) which contains the principal trunks of the coronary vessels; the sulcus is obliquely set and a study of its position and plane are quite fundamental to any understanding of cardiac anatomy. On the sternocostal surface it proceeds downwards and to the right separating the right atrium (and its auricular appendage) from the oblique right margin of the right ventricle and its infundibulum; the upper left part of the sternocostal course of the coronary sulcus is, however, obscured from the surface where it is crossed by the root of the pulmonary trunk (and deep to this the root of the aorta). Continuing to the left and posteriorly, it curves around the 'obtuse margin' of the heart and proceeds downwards and to the right separating the atrial base of the heart from its diaphragmatic surface. Finally, the posterior and sternocostal aspects of the coronary sulcus curve around the 'acute margin' of the heart at the latter's lower right extremity, where they become confluent. Thus, both the sternocostal and posterior parts of the coronary sulcus pass from high on the left aspect of the heart, downwards and to the right, meeting as indicated, at its lower right extremity: however, the posterior part of the sulcus is a little to the left of its sternocostal element. It will be clear, therefore, that a section through the heart which includes the coronary sulcus will be obliquely set at some 45° to the sagittal plane and at a rather less acute and variable angle to the transverse and coronal planes. Such a section, as will be detailed further below, will pass through the general locations of the lines of attachment of the atrioventricular (mitral and tricuspid) valves, and also (less precisely) those of the aortic and pulmonary valves (**6**.23, 24); further, a line at right angles to the centre of the plane of section will pass obliquely forwards to the left, and a little downards, towards the cardiac apex.

6.16A A dissection to display the heart, great vessels and lungs *in situ*. The sternum and the sternal ends of the costal cartilages, together with the parietal pleura on each side, have been excised, and the mediastinal pleura and parietal layer of the pericardium over the sternocostal surface of the heart have been removed. The lungs have been displaced to expose the heart, and the epicardium dissected off the heart and roots of the great vessels.

On the right side, the inferior cardiac branch of the vagus nerve descends between the brachiocephalic artery and the right brachiocephalic vein. On the left side, a communication descends from the left superior intercostal vein and crosses the aortic arch and the left pulmonary artery to become continuous with the oblique vein of the left atrium.

6.16B The anterior or sternocostal surface of the heart.

The ventricles are separated internally by the interventricular system (p. 649) and its mural margins are indicated superficially by two linear depressions—the *anterior* and *inferior* (*diaphragmatic*) *interventricular grooves*. The former is situated on the sternocostal surface of the heart quite near, and almost parallel to, its left ventricular obtuse margin; the latter is placed on the diaphragmatic surface nearer its acute border. The interventricular grooves extend from the coronary sulcus (i.e. the ventricular 'base') to a notch, the *apical incisure*, sited on the acute margin a little to the right of the true cardiac apex.

CARDIAC BASE, APEX, SURFACES, BORDERS

The *posterior aspect* or *base* (**6**.17) is somewhat quadrilateral in form centrally, but with curved lateral extensions beyond the quadrangle; it faces backwards and to the right, and is separated from the thoracic vertebrae (fifth to eighth in the recumbent, sixth to ninth in the erect posture) by the pericardium, right pulmonary veins, oesophagus and aorta. It is formed mainly by the left atrium, and, to a small extent, by the posterior part of the right atrium. Above, it extends as high as the bifurcation of the pulmonary trunk; below it is bounded by the posterior part of the coronary sulcus, containing the coronary sinus and rami of the coronary arteries (p. 669). On the right it is limited by the rounded right surface of the right atrium, and on the left by the rounded left surface of the left atrium. The four pulmonary veins, two on each side, open into the left atrium, whilst the superior vena cava opens into the upper part, and the inferior vena cava into the lower part of the right atrium. The portion of the left atrium between the openings of the right and left pulmonary veins constitutes the anterior wall of the oblique sinus of the pericardium (p. 635). It should be noted that the foregoing description applies to the true *anatomical base* of the whole heart *in situ*. Some confusion arises, however, because of alternative current usages of the term 'base'. Certain authorities apply the term to that aspect of the ventricular heart viewed after section through the coronary sulcus (**6**.29A): the qualified term *base of the ventricles* should be reserved for this aspect. Finally, in clinical practice, it is common to refer to auscultation or other forms of examination in or near the parasternal parts of the second intercostal spaces as applied to the *clinical 'base'* (as opposed to the *clinical 'apex'*). These multiple applications of the term, whilst unfortunate, seem likely to persist.

The cardiac apex, formed by the true apex of the conical left

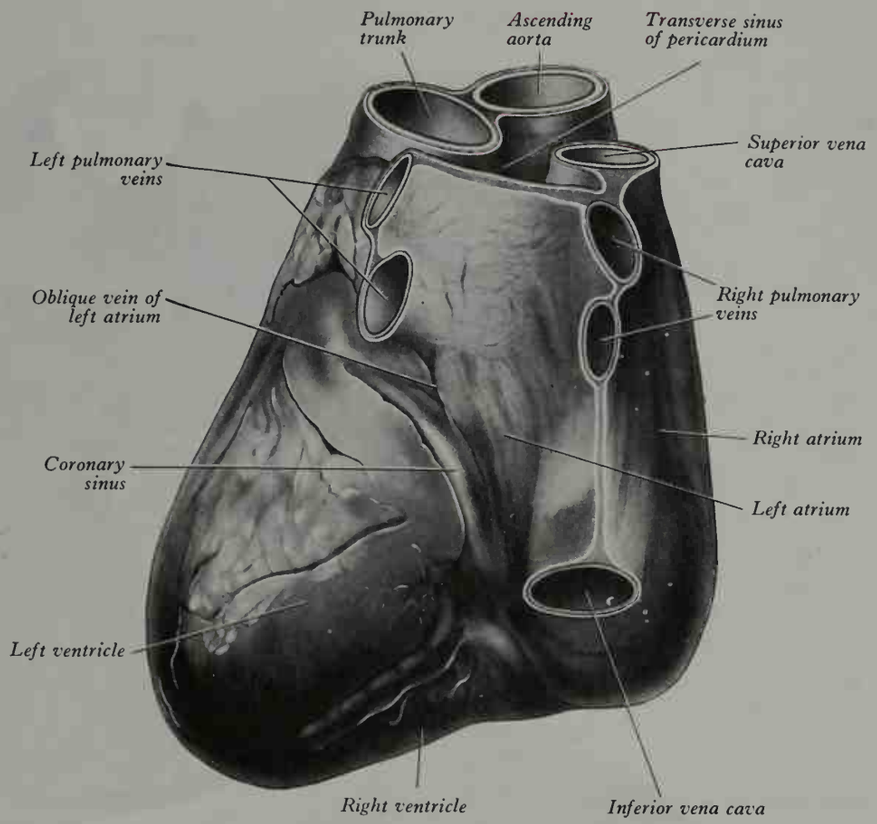
ventricle, is directed downwards, forwards and to the left, and the left lung and pleura overlap it anteriorly. It most commonly lies deep to the fifth left intercostal space, near or a little medial to, the mid-clavicular line.

The anterior or *sternocostal surface* (**6**.16B) is directed forwards, upwards and to the left. It consists of an atrial portion above and to the right, and a ventricular portion below and to the left of the oblique anterior part of the coronary sulcus. The atrial portion is almost entirely formed by the right atrium; the greater part of the left atrium is hidden by the ascending aorta and pulmonary trunk (**6**.16B), and only a small part of its auricle projects forwards on the left side of the pulmonary trunk. Of the ventricular portion about one-third is formed by the left, and two-thirds by the right ventricle, the line of separation between the ventricles being marked by the anterior interventricular groove. The sternocostal surface is separated by the pericardium from the body of the sternum, the sternocostalis muscles and the third to sixth costal cartilages; owing to the bulging of the heart towards the left side, the part of the surface which lies behind the left costal cartilages is much larger than the part which lies behind the right. The sternocostal surface is also covered by the pleurae and the thin, anterior parts of the lungs, with the exception of a small, triangular area corresponding with the cardiac incisure in the left lung; the latter and its associated pleura are, however, quite variable in extent.

The inferior or *diaphragmatic surface* (**6**.17), largely horizontal, is, however, directed downwards and forwards towards the apex. It is formed by the ventricles (chiefly by the left ventricle), and rests upon the central tendon and a small part of the left muscular portion of the diaphragm. It is separated from the base by the posterior part of the coronary sulcus, and is traversed obliquely by the inferior interventricular groove.

The left surface is directed upwards, backwards and to the left. It is formed almost entirely by the left ventricle, but a small part of the left atrium and its left auricle contribute to its formation superiorly. Convex from before backwards and from above downwards, it is widest above, where it is crossed by the coronary sulcus, and narrows to the apex. It is separated by the serous pericardium from the left phrenic nerve and its accompanying vessels, and by the left pleura, in addition, from the deep hollow on the left lung, below and in front of the hilus.

The right surface is formed by the wall of the right atrium; it is gently convex from above downwards and anteroposteriorly. This surface is separated from the mediastinal aspect of the right lung by the serous and fibrous pericardium and by the mediastinal and visceral pleura. The convexity merges below into the short intrathoracic part of the inferior vena cava, and above, into the superior vena cava. The sulcus terminalis curves approximately along the transitional zone between sternocostal and right surfaces.



The *upper border* of the heart is formed by the atria, principally the left; when the heart is viewed from the front this border is hidden by the ascending aorta and pulmonary trunk. The superior vena cava enters the right atrium at its right extremity.

The so-called *right 'border'*, formed by the convex profile of the right atrium, is rounded and almost vertical.

The *inferior border* or *'acute margin of the heart'* is sharp and thin and is nearly horizontal; it extends from the lower limit of the right border to the apex. It is formed mainly by the right ventricle but by the left ventricle near the apex.

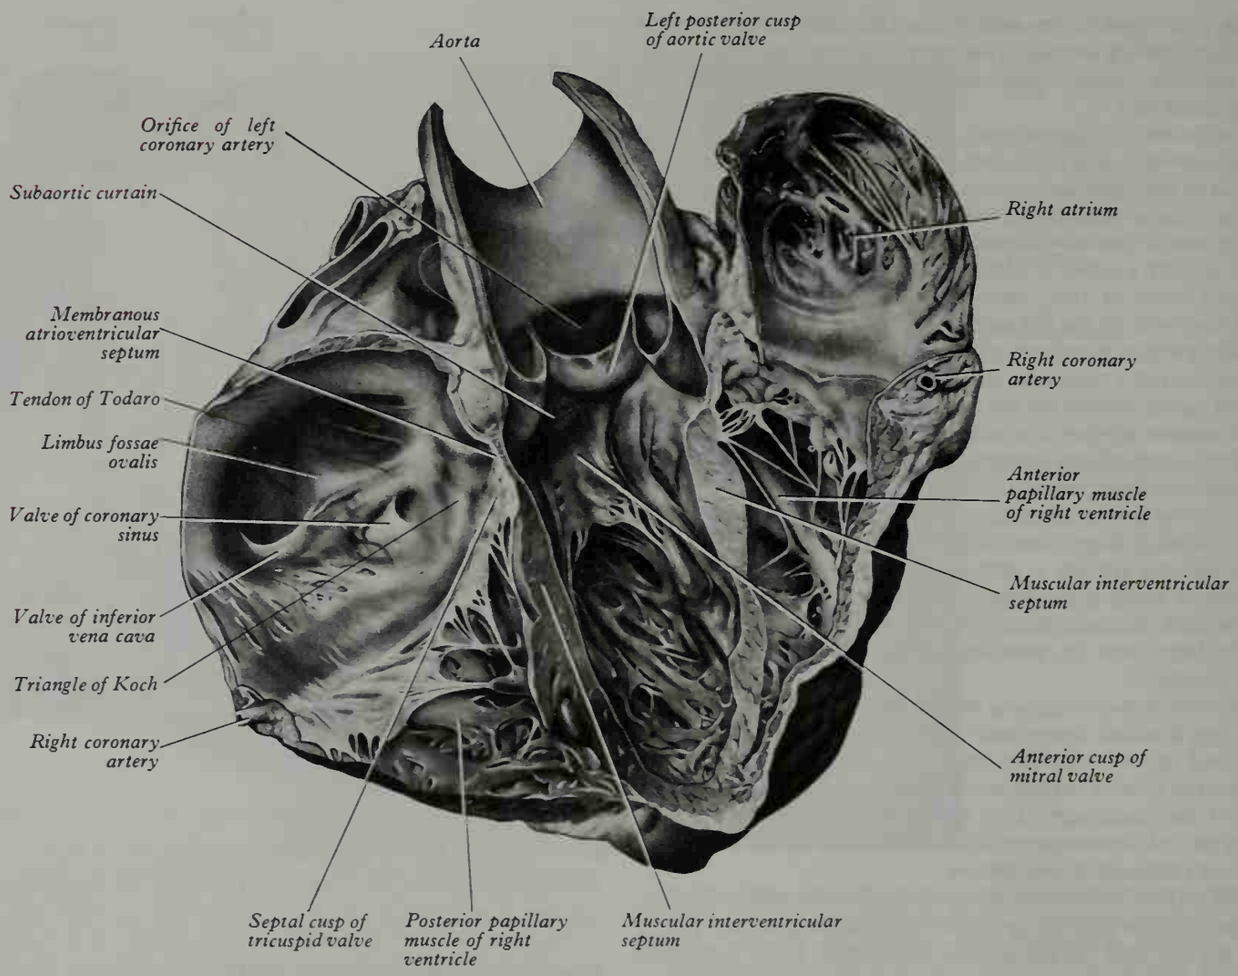
The *left border* or *'obtuse margin of the heart'* separates the sternocostal from the left surface; it is rounded, and is formed mainly by the left ventricle, but to a slight extent, above, by the left auricle. It extends from the left auricle obliquely downwards, with a convexity to the left, to the apex of the heart.

The borders of the heart, as indicated above, apart from the inferior, are rounded, indefinite and difficult to define precisely, they are more in the nature of 'aspects' than borders. The right and left surfaces are together referred to as the pulmonary surfaces but it should be noted that much of the sternocostal surface is also related to the lungs and pleurae with the pericardium intervening. The right and left margins of the cardiac *shadow* as seen in a postero-anterior radiograph of the thorax constitute the right and left borders of the radiologist.

6.17 The base and the diaphragmatic surface of the heart. The serous pericardium is *in situ* and its cut edge is seen around the great vessels.

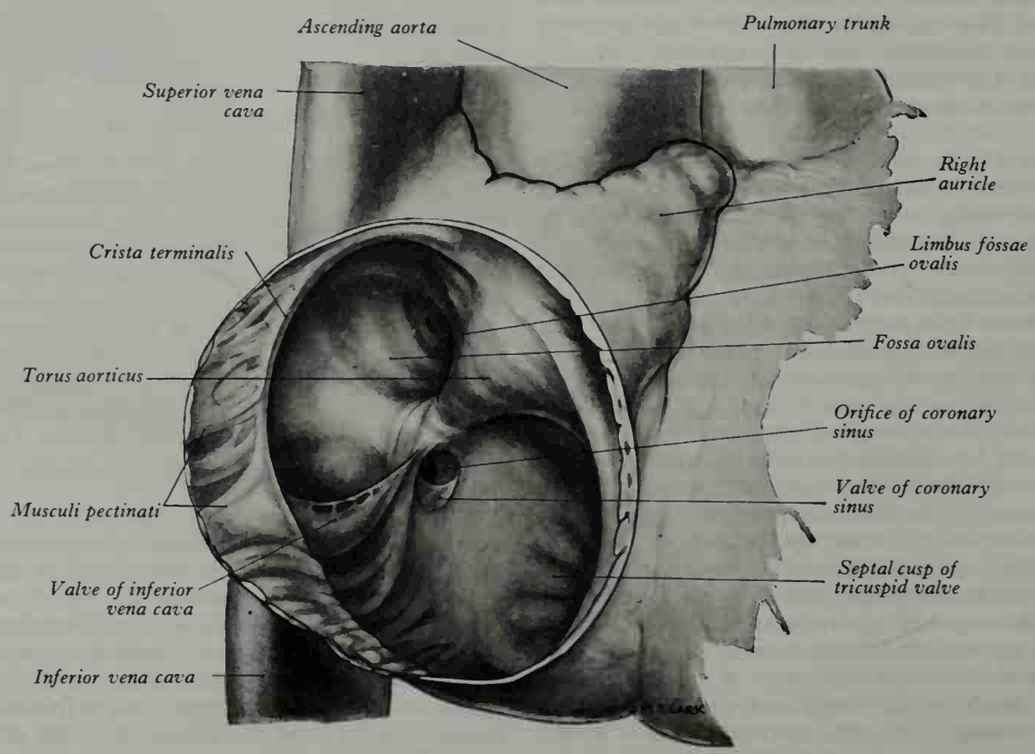
Cardiac Chambers and Internal Features

In the following sections the chambers of the right heart and the left heart will be described seriatim in terms of their general form, walls and principal internal topographical features. Some aspects of the two hearts, however, have much in common; for example, the structural makeup of the valve cusps or leaflets, chordae tendineae, and papillary muscles of the atrioventricular valves, and cusp architecture of the outflow tract valves, i.e. the pulmonary and aortic valves. Where possible repetition will be avoided.



THE RIGHT ATRIUM (**6**.16, 17, 18)

As noted above, the *interatrial*, or *atrial septum* is placed obliquely, so that the right atrium, a roughly quadrangular chamber, lies not only to the right of the left atrium, but anterior to it and also extends more inferiorly. Its walls form the right upper part of the sternocostal surface, the convex right (pulmonary) surface, and a small part of the right side of the base of the heart.



The superior vena cava opens into its upper and posterior part and the inferior vena cava into its lower and posterior part. A small, conical, muscular pouch, termed the *auricle*, projects towards the left from its upper and anterior part and overlaps the right side of the root of the ascending aorta. The margins of the auricle are notched, and its interior is encroached on by an irregular muscular reticulum.

In well-fixed hearts the outer surface of the lateral wall of the atrium is marked by a shallow groove, termed the *sulcus terminalis*, which extends between the right sides of the orifices of the superior and inferior venae cavae.

Anteriorly, the right atrium is related to the anterior part of the mediastinal surface of the right lung and is separated from it by the pleura and the pericardium. *Laterally*, it is related to the mediastinal surface of the right lung in front of the hilus but is separated from it by the pleura, the right phrenic nerve and pericardiacophrenic vessels and the pericardium. *Posteriorly* and to the left (**6**.13B, 15), the right atrium is related to the left atrium

6.18A The interior of the heart revealed by incising it along its right and lower surfaces and excising the pulmonary trunk and infundibulum. The rest of the front of the heart has been turned over to the left.

 6.18B The interior of the right atrium, viewed from the front.

and is separated from it by the interatrial septum; posteriorly and to the right, it is related to the right pulmonary veins. *Medially*, it is related to the commencement of the ascending aorta and, to a lesser extent, to the root of the pulmonary trunk.

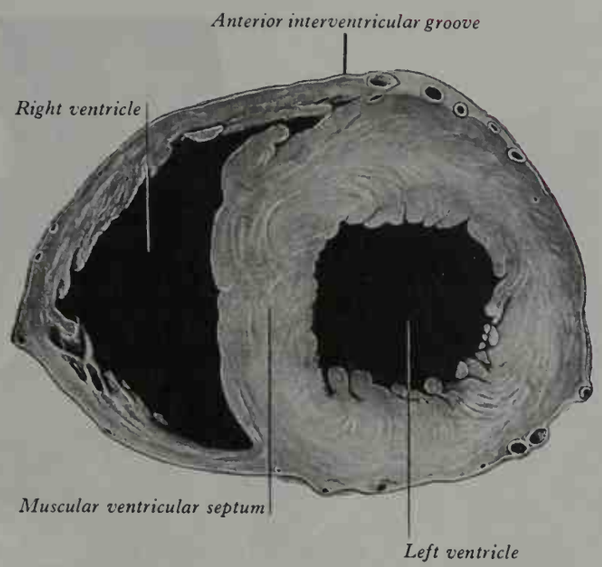
The interior of the right atrium (**6**.18B) presents two main parts for examination: posterior and anterior.

The posterior part, into which the great veins discharge, is derived embryologically from the absorbed right horn of the sinus venosus (p. 183); it has smooth walls and is termed the *sinus venarum*. *Anterior* to this is a portion with ridged walls derived embryologically from the *atrium* proper and which is in continuity anteriorly with the *auricle*. The atrium communicates with the right ventricle through the atrioventricular opening.

The *sinus venarum*. This region includes the posterior portion and the lateral wall of the cavity as far forwards as the crista terminalis (p. 184). Opening into it are the following vessels:

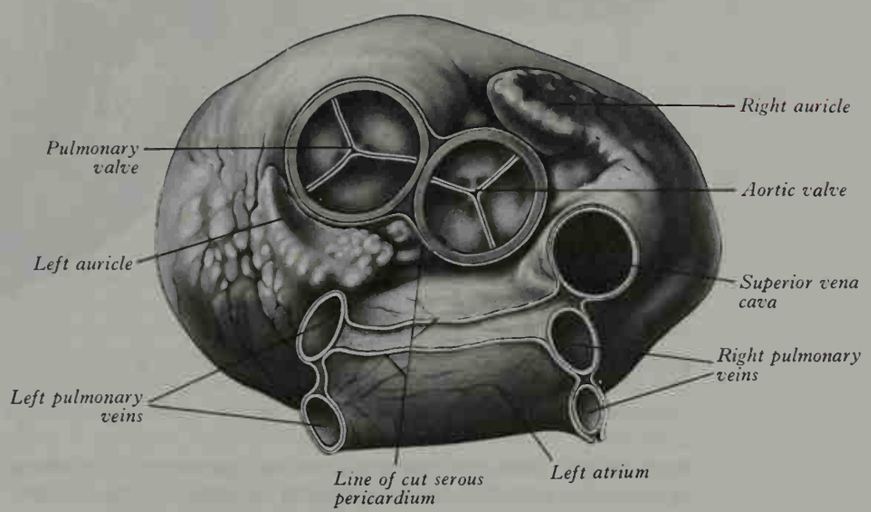
The *superior vena cava* (**6**.16B, 18B) returns the blood from the upper half of the body, and opens into the upper and posterior part of the atrium. Its orifice is directed downwards and forwards, and has no valve.

The *inferior vena cava* (**6**.18B), larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the atrium near the interatrial septum. The orifice is skirted anteriorly by a rudimentary semilunar valve, the *valve of the inferior vena cava*. Its convex margin is attached to the anterior margin of the orifice; its concave margin, which is free, ends in two *cornua*, of which the left is continuous with the anterior edge of the limbus fossae ovalis, while the right is lost on the lateral wall of the atrium where it is continuous with the lower end of the crista terminalis. The valve is formed by a duplication of the endocardium of the atrium, enclosing a few muscular fibres. During intrauterine life this valve is of large size, and serves to direct the flow from the *inferior vena cava* into the *left atrium* through an opening, the *foramen ovale*, in the interatrial septum. The valve varies considerably in size and is sometimes cribriform or filamentous; occasionally it is absent.



The *coronary sinus* (**6**.17) returns the greater part of the blood from the substance of the heart. Its opening is between the orifice of the inferior vena cava and the atrioventricular opening, and is protected by a thin, semicircular *valve of the coronary sinus* (**6**.18B), which covers the lower part of the orifice. It prevents the regurgitation of blood into the sinus during the contraction of the atrium. This valve may be double or cribriform.

The *foramina venarum minimarum* are the orifices of minute veins (*venae cordis minimae*), which return a small quantity of blood directly from the substance of the heart (p. 737). They are more numerous on the septal wall than elsewhere. Other small orifices opening into the atrium are those of the anterior cardiac veins and sometimes of the right marginal vein (p. 737).

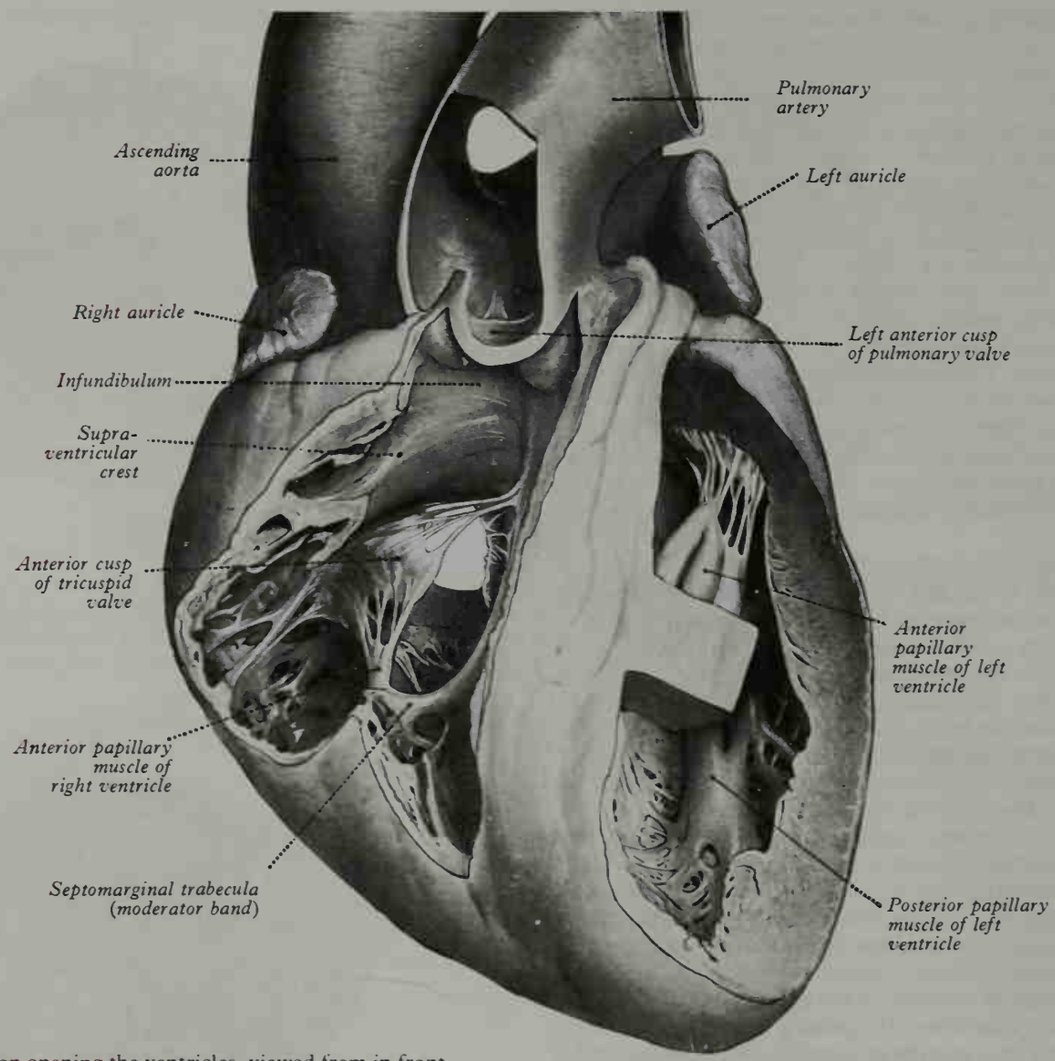


The *intervenous tubercle* is a small variably developed projection on the posterior wall of the atrium, just below the orifice of the superior vena cava. It is distinct in the hearts of quadrupeds, but in man is often scarcely visible. During intrauterine life it is much more prominent and may direct the blood from the superior vena cava towards the right atrioventricular opening.

The atrium proper and the auricle. This region is separated from the sinus venarum by the *crista terminalis*, a smooth, muscular ridge, placed mainly on the lateral wall of the right atrium. It begins on the upper part of the septum and, after passing anterior to the orifice of the superior vena cava, skirts the right margin of that orifice and then extends to the right side of the orifice of the inferior vena cava, where it is connected to the right end of the valve of the latter vessel. It occupies the site of the right venous valve of the embryo (p. 184) and corresponds in position with the sulcus terminalis (p. 641) on the outside of the heart. It indicates the junction between the part of the heart derived from absorption of the right horn of the sinus venosus and the part derived from the original atrium. The upper part of the crista terminalis accommodates the sinuatrial (sinus) node (*see* p. 661), whilst the remainder of the crista is regarded by some to be the route of the posterior internodal tract of specialized conducting tissue (p. 663).

The *musculi pectinati* are nearly parallel muscular ridges which run forwards from the crista terminalis across the lateral and anterior walls of the right atrium, inclining towards the atrioventricular orifice. In the auricle they are connected to one another so as to form a muscular network.

6.19A A transverse section through the ventricles of the isolated heart, viewed from below. Note that in this illustration the heart is *not* positioned as it would be *in situ*: in the latter position the crescentic 'right' ventricle overlaps most of the anterior surface of the 'left' ventricle.



6.19B The heart, viewed from above. The two continuous white lines which enclose the pulmonary trunk and aorta on the one hand, and the pulmonary veins and the superior vena cava on the other, indicate the continuation of the parietal layer of the serous pericardium with the serous epicardium. The floor of the transverse sinus is seen from above, with the left coronary artery running in it. This diagram, from an earlier edition, has been retained for its pericardial details. However, in some respects it is misleading—the aortic and pulmonary valves are *not* coplanar. The pulmonary valve is distinctly higher than the aortic valve; furthermore the planes of the valves 'face' approximately at right angles to each other.

The septal wall presents the following features:

The *fossa ovalis* (**6**.18B) is an oval depression on the lower part of the septal wall of the atrium, above and to the left of the orifice of the inferior vena cava. Its floor is formed originally by the septum primum of the fetal heart (p. 184). The *limbus fossae ovalis* is the prominent margin of the fossa ovalis and represents the free edge of the septum secundum (p. 186) of the embryonic heart. It is most distinct above and at the sides of the fossa; below, it is deficient. Its anterior edge is continuous with the left horn of the valve of the inferior vena cava. A small, slit-like valvular opening is occasionally found at the upper margin of the fossa, leading upwards, beneath the limbus, into the left atrium; it is the remains of the foramen ovale between the two atria.

The antero-inferior part of the right atrium is occupied by the

6.20A A dissection opening the ventricles, viewed from in front.

large roughly oval *atrioventricular orifice*, the margins of which approximate to the line of attachment of the leaflets of the *tricuspid valve*; both orifice and valve are considered further below.

The roughly triangular zone (*triangle of Koch—see* **6**.18A) bounded by the base of the septal leaflet of the tricuspid valve, the anteromedial margin of the orifice of the coronary sinus, and the rounded collagenous, palpable, subendocardial *tendon of Todaro* which curves from the '*right fibrous trigone*' (*central fibrous body—see* p. 657) towards the medial extremity of the valve of the inferior vena cava, is a landmark of surgical importance, indicating the septal site of the atrioventricular node and its associated juxtanodal bundles of conducting tissue (p. 663). Immediately dorsal to the septal leaflet of the tricuspid valve the septal wall is formed by an extension of the pars membranacea septi which is *atrioventricular* here, since it intervenes between the right atrium and left ventricle.

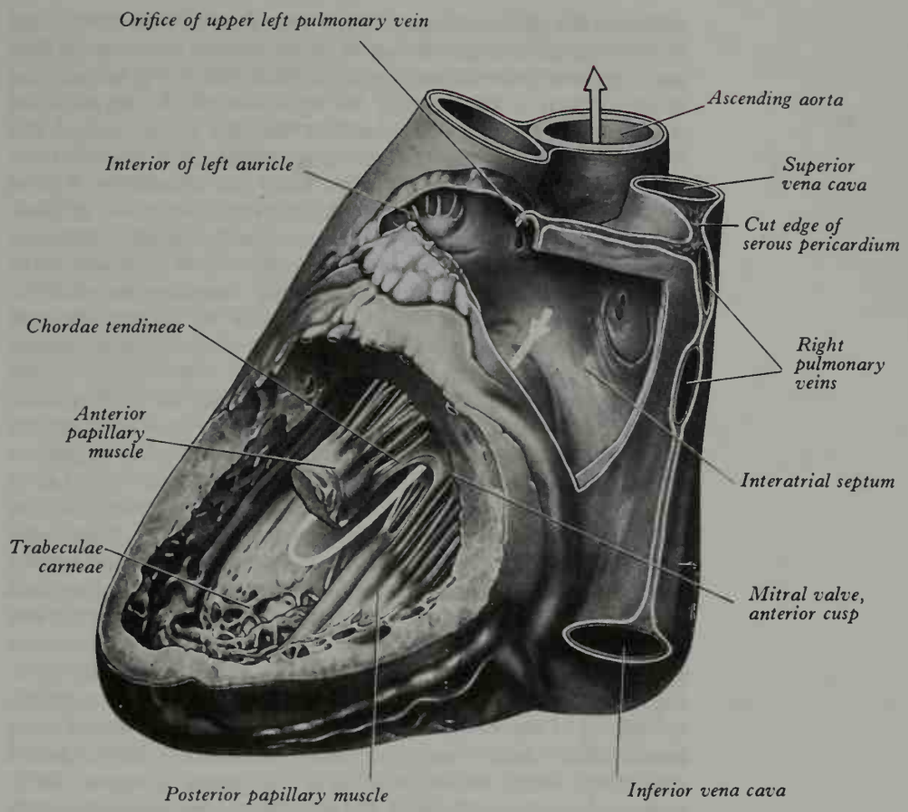
The anterosuperior part of the septal wall of the right atrium bulges to a variable degree into the atrial cavity as the *torus aorticus*: the torus is caused by the proximity of the right posterior (non-coronary) aortic sinus and cusp (p. 651).

THE RIGHT VENTRICLE

The right ventricle extends from the right atrioventricular (tricuspid) orifice nearly to the cardiac apex and then continues upwards and to the left as a conical pouch, the *conus arteriosus* (*infundibulum*) reach the pulmonary orifice from which the pulmonary trunk arises. On this view, therefore, the right ventricle possesses an inflow orifice and tract, succeeded at an obtuse angle by an outflow tract and orifice; (although some authorities prefer to include an intermediate 'body' of the ventricle, this practice will not be followed here).

In the following paragraphs the external features of the right ventricle will be followed by considerations of the topographical internal features of its inflow and outflow tracts, the tricuspid valve complex, the pulmonary valve, and finally brief functional allusions related to valve operation and flow vectors.

External features: The *anterosuperior surface* of the right ventricle is convex and forms a large part of the sternocostal surface of the heart. In the greater part of its extent it is separated from the chest wall only by the pericardium, but the left pleura and, to a lesser extent, the anterior margin of the left lung are interposed both above and to the left side (**6**.23). Its *inferior surface* is rather flat and is related to the central tendon and the adjoining part of the diaphragm, but is separated from it by the pericardium. Its *left* and *posterior* wall is formed by the ventricular septum, which bulges into the right ventricle, so that when a section is made that is transverse to the midbase-apex axis of the heart, the cavity of the right ventricle presents a crescentic outline (**6**.19A). A collagenous band (6.29A, B), the *tendon of the infundibulum* (*conus ligament*) connects the posterior surface of the pulmonary annulus and the muscular infundibulum to the root of the aorta where it blends with the wall and one margin of its right posterior (non-coronary) sinus (p. 651); inferiorly this tendon is continuous with the membranous part of the ventricular septum (p. 649). The wall of the right ventricle varies greatly in thickness (*vide infra*), but is much thinner (3–5mm on average) than that of the left, the proportion between them being about 1 to 3; it is thickest at its atrial end and gradually becomes thinner towards the apex of the ventricle.



Internal features: The internal surfaces of the inflow and outflow tracts have a completely contrasting topgraphy and the transition between the two occurs superiorly at the supraventricular crest and anteroinferiorly near the apex of the ventricle at

the septomarginal trabecula (*vide infra*). The *supraventricular crest* is a massive muscular arch placed between the right atrioventricular and pulmonary orifices (**6**.20A). It is obliquely set, curving forwards and to the right from the interventricular septum (its '*septal limb*') to the right anterolateral ventricular wall (its '*mural or parietal limb*'). The concavity of the arch lies between these limbs in the long axis of the crest; at right angles to this, i.e. between the valve orifices, the crest is highly convex. Posteriorly the crest gives partial attachment to the anterior leaflet of the tricuspid valve. Its septal limb is often continuous with the septal extremity of the septomarginal trabecula (*vide infra*).

The inflow tract has rough walls due to the presence of the *trabeculae carneae* which are round or irregular muscular ridges, columns, bands or protrusions, covered with endocardium, which project into the ventricular cavity: the elevations are, of course, surrounded by or have intervening valleys, grooves or depressions; hence the great variation in thickness of the ventricular myocardium. There are three main types of trabeculae: some, as indicated, are mere ridges, others are fixed to the ventricular wall or septum at their ends but are free in the middle, while a third set, the *papillary muscles* are continuous by their bases with the wall of the ventricle, while their apices project into the cavity and are continuous with the (true) *chordae tendineae*—fine, glistening collagenous cords which, together with the muscles, are part of the tricuspid valve complex (and are further described with it). The *septomarginal trabecula*, a curved muscular band which extends from the lower part of the interventricular septum to the base of the anterior papillary muscle, although variably developed, deserves special mention. Forming the lower limit of the trabeculated inflow tract, it carries the continuation of the right bundle-branch of the specialized conducting tissue (p. 663). Its alternative name of 'moderator band', implied a tenet of the earlier anatomists, namely that it prevented 'over distention' of the ventricle; the latter is of dubious validity.

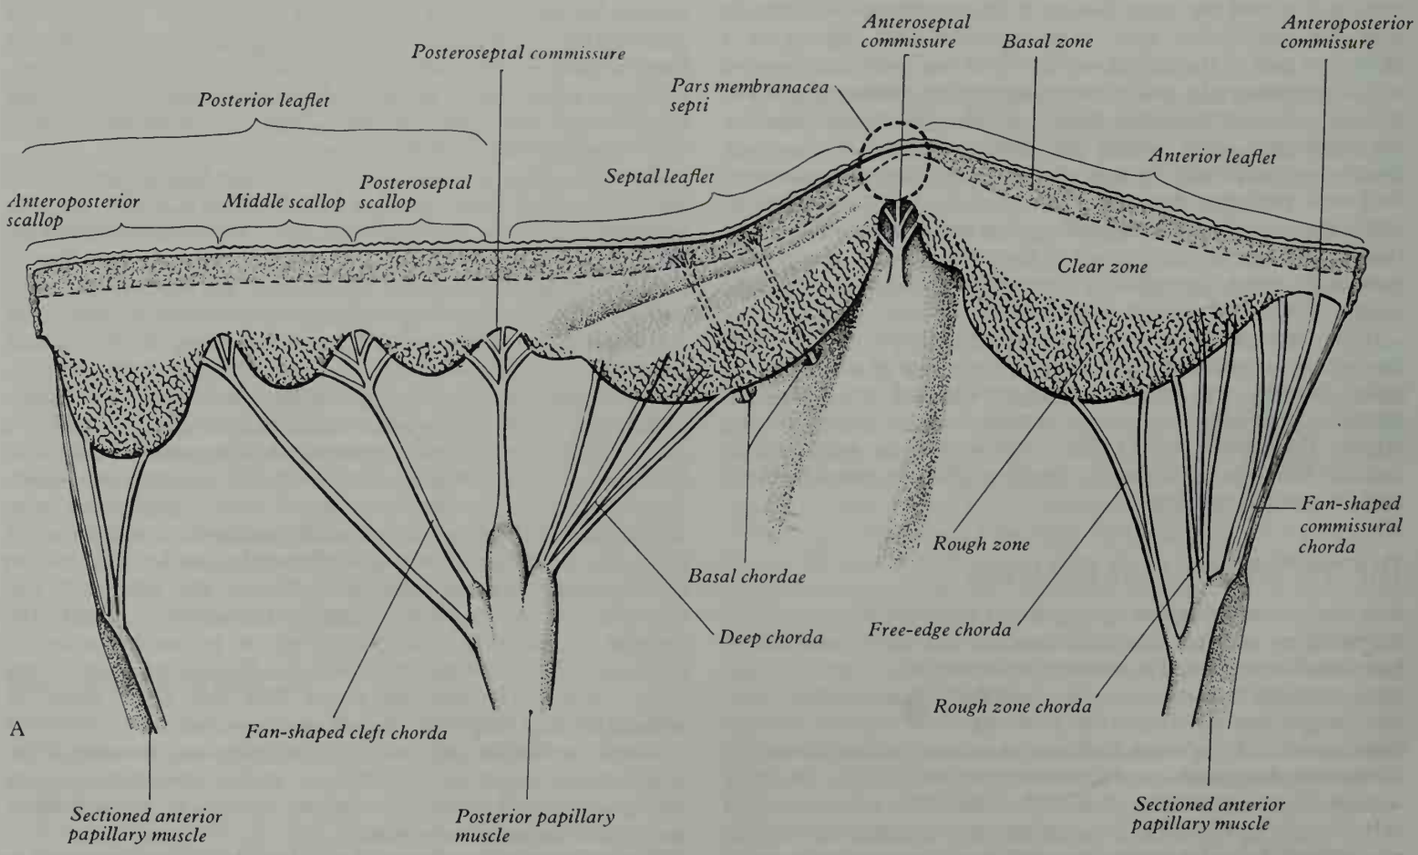
The outflow tract, conus arteriosus (or *infundibulum*) has smooth walls and leads upwards, to the left, inclining posteriorly to reach the *pulmonary orifice*. In the cadaver it is impossible to recognize the lower limit of the infundibulum on the surface of the heart but it is formed by the free rounded border of the supraventricular crest (**6**.20A) and the upper border of the septomarginal trabecula near the ventricular apex. The infundibulum represents a persistent part of the bulbus cordis which has been incorporated in the right ventricle, and its persistence as the outflow channel of this ventricle is attributable, in part, to the support it provides for the pulmonary valve during ventricular diastole. It has been shown experimentally (in dogs) that, when subjected to increased backward pressure, the pulmonary valve becomes incompetent much more readily than the aortic valve, and it has been inferred that, in life, the muscular walls of the infundibulum retain their contractile tonus throughout ventricular diastole thus providing support for the valve cusps (Brock 1955).

It has been proposed that the trabeculated walls of the inflow tract assist in controlling and slowing the inflow of blood during early diastole, and by their contraction and interdigitation increase the *volumetric efficiency* of ventricular emptying during systole: the smooth walls of the outflow tract are presumed to increase the *velocity* of systolic ejection. (Similar considerations apply to the left ventricle.)

6.20B A dissection showing the interior of the left side of the heart. The white arrow indicates the course of blood flow from the left atrium through the left ventricle to the aorta.

THE TRICUSPID VALVE COMPLEX

It is undesirable that the tricuspid and mitral valves should be described as isolated structural entities, but rather as parts of functionally integrated complexes of structures. The tricuspid valve complex comprises: (*a*) the so-called *tricuspid atrioventricular 'orifice'* and the tissues that make up its associated *tricuspid valve annulus*; (*b*) the *valve leaflets* or *cusps* and their subdivisions; (*c*) the *chordae tendineae* of various types; and (*d*) the *papillary muscles*. Further, it will be clear to the reader that effective action of the foregoing also depends upon harmonious interplay with the activities of the atrial, ventricular and septal myocardia (p. 657), the specialized conducting tissues (p. 659), and the mechanical cohesion provided by the fibro-elastic 'skeleton' of the heart. It will be appreciated that all of these elements undergo substantial changes in position, shape, angulation and dimensions throughout the various phases of the cardiac cycle; the *in vivo* condition being the resultant, at any instant, of the state of myocardial contraction or relaxation balanced against the internal pressure profiles and flow patterns of the blood. Thus, either qualitative or quantitative observations made on cadaveric hearts, whether fixed or unfixed, removed or *in situ*, may prove quite misleading; similar strictures apply to many observations made during open heart surgery where the (abnormal) heart has been subjected to severe haemodynamic interference.



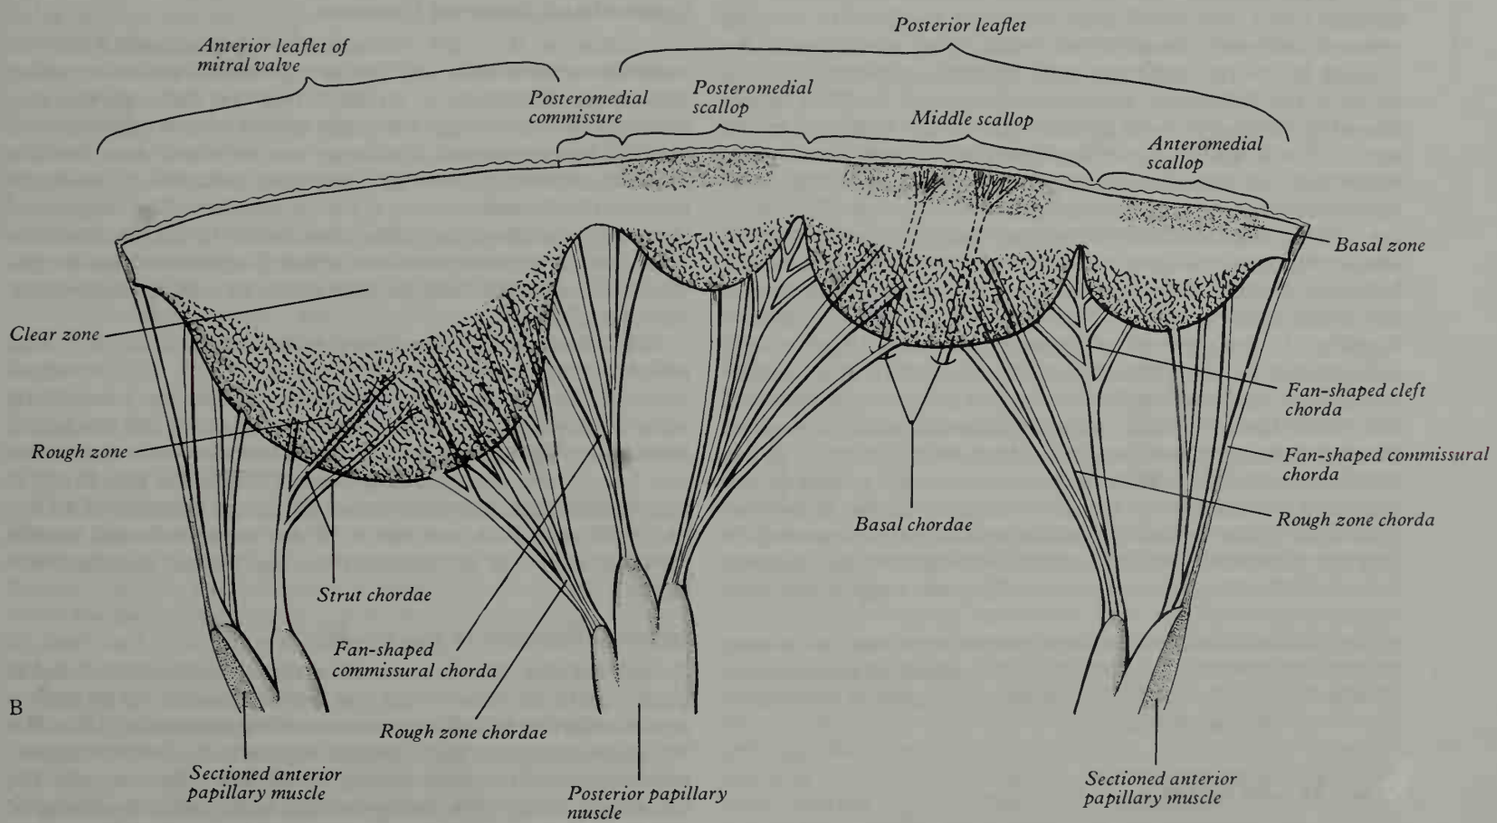
The *tricuspid atrioventricular 'orifice'*, the largest of the valve orifices (circumference 11·4 ±1·1 cm in males and 10·8 ±1·3 cm in females according to Silver *et al.* 1971), is best viewed from the atrial aspect (**6**.29A), and is the clearly recognizable line of transition from atrial wall or septum into the bases of the valve leaflets. Thus is it not a true orifice, only becoming so after leaflet removal by dissection; deep to its endocardium lie the various components of the valve annulus. The orifice, as defined above, has been variously described as almost circular, oval, or roughly triangular with rounded angles, doubtless reflecting differences in age, normality, method of preparation and inspection. As detailed below, the margins of the orifice do not lie precisely in a single plane, but for our present purposes, the nearest approximation to such a plane is placed almost vertically at about 45° to the sagittal plane, but also slightly inclined to the vertical so that it 'faces' (on its ventricular aspect) anterolaterally to the left, and also somewhat inferiorly. When roughly triangular in shape, the margins of the orifice are described as presenting anterior, posterior, and septal aspects, corresponding to the bases of the valve leaflets. (It may be noted that the name septal is unambiguous; however, the terms anterior and posterior although having the advantage of simplicity are, because of the near-vertical plane of the orifice, rather misleading—right superolateral and right inferolateral would be more strictly accurate, although cumbersome.)

The *tricuspid valve annulus* is a rather ill-defined term used in different ways by different authorities. In many elementary accounts the view is advanced that all four valve orifices are surrounded by relatively *uniform rings* of collagenous tissue (of

different strength and dimensions in the case of each valve), and these rings are interconnected by dense masses of collagen; they are supposed to correspond precisely with the topographical line of attachment of the bases of the valve leaflets, fusing with the lamina fibrosa of the latter, and in the case of the mitral and tricuspid valves, to be situated throughout their extent at the atrioventricular junction (i.e. separating the myocardia of these cavities). However, it has become clear that only some of these propositions are true: with the atrioventricular valves, whilst it is undeniable that connective tissue in some form separates atrial and ventricular myocardium around the complete periphery of the associated 'orifice', it varies greatly in its density and disposition in different regions of the circumference, and with the sex and age of the individual (Walmsley and Watson 1978). Further, the topographical line of 'attachment' of the *free* valve leaflet does not correspond *at all points* to the level of the atrioventricular connective tissue (although it does throughout a considerable part of its extent). Some authorities limit the use of the term valve annulus simply to the line of attachment of the free leaflet: it should be appreciated, however, that the collagenous central stratum of the leaflet may, in some regions, pass basally and then subendocardially for some distance before merging with the atrioventricular connective tissues concerned. The latter will be considered to constitute the valve annulus in the present account, and in the case of the tricuspid valve they include: (*a*) an angulated line crossing the membranous part of the septum, (*b*) the tricuspid aspect of the right fibrous trigone, (*c*) the tapering dense fibro-elastic 'anterior' and 'posterior' *fila coronaria* extending from the trigone, and (*d*) more tenuous sulcal connective tissue completing the annular circumference between the tips of the fila. These elements will be discussed further below and are illustrated in **6**.29B.

The *tricuspid valve leaflets*, customarily regarded as three in number and hence the name of the valve, are termed *septal*, *anterior* and *posterior*, corresponding to the marginal sectors of the atrioventricular orifice similarly named, and each consists of a reduplication of the endocardium within which is sandwiched a collagenous *lamina fibrosa*. The latter is continuous marginally, and on its ventricular aspect, with the diverging fascicles of the chordae tendineae (*vide infra*), whilst basally is confluent with the connective tissue of the valve annulus. Numerous earlier anatomists described the occurrence of small 'accessory leaflets' or 'islands of leaflet tissue' between the major ones, but recent critical quantitative reviews of tricuspid valve architecture have largely rejected the need for such a view (*see* Silver *et al.* 1971). The leaflet tissue of the tricuspid (and mitral—*see* p. 649) valve may be regarded as a *continuous curtain* arising from or near the valve annulus, descending into the ventricular cavity, but presenting three principal grades of indentation in its free border, dividing the tissue into definable subregions. The deepest indentations are bays projecting towards the basal attachment of the principal, smoothly arched, *valve commissures* which separate the main leaflets and are therefore termed anteroseptal, posteroseptal, and anteroposterior. (Thus, a particular region of a leaflet may be designated, for example, 'the anteroseptal half of the septal leaflet'.) The commissures can be identified with precision in most cases (although not as precisely as in the case of the mitral valve) by their characteristic fan-shaped chordae tendineae, and other adjacent anatomical features (Silver *et al.* 1971). Intermediate marginal indentations or '*clefts*', possessing smaller fan-shaped chordae divide the posterior leaflet into three *scallops*, while one small '*notch*' is usually present on the margin of both the septal and the anterior leaflet. Thus viewed from either the atrial or ventricular aspect, the true valve orifice presents a highly irregular profile.

Simple palpation, transillumination, and histology reveal that (except for those parts extending on to the membranous septum) all the tricuspid leaflets possess three *zones*, named from the free margin, rough, clear and basal. As the name implies, the *rough zone* is relatively thick, opaque, uneven on both, but particularly the ventricular aspect; the latter receives the insertion of the majority of the chordae tendineae, whilst the obverse 'atrial' or



6.21 A, B Diagrams of the tricuspid (A) and mitral (B, facing page) valves, laid flat after division of their fibrous annuli with the atrioventricular axis placed vertically, showing the relative shapes, dimensions and zones of the leaflets and their subdivisions; also the varieties of chordae tendineae. Drawn to scale. A—after Silver *et al.* (1971); B—after Lam *et al.* (1970). Consult text for further details.

'inflowing' aspect of the zone is that area making contact with another leaflet during full valve closure. The *clear zone* is smoother, translucent, receives relatively few chordae, and has a more delicate lamina fibrosa. The *basal zone*, some 2–3 mm in extent from the peripheral attachment, is again thicker, possesses more connective tissue, is vascularized and frequently contains tails of atrial myocardium.

The *anterior leaflet* is the largest and in the main is attached to the atrioventricular junction on the posterolateral aspect of the supraventricular crest, but it extends along its septal limb to reach the membranous septum, ending at the anteroseptal commissure: one or more notches indent its margin. The *septal leaflet* is the smallest, its attachment passing from the posterior ventricular wall across the muscular septum and then angulating over the membranous septum to the anteroseptal commissure. The *posterior leaflet* is wholly mural in its attachment. Diagram **6**.21A, based on the researches of Silver *et al.* (1971), summarizes some of the main features of the tricuspid valve leaflets, their attachments and chordae: the heart has been incised along its acute margin, opened, and the valve annulus cut through the anteroposterior commissure and laid flat, with the base-apex ventricular axis placed vertically. Note that the posterior leaflet and posteroseptal half of the septal leaflet are horizontal, whereas the anteroseptal half of the septal leaflet and anterior leaflet slope upwards to meet on the surface of the membranous septum at the anteroseptal commissure. The distribution of commissures, clefts, notches, zones, and the pleated form of the septal leaflet are clearly shown, and are drawn to scale.

The *chordae tendineae* are, as noted, glistening white fibrous collagenous cords: as in the left ventricle the majority are *true chordae* associated with the atrioventricular valve complex. The *false chordae* that merely pass between papillary muscles, from papillary muscles to ventricular wall, or between two points on the ventricular wall, are irregular in numbers, dimensions and of no known functional significance – they will not be further discussed here. The *true chordae* usually arise from small projections from the tips or margins of the apical thirds of the papillary muscles, but on occasion from the papillary bases or general ventricular (including septal) walls, and are inserted into some aspect of the valve leaflets, their clefts, commissures or bases. They were early classified by Tandler (1913) into first, second and third order chordae according to their distance of insertion from the free margins of the leaflets: most subsequent authors followed this tripartite classification which, however, possessed little functional or morphological merit. Following an extensive quantitative study of the mitral valve chordae and leaflets, Lam *et al.* (1970) proposed a new and much more generally useful classification, and this was soon applied, with additions, by Silver *et al.* (1971) to the tricuspid valve. This will be followed briefly here: five principal classes of chordae are described in relation to the tricuspid valve complex and have been named *fan-shaped*, *rough zone*, *free edge*, *deep*, and *basal* chordae.

Fan-shaped chordae, as the name implies, possess a short single stem from which a series of branches radiate to attach, in the case of the stouter fans, to the margins (or a short distance on the ventricular aspect) of the main interleaflet commissures (i.e. *commissural chordae*) and also to the extremities of the adjacent leaflets; the more delicate fans have a similar attachment to the inter-scallop clefts of the posterior leaflet (*cleft chordae*). *Rough zone chordae* again arise from a single stem which splits into three soon after its origin, one cord inserting into the free margin of a leaflet; another passes on to the ventricular aspect of the rough zone to insert at its outer limit which corresponds to the line of leaflet contact in full valve closure; the third cord terminating at some intermediate point. *Free edge chordae* are single, threadlike, often long chordae, arising either from the apex or base of a papillary muscle and having a marginal leaflet attachment usually near the mid-point of a major leaflet or one of its scallops. *Deep chordae*, also long, pass deep to the free edge and, sometimes bi- or tri-furcating just before insertion, they reach the more peripheral part of the rough zone, or even the clear zone. *Basal chordae*, the most variable in shape, being either round cords, flattened

ribbons, long and slender, or short and muscular, arise directly from either smooth or trabeculated ventricular wall and insert into the basal 2 mm of the leaflet. (Consult the references quoted above for quantitative details and bibliographies and appertaining to the tricuspid leaflets and chordae tendineae.)

The *papillary muscles* of the right ventricle comprise two principal ones, *anterior* and *posterior*, and a less prominent, variable set of *septal* muscles. The *anterior papillary muscle* is the largest; its base arises from the right anterolateral ventricular wall below the anteroposterior commissure and blends with the right extremity of the septomarginal trabecula (*vide supra*); its apex, usually single but occasionally bifid, gives origin (both apically and subapically) to chordae tendineae which insert into *corresponding zones* of the anterior and posterior tricuspid leaflets. The *posterior papillary muscle* arises from the ventriculoseptal myocardium below the posteroseptal commissure; it is frequently bifid or trifid and its chordae are distributed to the septal and posterior leaflets and their associated commissure and clefts. 'Accessory' *septal papillary muscles* are occasionally absent or merely represented by irregular fibrous cords; more commonly a group of small papillary projections arise from the septal wall of the infundibulum below the level of the crista supraventricularis and are located on the apical aspect of the anteroseptal commissure—their chordae tether the adjoining parts of the anterior and septal leaflets, and the highest muscle of the group is often termed the *papillary muscle of the conus*.

The mechanism of closure of the tricuspid valve has much in common with the mitral valve and since there is firmer evidence with regard to the latter, this will be considered later (p. 650).

THE PULMONARY VALVE

The pulmonary valve, the outflow valve of the right ventricle, surmounts the infundibulum and is somewhat separated from the other three principal cardiac valves, lying anterior and superior to them; its general plane faces superiorly, to the left, and slightly posteriorly. It consists of three semilunar segments or *cusps* (*valvules*), which are attached by their convex margins to the triple-scalloped fibrous thickening in the wall of the pulmonary trunk at its junction with the ventricle and constitutes the valve annulus (*see* p. 657 and **6**.29B); their free borders are directed upwards into the lumen of the vessel. Two of the cusps are situated anteriorly (right and left), the third is posterior. (The cusps of the pulmonary and aortic valves are, in this account, named according to their approximate *in situ* positions in the normal adult heart; this differs from the *Nomina Anatomica* where they are named according to their positions in the fetus before rotation of the heart to its definitive position.) Each cusp consists of a duplication of the endocardium, with an intervening *lamina fibrosa* of collagen fibres variably developed in different locations; the lamina fibrosa is well developed along both the free and attached borders, and at the latter blends with the fibrous 'annulus'. In the centre of the free margin a localized thickening of collagen, the *nodulus* (Arantii) occurs, from which fibres radiate through the lamina fibrosa to the attached margin; on each side of the nodule, however, the collagen is much reduced in the narrow, more delicate, crescentic regions, the *lunules*. Opposite to the semilunar cusps the wall of the pulmonary trunk presents three dilatations, the *sinuses* of Valsalva; the walls of the sinuses are considerably thinner than the general wall of the trunk, and whilst they are predominantly collagenous near the annulus, the proportion of elastic tissue increases rapidly as the upper zones of the sinuses are reached.

Except for differences in time relationships and, of course, contrasting pressure profiles, the mechanism of opening and closure of the pulmonary valve has much in common with that of the aortic valve (*see* p. 652, **6**.33).

THE LEFT ATRIUM

Smaller than the right atrium volumetrically, the walls of the left atrium are, however, thicker (some 3 mm on average); it will be recalled that the cavity and walls of the left atrium are formed to a large extent by the proximal parts of the pulmonary veins which are incorporated during its development (p. 184). The left atrium is roughly cuboidal and extends to the right *behind* the right atrium from which it is separated by the obliquely set interatrial septum (*see* p. 643 and **6**.15). Thus the right atrium forms its right anterolateral relation; anteriorly, and to the left, it is concealed by the roots of the pulmonary trunk and aorta, part of the transverse sinus of the pericardium intervening between the atrium and the arterial trunks. Antero-inferiorly and to the left, it abuts against the base of the left ventricle where it presents the left atrioventricular orifice (*vide infra*). Its posterior aspect forms most of the anatomical base of the heart; it is approximately quadrangular in shape, receives the terminations of (usually) two pulmonary veins on each side, and provides the anterior wall of the oblique sinus of the pericardium (p. 635).

The *auricle* is somewhat constricted at its junction with the atrium; it is longer, narrower and more curved than that of the right atrium, and its margins are more deeply indented. It is directed forwards on the left side of the pulmonary trunk, and overlaps the commencement of this vessel. (The intimate relation of the auricle to the stem and initial branches of the left coronary artery are mentioned on p. 671).

The interior of the left atrium (**6**.20B) presents several features for examination:

The *pulmonary veins*, four in number, open into the upper part of the posterior surface of the atrium—two on each posterolateral aspect; their orifices are smooth, oval and are not provided with valves. The two left veins frequently end via a common opening.

The *left atrioventricular orifice* is described below.

The *foramina venarum minimarum* are the orifices of minute veins (venae cordis minimae) which return blood from the muscular substance of the heart.

The *musculi pectinati*, fewer and smaller than those in the right atrium, are confined to the inner surface of the auricle.

On the atrial septum a lunate impression may be seen, bounded below by a crescentic ridge, the concavity of which is directed upwards; it corresponds to the site of the ostium secundum of the developing heart (p. 184).

THE LEFT VENTRICLE

General and External Features

In contrast to the right ventricle, the construction of the left ventricle accords with its role as a powerful expulsive pump capable of sustaining a pulsatile flow in the high-pressure systemic arterial system. Variously described as a half-ellipsoid, or roughly cone-shaped, it is longer and narrower than the right ventricle, extending from its ventricular base which lies in the plane of the coronary sulcus, to the cardiac apex. The long axis of the cone points downwards, forwards and to the left. In transverse section its cavity presents an oval or nearly circular outline (**6**.19A) with walls about three times as thick (8–12 mm) as those of the right ventricle.

The left ventricle forms part of the sternocostal, left, and inferior (diaphragmatic) surfaces of the heart. Except where obscured by the aorta and pulmonary trunk, the base of the ventricular cone is superficially separated from the left atrium and its auricular appendage by part of the coronary sulcus; anterior and inferior interventricular grooves indicate the line of mural attachment of the interventricular septum and the limits of the left and right ventricular territories. Where the sternocostal surface curves bluntly into the left surface is the 'obtuse' margin of the heart.

Internal Features (**6**.20A, B)

As with the right ventricle, the left ventricle may be considered as consisting of an *inflow orifice* and *tract* succeeded by an *outflow orifice* and *tract*, with their attendant valve complexes. Thus, the left atrioventricular orifice, guarded by the mitral valve complex, admits left atrial blood during ventricular diastole into the ventricular cavity, flow being directed towards the cardiac apex (i.e. the *inflow vector*). After mitral valve closure, and throughout the ejection phase of ventricular systole (**6**.35) blood is expelled along a path from the apex towards and through the aortic orifice, thus defining the *outflow vector*. It should be noted here, that in

complete contrast to the orifices of the right ventricle, the inflow and outflow orifices of the left ventricle are in *close contact*; in part of their extent they are merely separated by the subaortic curtain (intervalvar septum—*vide infra*) and by the anterior leaflet of the mitral valve; further, the inflow and outflow vectors are acutely angled with respect to each other.

The anterolateral wall of the left ventricle is formed by the interventricular septum (i.e. the septal wall as opposed to the 'free' ventricular wall) which is thick and muscular throughout most of its extent. The muscular septum is concave towards the left ventricular cavity, its convexity forming the posteromedial profile of the (sectioned) right ventricle: it thus completes the myocardial circular outline of the left ventricle mentioned above (**6**.19A). However, as the aortic orifice is approached, the interventricular septum becomes thin and collagenous, the *pars membranacea septi*, an oval to round area situated below and partly confluent with the fibrous supports of the anterior (right coronary) and right posterior (non-coronary) cusps of the aortic valve (for further comments *see* pp. 651, 653, 657 and **6**.29B).

Between the lower limits of the free margins of the mitral valve leaflets and the ventricular apex, including the apical two-thirds of the interventricular septum, the muscular walls are intensely trabeculated. These *trabeculae carneae* are stouter and more intricate than, but of the same three varieties as, those of the right ventricle (mere ridges, terminally attached but free centrally, or papillary muscles). They form a particularly dense labyrinthine interlacement towards the apex of the ventricle. The endocardial walls of the outflow tract (as in the right ventricular infundibulum) are, however, smooth; additionally, the subendocardinal tissue in the walls of the final part of the outflow tract, the *aortic vestibule*, becomes increasingly fibrous with a corresponding reduction in myocardial tissue.

THE MITRAL VALVE COMPLEX

Many of the *general* comments concerning the tricuspid valve apply equally to the mitral valve, and to avoid excessive repetition, remarks will be confined to particular features of the following components of the mitral complex: (*a*) the *mitral atrioventricular 'orifice'* and its associated *valve annulus*; (*b*) the *valve leaflets* and their subdivisions; (*c*) varieties of *chordae tendineae*; and (*d*) the *papillary muscles*.

The *mitral atrioventricular orifice*, the well-defined transitional zone between atrial (or aortic) wall into the bases of the leaflets and best viewed from the atrial aspect, is smaller than the tricuspid orifice (mean circumference—9·0 cm in males, 7·2 cm in females according to Ranganathan *et al.* 1970, based on a study of 50 Caucasian hearts from 15 to 85 years: other literature was reviewed and much variation recorded). In diastole the orifice, approximately circular in outline, is placed almost vertically at 45° to the sagittal plane, but with a slight forward inclination: thus, its ventricular aspect 'faces' anterolaterally to the left and also slightly inferiorly, i.e. towards the left ventricular cardiac apex. It is virtually in the same plane as the tricuspid orifice but posterosuperior to it, whereas it lies postero-inferior and a little to the left of the aortic orifice. However, as we shall see, all three orifices are intimately interconnected by the various constituents of the fibrous skeleton of the heart (p. 654).

The *mitral valve annulus* is, again, *not* a simple circumferential fibrous ring, but comprises those elements that vary greatly in consistency, with which the laminae fibrosae of the valve leaflets become continuous. Variations in different parts of the annulus are of the greatest functional importance, allowing major changes in shape and dimensions at different stages of the cardiac cycle; this dynamism ensures optimal efficiency of both the true valvular actions of the mitral complex, and its equally important role in controlling the inflow/outflow patterns of blood passage through the left ventricle. It may also be noted that structural variations are not only related to different locations around the periphery of the valve, but that these are accentuated in some specimens, particularly with advancing years.

The constitution of the mitral annulus is illustrated in **6**.19B. It consists of the inner aspects of parts of the left and right fibrous trigones, and extending from the latter the anterior and posterior fila coronaria—long, tapering, fibrous, whip-like subendocardial tendons which partially encircle the valve orifice at the atrioventricular junction. Between the tips of the fila the atrial and ventricular myocardia are separated by a more tenuous sheet of deformable fibro-elastic sulcal connective tissue. Spanning the zone between the trigones, the lamina fibrosa of the central part of the anterior mitral leaflet is a continuation of the fibrous *subaortic curtain* (*intervalvar septum*) which descends from the adjacent halves of the left posterior (left coronary) and right posterior (non-coronary) cusp regions of the aortic valve annulus; there is no specialized thickening of the curtain where it passes into the base of the free valve leaflet. (It should perhaps be stated that since the line of connective tissue attachment of the valve consists of a malleable fibrous sheet, two dense collagenous masses, two tapering 'tendons', and delicate fibro-areolar tissue at different locations, the official term annulus fibrosus seems singularly inappropriate; however, its use is so deeply engrained in anatomical and cardiological literature that it is retained in this account.)

The *mitral valve leaflets*, since the earliest descriptions, have been widely held as two in number, and hence the name *bicuspid valve* as a more explicit but less picturesque alternative to the familiar term mitral valve. However, considerable confusion, controversy, and difficulties in quantitation have arisen because some authors described occasional or frequent occurrence of small accessory leaflets between the two major ones. These problems have now been resolved by an excellent quantitative study using strict criteria to define the leaflet areas and their subdivisions (for details and a bibliographic review *see* Lam *et al.* 1970; and Ranganathan *et al.* 1970). It is now proposed that the mitral valve "consists of a continuous veil inserted around the entire circumference of the mitral orifice" (Harken *et al.* 1952); the free edge of the veil shows several indentations. Two of the latter are deep and regularly positioned which receive the insertions of unique fan-shaped commissural chordae tendineae (*vide infra*); additionally, the tips of the papillary muscles may be used as guides to identify them (Rusted *et al.* 1952). These deep indentations are the *anterolateral* and *posteromedial commissures* and the valvular tissue may therefore be allocated into two commissural areas, and two leaflet areas termed *anterior* and *posterior*. (It should be noted that naming of the tricuspid commissures was derived from the names of their adjacent cusps, whereas the mitral commissures are named according to their overall position. Further, the official terms anterior and posterior for the valve leaflets, whilst having the advantage of simplicity, are rather misleading because of the oblique positioning of the whole valve; as will be indicated below many authors prefer alternative names.) The general anatomy of the mitral valve, opened and laid flat is diagrammed in **6**.21B (after Ranganathan *et al.* 1970).

The *anterior leaflet* (also called the aortic, septal, 'greater', or anteromedial leaflet—Chiechi *et al* 1956) is large, semicircular or triangular, with a free margin which bears few or no indentations. Peripherally, its lamina fibrosa is continuous centrally with the fibrous subaortic curtain, and at the margins of the curtain with the mitral aspect of the right and left fibrous trigones, and beyond these with the substantial trigonal roots of the fila coronaria (**6**.29B). The leaflet presents a deep crescentic opaque *rough zone* which receives the insertions of various types of chordae tendineae (*vide infra*), and the ridge limiting the outer margin of the rough zone indicates the maximal extent of surface contact with the posterior leaflet in full valve closure during ventricular systole; from the rough zone to the valve annulus is a translucent *clear zone*, devoid of chordal insertions, but its lamina fibrosa carries extensions from the chordae inserting into the rough zone. The anterior leaflet possesses no basal zone. It will be appreciated that the anterior leaflet, hinging on its substantial annular attachment, and continuous centrally with the deformable subaortic curtain, is critically placed between the inflow and outflow tracts of the left ventricle, the whole mechanism having been called the *aortic baffle*. During passive filling of the ventricle and during atrial systole, the smooth atrial surface of the leaflet functions as an important surface directing a relatively turbulence-free flow of blood towards the highly trabeculated ventricular body and apex. After the onset of ventricular systole and mitral valve closure, the

ventricular aspect of its clear zone merges into the smooth surface of the subaortic curtain which, together with the remaining fibrous walls of the subvalvular aortic vestibule, form the low-friction boundaries of the terminal part of the outflow tract. The approximate dimensions of the anterior leaflet are—mean vertical height centrally 2·4 cm in males and 2·2 cm in females, mean basal width being 3·6 cm in males and 2·9 cm in females; the mean vertical height of the rough zone is 0·9 cm in males and 0·8 cm in females (these data are derived from Ranganathan *et al.* 1970, who give many further quantitative details and ranges, and also analyse the data of Rusted *et al.* 1952, and Cheichi and Lees 1956; the results are too extensive to be quoted here and the interested reader should consult the original papers).

The *posterior leaflet* (also called the ventricular, mural, 'smaller', or posterolateral leaflet) possesses minor indentations or 'clefts', usually two, in its free border and because for many years there was a lack of precise definition of what features distinguished a major interleaflet commissure from an intraleaflet cleft, much disagreement and confusion existed concerning the territorial extent of the posterior leaflet and the existence, or otherwise, of small accessory leaflets. Lam *et al.* (1969) in a detailed analysis of the chordae tendineae of the mitral valve provided precise criteria for distinguishing commissural chordae (*vide infra*) and showed that the posterior leaflet is best regarded as all the valvular tissue lying posterior to the anterolateral and posteromedial commissures. When defined thus, the posterior leaflet has a wider attachment to the atrioventricular valve annulus than the anterior leaflet (mean values are 5·4 cm in males and 4·3 cm in females). The clefts receive the insertion of characteristic cleft chordae tendineae (*vide infra*) and divide the posterior leaflet into a relatively large *middle scallop*, and smaller *anterolateral commissural* and *posteromedial commissural scallops*. Each scallop bears a crescentic, opaque, rough zone, which receives chordal attachments on its finely serrated margin and ventricular aspect and defines the area of leaflet apposition in full valve closure. From the rough zone to within 2–3 mm of the annular attachment is a translucent, membranous or *clear zone* devoid of chordal insertions, whilst the basal 2–3 mm is thickened, vascularized, and receives the insertions of basal chordae tendineae. The rough zone to clear zone ratio in the anterior leaflet is about 0·6 whilst in the middle scallop of the posterior leaflet it is 1·4; thus a much greater proportion of the posterior leaflet is in apposition with the anterior leaflet during mitral valve closure.

The *chordae tendineae* of the mitral valve have the same general structure and characteristics as those of the right ventricle; false chordae are found irregularly distributed in the left ventricle as in the right, and will not be further considered.

The *true chordae* of the mitral complex may first be divided into *interleaflet* or *commissural chordae* and into varieties of *leaflet chordae*; of the latter those of the anterior leaflet are classified as *rough zone chordae* including specialized *strut chordae*; those of the posterior leaflet include *rough zone chordae*, *cleft chordae*, and *basal chordae*. Most true chordae either divide into a number of branches from a single stem soon after their origin from the tip or apical third of a papillary muscle, or they proceed as single cords only radiating into multiple fine cords immediately before their insertion.

The anterolateral and posteromedial *commissural chordae* arise near the tips of their corresponding papillary muscle as a single stem that branches almost immediately into radiating strands like the struts of a fan and insert into the smooth free margin of the commissure; some pass into the lamina fibrosa of the immediately adjacent leaflet tissue and continue towards the annular attachment. The branches of the posteromedial commissural chorda are longer, thicker and have a wider spread than the anterolateral ones.

Rough zone chordae typically divide into three cords soon after their origin from the papillary muscle; one inserts into the free margin, one beyond the free margin on the ventricular surface of the leaflet at the line of closure, and an intermediate cord inserts between these. Chordae of this type are found in relation to both the posterior and anterior leaflets. Peculiar to the anterior leaflet are, however, two that are much the thickest and strongest tendinous chordae of the mitral valve; they originate from the tips of the anterolateral and posteromedial papillary muscles and insert near the line of valve closure between the '4 & 5 o'clock' positions posteromedially, and between the '7 & 8 o'clock' positions anterolaterally. They are termed *strut chordae* and were present in more than 90 per cent of hearts examined according to Lam *et al.* (1970); in a much earlier publication their zone of attachment was termed the *critical point of tendinous insertion* of the anterior leaflet (Brock 1952).

Cleft chordae are miniature fan-shaped structures, their tiny radial branches attaching to the free margins of the inter-scallop clefts, whilst some deeper branches pass on to the ventricular aspect of the adjacent rough zones.

Basal chordae are confined to the posterior leaflet (most commonly the large middle scallop and one of the two smaller scallops); they arise directly from the mural ventricular myocardium as a single strand which flares into minute branches before insertion into the ventricular aspect of the basal zone of the leaflet. Sometimes the basal chordae are partly or wholly muscular.

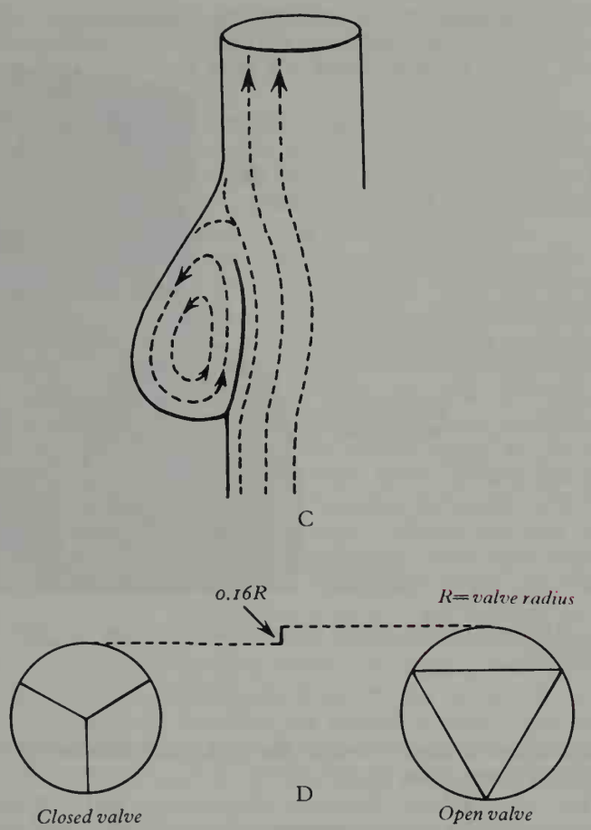
The *papillary muscles* of the left ventricle are two in number and vary considerably in their formation from long and finger-like to short and stubby; occasionally their tips are bifid. The *anterior* (anterolateral) *papillary muscle* arises from the sternocostal mural myocardium and the *posterior* (posteromedial) *papillary muscle* has its base attached to the diaphragmatic wall of the ventricle. Chordae tendineae arise most commonly from the tip and margins of the apical third of each muscle, but occasionally they emerge near its base. The chordae from each muscle diverge and are inserted into corresponding points (i.e. points in close apposition in valve closure) on *both* cusps of the mitral valve.

Opening of the mitral valve at the onset of diastole is an entirely passive but rapid process, the leaflets parting and projecting into the ventricular cavity as the pressure of the left atrial venous blood returning from the lungs exceeds the left ventricular diastolic pressure. Passive ventricular filling proceeds as the atrial blood pours towards the ventricular apex, directed by the pendant anterior leaflet of the mitral valve. With increased filling, however, the valve leaflets begin to float passively towards each other, hinging on their annular attachments, and partially occluding the ventricular inflow orifice. Atrial systole now supervenes, directing a powerful jet of blood towards the ventricular apex and causing a transient re-opening of the valve. As the atrial jet-stream approaches maximal ventricular filling, the valve leaflets again float rapidly towards each other; ventricular systole now ensues commencing with papillary muscle and followed, extremely rapidly, by general mural and septal contraction. Coordinated papillary activity causes a progressive increase in tension in the chordae tendineae and coaptation of corresponding points on the opposing valve cusps. With general mural and septal myocardial excitation and contraction left ventricular blood pressure rises with great speed (**6**.35); the valve leaflets 'balloon' towards the atrial cavity and the atrial aspect of their rough zones come into tight apposition and maximal areal contact. Precisely graded continuing papillary contraction and increasing tension in the various grades of chordae tendinease prevents retropulsion of the leaflets into the atrial cavity, and maintains valvular competence. The essentially *biphasic* nature of mitral valve closure just described is vividly demonstrated in a normal echocardiogram recorded in an appropriate plane (**6**.28). With the fast drop in ventricular pressure following the end of the ejection phase of systole and the onset of diastole, the valve leaflets part and the next cycle of ventricular filling restarts.

It is assumed that, despite slight differences in time scale, and marked differences in pressure profiles, the general forms of valve opening and closure are similar in the tricuspid valve.

In addition to the foregoing it should be noted that both atrioventricular orifices and their valves undergo large changes in position, form and surface area at different stages of the cardiac cycle. Thus, both valves move anteriorly and to the left during systole and retrace this path during diastole. Also during systole the mitral valve (for which the data are more complete) reduces its orificial (annular) *area* by as much as 40 per cent; furthermore, its

shape changes from the circular profile characteristic of diastole to a *crescentic form* at the height of systole. The annular attachment of the anterior leaflet provides the concavity of the crescent, whilst the attachment of the posterior leaflet, although remaining convex, contracts towards the former.

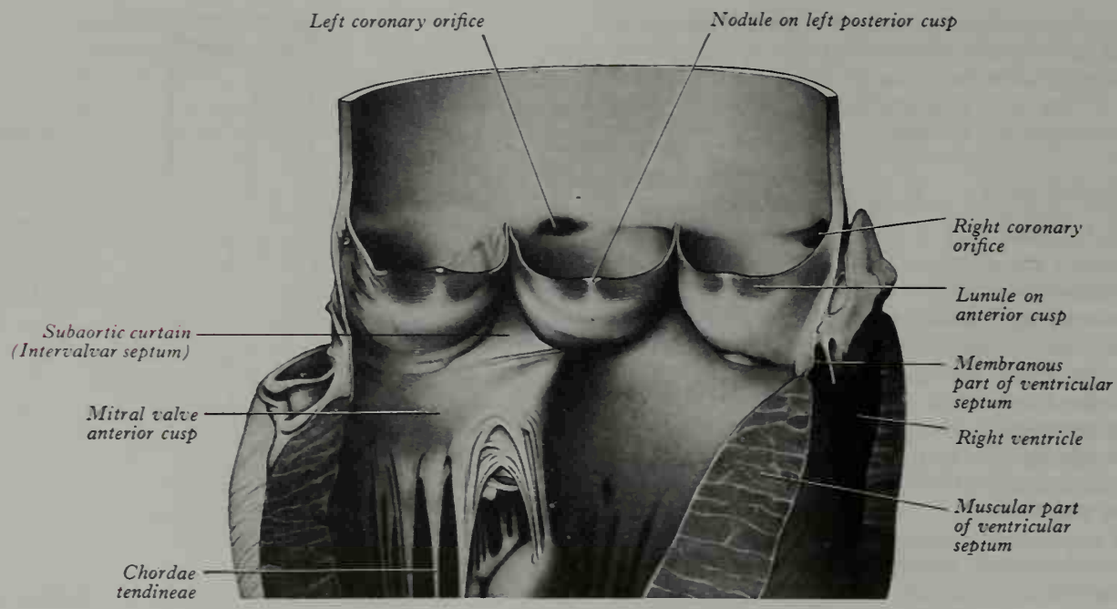


THE AORTIC VALVE (6.21A, B, 22, 29B)

The smooth-walled outflow tract of the left ventricle, the aortic vestibule, terminates at the aortic orifice and its associated aortic valve, the attached margins of which continue into the root of the aorta. Although considerably stouter in its general construction, the aortic valve has many structural features in common with the pulmonary valve (p. 648), consisting therefore of a fibrous 'annulus' of complex form, three semilunar cusps or valvules attached basally to the annulus, and three dilatations of the aortic wall termed aortic sinuses corresponding to the cusps.

Because of the complex form of the annulus, it is difficult to define a 'plane' in which the aortic valve lies (some authorities choose the apical intercuspid commissures as reference points, whilst others prefer the deepest and most proximal points on the attached margins of the cusps, i.e. the three nadirs of the fibrous annulus). Nevertheless, in general the valve faces superiorly, to the right, and slightly anteriorly; in overall position it lies anterosuperior and slightly to the right of the mitral atrioventricular orifice; in overall shape it approximates to a truncated cone or *frustum*.

The *aortic fibrous annulus* consists of three almost semicircular condensations of collagen forming three 'scallops' which are so arranged that they encircle the vestibulo-aortic junction in the form of a three-pronged coronet; the 'prongs' point distally and apically form the fibrous framework of the commissural regions between adjacent cusps (*vide infra* and **6**.29B). The luminal aspect of each scallop fuses with the cuspid lamina fibrosa through the attached border of a semilunar cusp. The proximal aspect of the scallops are thickened at their nadirs (*see* p. 657 for further details) whilst the triangular intervals between the proximal aspects of their ascending limbs are filled, and fuse with, extensions of the largely fibrous walls of the aortic vestibule. As will be noted further below, specialized regions of the latter include the subaortic curtain (intervalvar septum) and part of the *pars membranacea septi*. The distal deeply concave aspect of each scallop forms the lower limit of and continues into the fibro-elastic wall of an aortic sinus. Some observers maintain that although largely fibrous, the walls of the aortic vestibule contain myocardial strands, some of which approach and cross the line of the fibrous annulus, continuing as fine irregular strands into the walls of the sinuses.



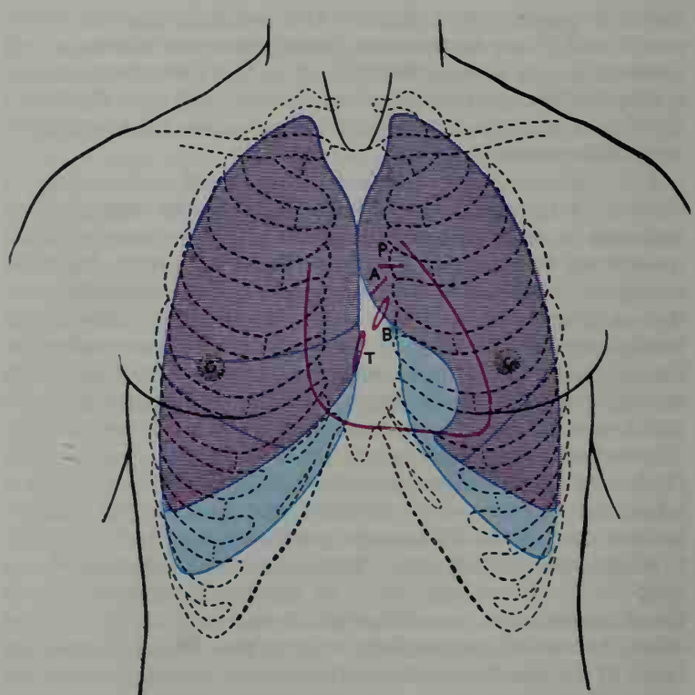
The *semilunar cusps* or *valvules* of the aortic valve, three in number (**6**.22), are again reduplications of the endocardium enclosing a central lamina fibrosa which shows thickened specializations in certain locations. With the valve in the half-open position, each cusp would cover the surface of slightly more than a quarter of a sphere (or ellipsoid), the approximate hemisphere (or hemi-ellipsoid) being completed by the wall of the corresponding aortic sinus. Each cusp possesses a thickened basal attached border which is deeply concave when viewed from the aortic aspect, and an approximately horizontal free border. Throughout most of its extent the latter shows only a slight thickening of its fibrous core, but at the mid-point occurs a substantial aggregation of fibrous tissue forming the valvular *nodule* (Arantii); fine collagenous bundles radiate from the nodule to the attached border where the basal fibrous thickening blends with the corresponding scallop of the fibrous annulus. At the apical commissures, few collagen fibres pass between the adjacent cusps, but strong longitudinal fascicles pass into the ascending limbs of the annular fibrous scallops (*see* p. 657 and **6**.29B). On each side of the nodule and its collagenous radiation the lamina fibrosa is tenuous, and in these regions, the *lunules* of the cusp, the valvular tissue is thin, translucent, and occasionally fenestrated. The aortic surface of each cusp is rougher than its ventricular (outflow) surface and it has been shown that the endocardial cells are elongated with respect to the direction of blood flow (Clarke and Fink 1974).

6.21C, D. C. A diagram of the vortices formed within an aortic sinus during the ejection phase of left ventricular systole. Note the position of the valve cusp and sinus wall. D. *Left:* the general position of the apposed valve cusps during diastolic closure of the aortic (and pulmonary) valve. *Right:* the open position of the aortic (and pulmonary) valve during the ejection phase of ventricular systole. Note the increase in diameter of the arterial trunk root at the level of the valve commissures and the *triangular* form of the open valve. Consult text for further discussion.

It is unfortunate and the source of considerable confusion, that *three* different systems of naming the aortic cusps are currently in use. The official names advanced by the *Nomina Anatomica* (1977) refer to the embryonic/fetal positions of the cusps before full and definitive cardiac rotation has occurred; hence they are termed posterior, right and left. In this volume it has been preferred to retain the widely used system which refers to the approximate positions of the cusps in the mature heart and in which they are named the *anterior*, *left posterior*, and *right posterior*, corresponding names applying also to the sinuses. However, in clinical literature the practice is widespread of basing the terminology on the relation of cusps and sinuses to the origins of the coronary arteries; thus the anterior is termed *right coronary*, the left posterior the *left coronary*, and the right posterior the *non-coronary*. (In the present volume the mature positional names are often followed by the clinical terms in parenthesis.)

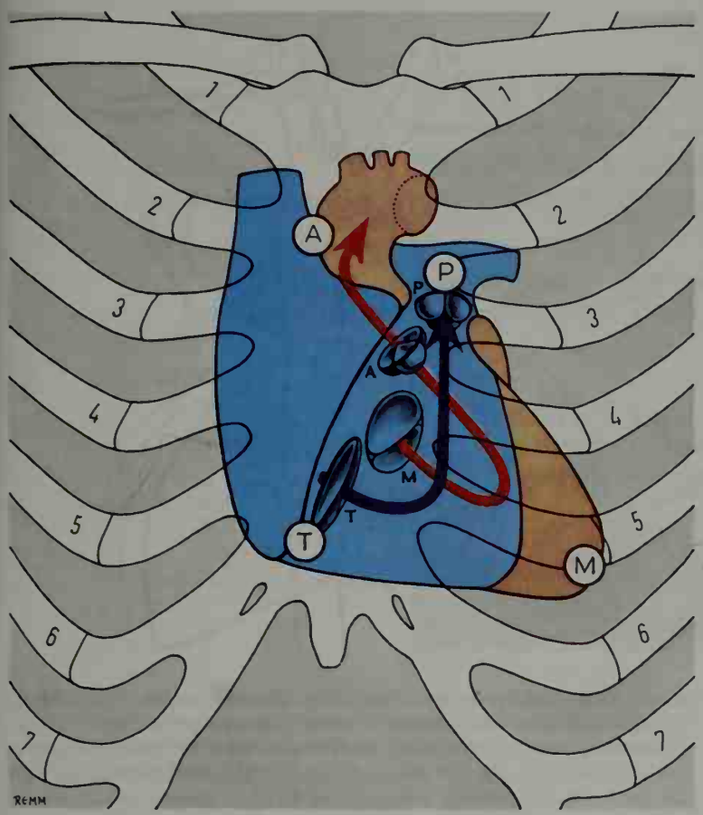
The *aortic sinuses* (of Valsalva) are more prominent than those of the pulmonary trunk, but similarly, are dilatations of the aortic root wall above the attached margin of each cusp. The upper margin of each sinus reaches considerably beyond the level of the free border of the cusp and is limited by a well-defined circumferential *supravalvar ridge* when viewed from the luminal aspect (**6**.18A). The ostia of the coronary arteries usually open near this ridge from the *upper* part of their sinus of origin, the ostium of the left artery often being a little lower than the right (*see* p. 669). The walls of the sinuses are largely collagenous near the fibrous annulus but the proportion of collagen diminishes and the amount of lamellated elastic tissue increases in the upper part of the sinus; as mentioned above, strands of myocardium may extend into this fibro-elastic wall. At mid-sinus level its wall is about one-half the thickness of that of the general wall of the supravalvar aorta, and less than one-quarter the thickness of the supravalvar ridge; also at this level the mean luminal diameter of

6.22 The aortic orifice opened from the front to show the cusps of the aortic valve.



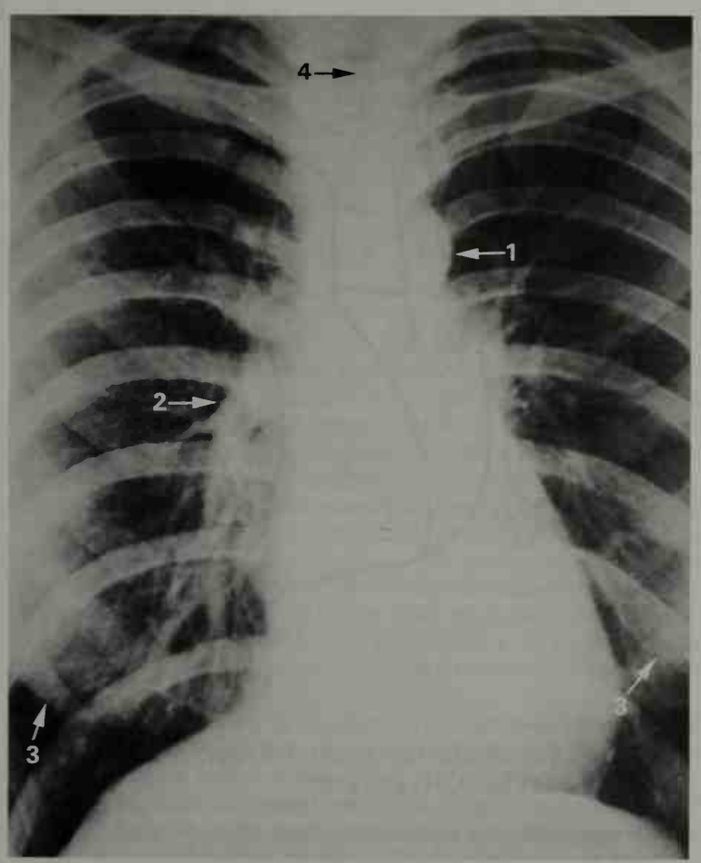
the aortic root is almost double that of the commencement of the ascending aorta (Reid 1970).

The topographical features, dimensions, and mechanical properties of both cusps and sinuses are widely considered to be of great functional significance in valve opening and effective closure at appropriate points during the cardiac cycle. Throughout diastole the aortic valve is closed, maintaining the aortic column of blood which is at high but slowly diminishing pressure (**6**.33); each cusp and its associated sinus form a roughly hemispherical chamber, the three nodules are in tight apposition centrally, and the free borders and lunular parts of adjacent half-cusps are in tight apposition on their ventricular aspects. Thus, viewed from the aortic aspect the closed valve has a tri-radiate appearance, three pairs of closely compressed lunular segments passing in straight lines out to the peripherally sited commissures. With the onset of ventricular systole and full mitral valve closure, left ventricular pressure rises rapidly and when this exceeds aortic pressure, the aortic valve cusps open passively. The fibrous wall of the sinuses nearest to the ventricular aortic vestibule (i.e. at the nadirs of the annular fibrous scallops) is relatively dense, inextensible, and undergoes little dimensional change. However, in the upper parts of the sinuses, at the level of the valve commissures, the sinus wall is fibro-elastic and deformable; under the influence of full left ventricular ejection pressure, the *radius* of this part increases some 16 per cent in systole compared with its dimension in diastole. As a result, the commissures move apart and the fully open aortic orifice is *triangular*, the free margins of the cusps passing in virtually straight lines between the commissures. It must, however, be emphasized again that the aortic cusps do *not* flatten against the sinus walls, even at the height of ventricular systole, and it is considered that this cuspid position together with the shape of the sinus wall are important factors as a prelude to efficient valve closure. During systolic ventricular ejection most of the blood passes directly into the ascending aorta, but a proportion is thought to enter each sinus centrally forming vortices within the sinus and then leaving through its marginal angles. The vortices help to maintain the triangular 'mid-position' of the cusps throughout most of ventricular systole, and probably initiate the floating together of the cusps at the extreme end of systole; tight approximation and full valve closure ensues with the rapid drop of ventricular pressure accompanying the onset of diastole—the commissures move together, the nodules aggregate centrally, and the valve reassumes its tri-radiate form. It may be noted that experimental results indicate that about 4 per cent of the ejected blood regurgitates through a valve possessing normal aortic sinuses, whereas 23 per cent regurgitation occurs through a valve without sinuses (Bellhouse 1968). Additionally, it has been suggested that normal aortic sinuses promote a non-turbulent flow of blood into the ostia of the coronary arteries.



It is generally thought that considerations similar to those just outlined apply also to the opening and closure of the pulmonary valve even though the events are more leisurely, the pressure profiles much less extreme (**6**.35), and the structure of the valve complex more delicate in all its features.

CARDIAC SURFACE ANATOMY (**6**.23, 24)



It should be emphasized that the surface projection data given apply to an average adult, and that they are considerably modified

6.23 The front of the thorax, showing the surface relations of the bones, lungs (purple), pleurae (blue), and heart (red outline).
A = Orifice of aorta.
B = Left atrioventricular (mitral) orifice.
P = Orifice of pulmonary trunk.
T = Right atrioventricular (tricuspid) orifice.

6.24 A diagram illustrating the relation of the sternocostal surface and valves of the heart to the thoracic cage. The right heart is blue, the arrow denoting the inflow and outflow channels of the right ventricle; the left heart is treated similarly in red. The positions, planes and relative sizes of the cardiac valves are shown. The position of the letters A, P, T and M indicated the aortic, pulmonary, tricuspid and mitral *auscultation* areas of clinical practice.

6.25 Radiograph of chest, postero-anterior view. Adult female. Note the difference in level of the right and left halves of the diaphragm. 1. Aortic 'knuckle'. 2. Pulmonary vessels of right side. 3. Edge of shadow caused by breast. 4. Position of trachea.

by age, sex, bodily size and proportions, by respiration and by position. Moreover, the surface projections of the valves do *not correspond* to the best sites for *auscultation* of valvar sounds (**6**.24).

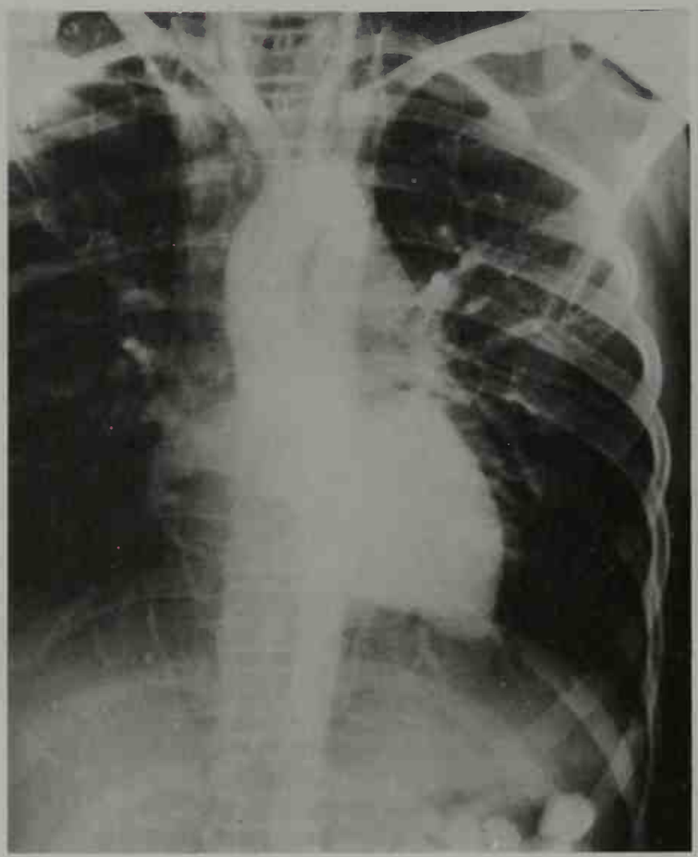
The *apex* of the heart almost corresponds in position to the *apex beat*, which can usually be seen and can always be felt a little below and medial to the left (male) nipple. As a rule it is in the fifth intercostal space, slightly medial to the mid-clavicular line, or about 9 cm from the midline in an average adult male.

The sternocostal surface of the heart can be projected on to the anterior chest wall and forms an irregular, quadrangular area. The *right border* (**6**.23, 24) corresponds to a line drawn from the upper border of the right third costal cartilage, 1·2 cm from the margin of the sternum, downwards to the sixth costal cartilage. This line is gently convex to the right and is at its maximum distance from the median plane—about 3–4 cm—in the fourth intercostal space. It represents the lateral aspect of the right atrium. The continuation of this line in an upward direction, marks the lateral border of the superior vena cava and, in a downward direction the lateral border of the inferior vena cava.

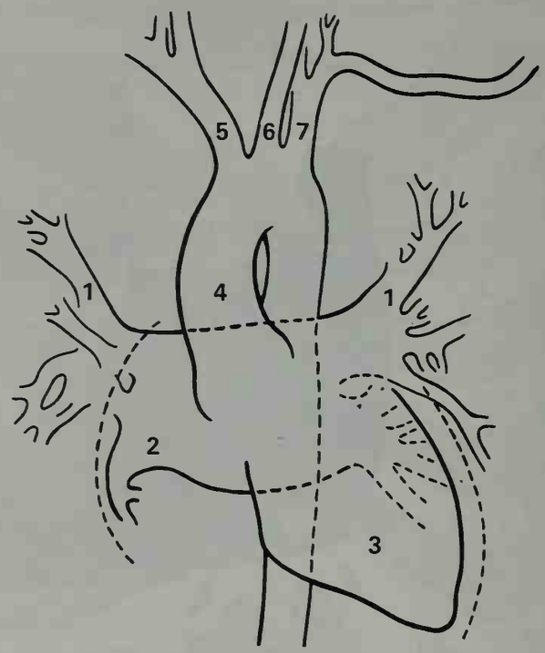
The *lower border* of the cardiac projection can be represented by a line joining the lower end of the right border to the apex beat; it passes through the xiphisternal joint, and corresponds for the most part to the lower margin of the right ventricle. The *left border* is represented by a line drawn from the apex beat upwards and medially to a point on the lower border of the left second costal cartilage, 1·2 cm from the sternal margin. This line is convex upwards and to the left; with the exception of its upper part, which demarcates the left auricle, it corresponds to the left ventricle.

The four-sided area may be completed by a line which joins the upper ends of the right and left borders, and corresponds roughly to the upper limits of the atria. The left and right borders can be mapped out by heavy percussion.

The *pulmonary orifice* lies partly behind the upper border of the left third costal cartilage and partly behind the sternum. It can be represented by a horizontal line, 2·5 cm long. Two parallel lines, drawn from the extremities of this line upwards to reach the left second costal cartilage, map out the *pulmonary trunk*.

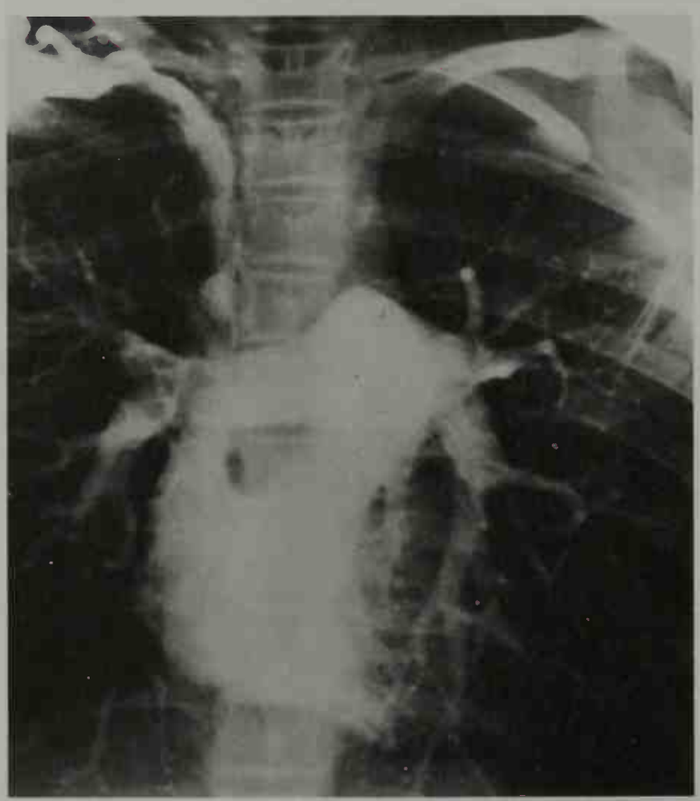


The *aortic orifice* lies below and a little to the right of the pulmonary orifice. It corresponds to a line, 2·5 cm long, drawn from the medial end of the left third intercostal space downwards and to the right. Two parallel lines, drawn from the extremities of this line upwards and to the right as far as the right half of the sternal angle, outline the *ascending aorta*.



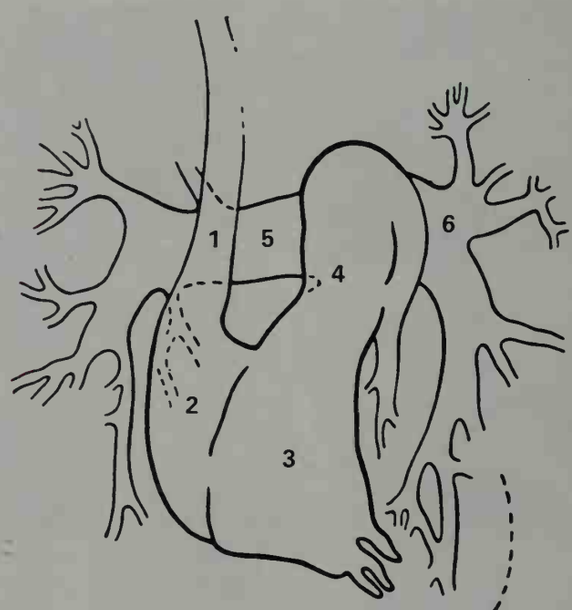
The *right atrioventricular*, or *tricuspid*, *orifice* can be represented by a line, 4 cm long, commencing in the median plane opposite the fourth costal cartilage, and passing downwards and slightly to the right. The centre of this line should be opposite the middle of the fourth intercostal space. The *left atrioventricular*, or *mitral*, *orifice* lies behind the left half of the sternum opposite the fourth costal cartilage and can be represented by a line, 3 cm long, passing downwards and to the right.

The *area of superficial cardiac dullness* is a roughly triangular area, which can be mapped out by light percussion, and corresponds to the portion of the heart which is not covered with lung (p. 1254).

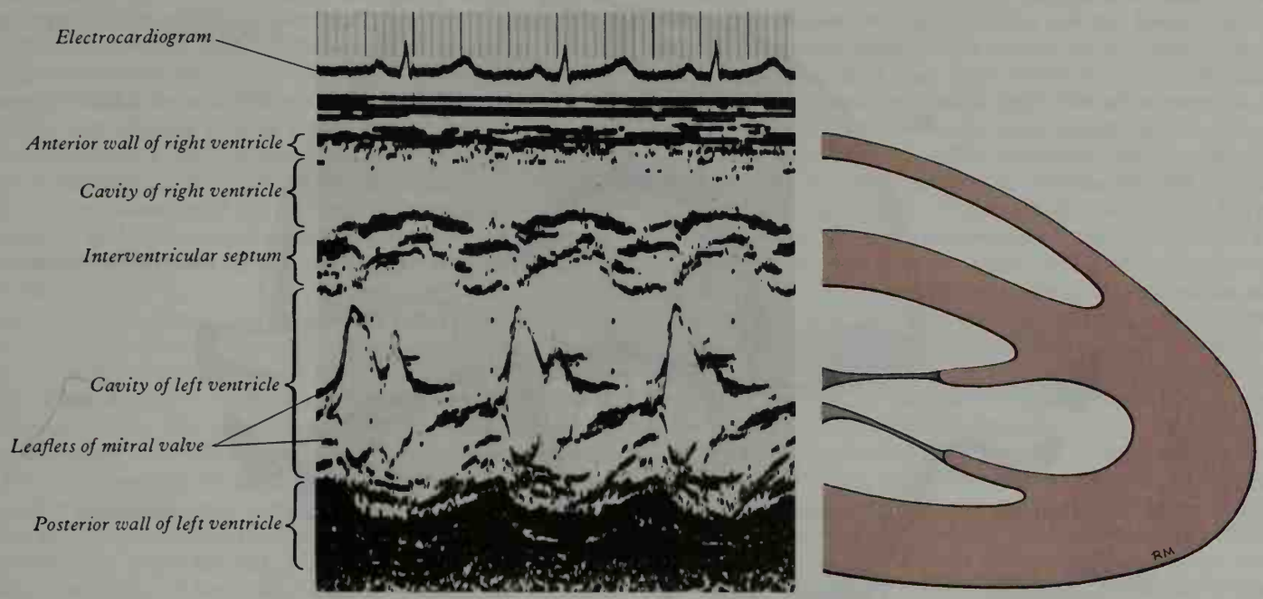


RADIOLOGICAL APPEARANCE OF THE HEART (**6**.25, 26, 27)

The heart, being full of blood, casts a shadow, occupying the lower part of the mediastinum, which is in sharp contrast with the clearer areas occupied by the air-filled lungs. The pulsatile movements of this shadow are evident on screening. In full inspiration the shadow of the apex is clear of the diaphragm, and presents, in radiographs, a rather blurred outline due to its movement. The shadow of the convex right border of the heart is continuous above and below with those of the superior and inferior venae cavae. Owing to the attachment of the pericardium to the diaphragm, during inspiration the heart becomes longer and narrower and during expiration shorter and broader. The shape of the heart also varies with the bodily proportions and attitude of the individual (*see* p. 1321). In lateral radiographs the



6.26 Angiocardiogram (provided by Dr. Frances Gardner), showing the left side of the heart in a child of 11 years; anteroposterior view. 1. Upper pulmonary vein. 2. Left atrium. (Note that owing to the great obliquity of the atrial septum, the left atrium extends to the right behind the right atrium.) 3. Left ventricle. 4. Ascending aorta. 5. Brachiocephalic trunk. 6. Left common carotid artery. 7. Left subclavian artery. (The arms of the patient are raised above the head and, as a result, the distal end of the artery passes upwards.)

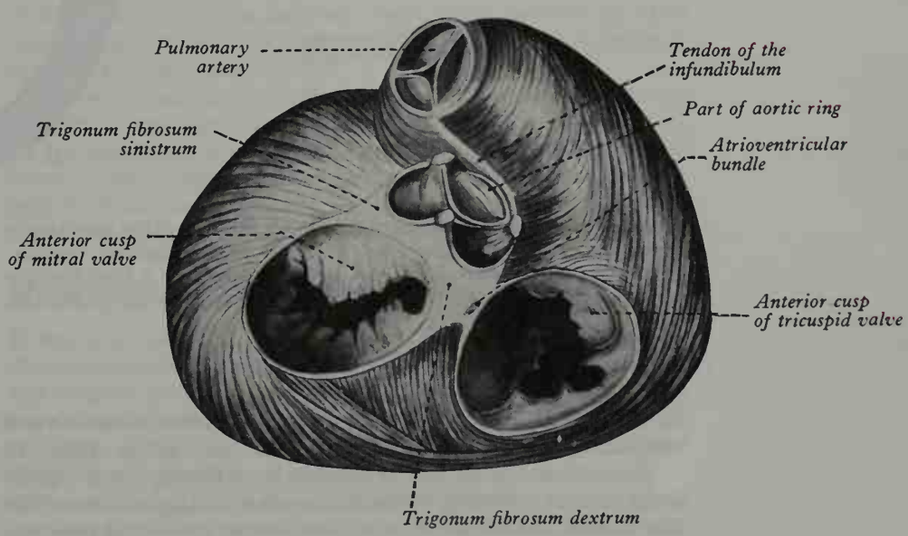


6.27 Angiocardiogram (provided by Dr. Frances Gardner), showing the right side of the heart in a child of 12 years; anteroposterior view. 1. Superior vena cava. 2. Right atrium. 3. Right ventricle. 4. Pulmonary trunk. 5. Right pulmonary artery. 6. Left pulmonary artery.

retrocardiac space may be recognized as a translucent area between the heart and the vertebral column. This space is occupied by the descending aorta and the oesophagus (**8**.90). For a detailed study of the cavities of the heart and the large blood vessels the method of angiocardiography can be used (Robb and Steinberg 1939, Gardner 1949). A suitable contrast medium miscible with blood is injected intravenously and the course of the intravascular injection is followed in serial X-ray exposures, usually in anteroposterior or oblique views (**6**.26, 27).

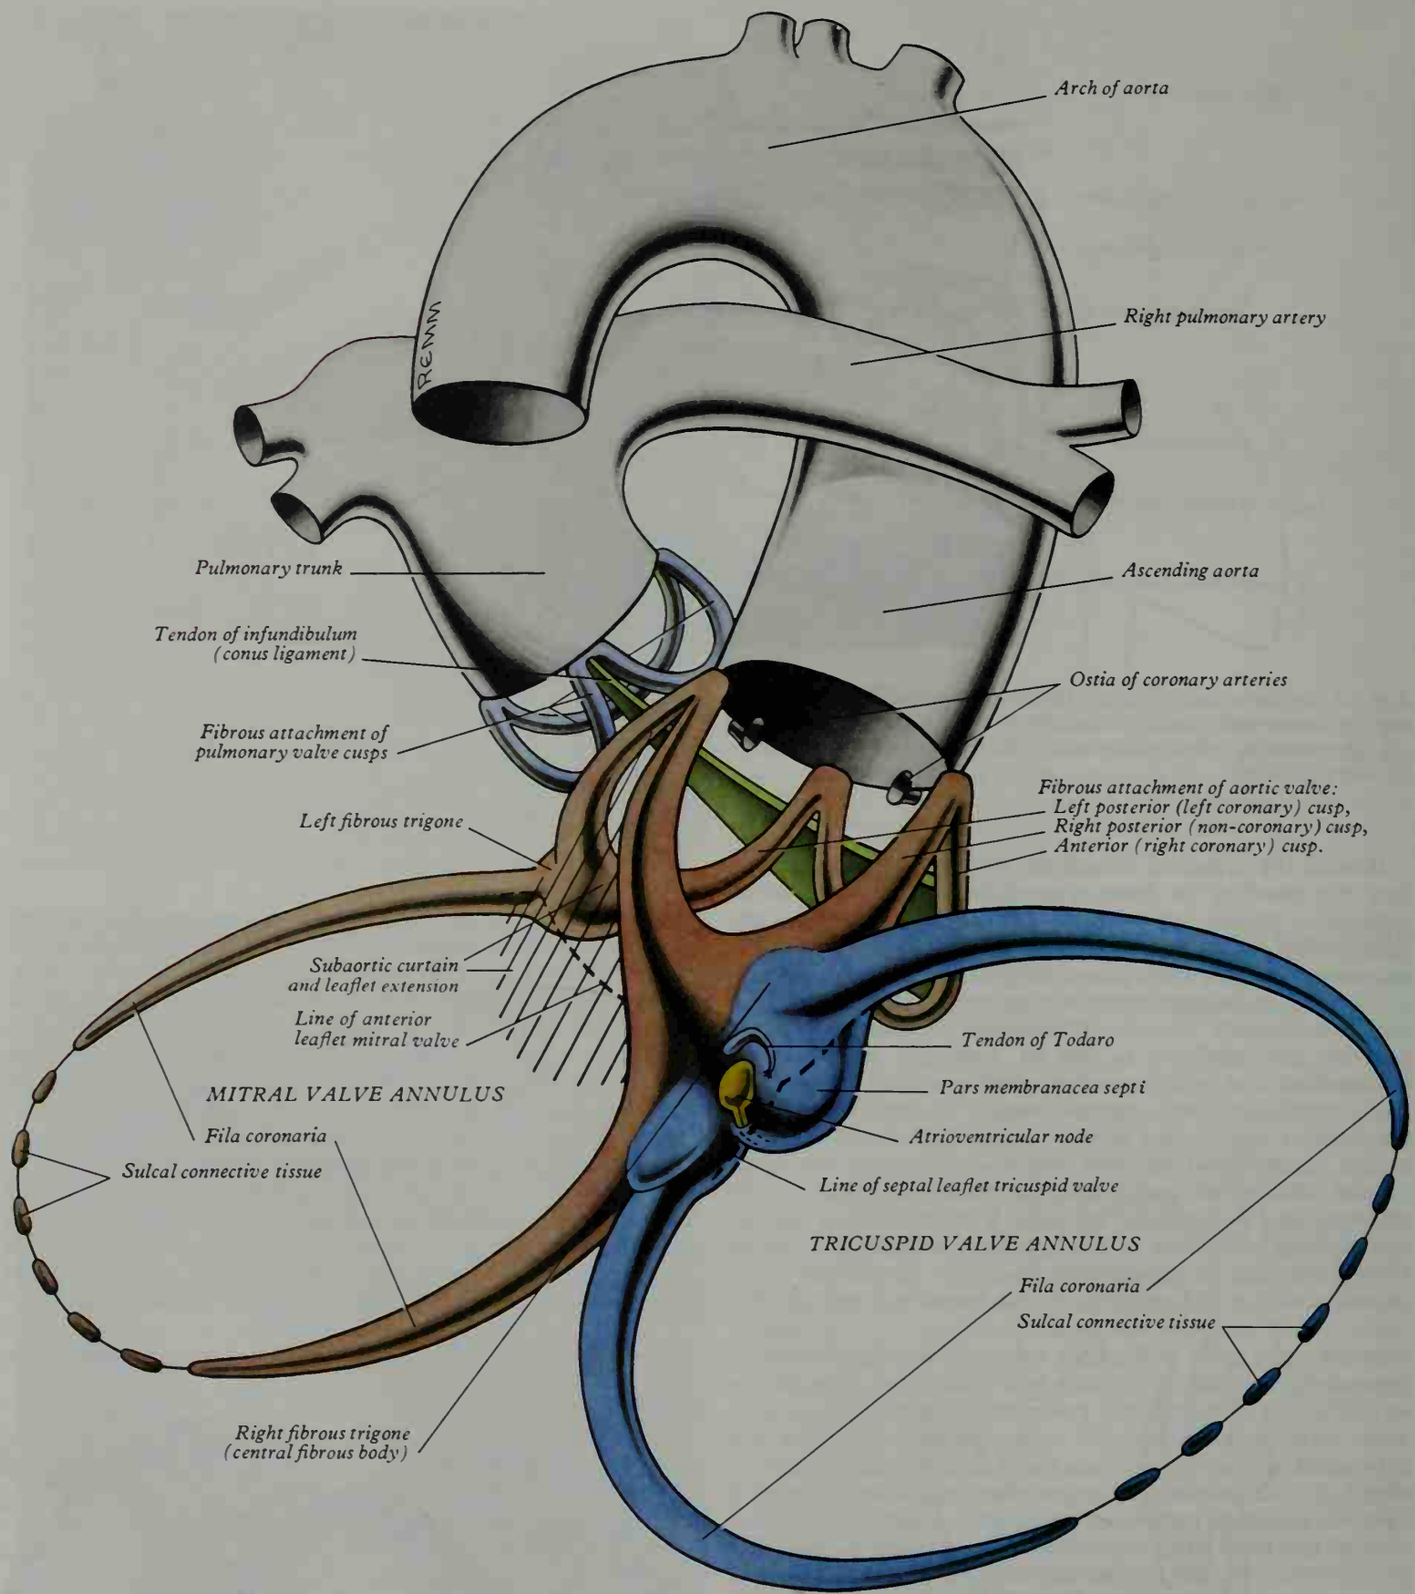
CARDIAC CONNECTIVE TISSUES AND FIBROUS SKELETON (**6**.29A, B)

From epicardium to endocardium and from the orifices of the entrant great veins to the roots of the outflowing great arterial trunks, the intercellular crevices, intra- and inter-tissue planes, between the essential contractile and conducting elements, are everywhere permeated by connective tissue, but this varies greatly in its organization and constitution in different locations.



6.28 A standard echocardiogram of the heart recorded from the anterior aspect as increasingly used in clinical practice. The outline diagram shows the corresponding reflecting surfaces. Note the biphasic closure of the mitral valve leaflets.

Beneath the squamous cells of the serous visceral epicardium lies, over much of the heart, a fine layer of subserous areolar connective tissue; but this accumulates adipose cells, the *subepicardial fat*, often considerable in quantity and gradually increasing with age, which is concentrated along the acute margin of the heart, in the coronary sulcus, interventricular grooves and their side channels. The principal coronary vessels and their main branches are embedded in this fat. Similarly, the squamous endocardium lies on a fine subendocardial areolar tissue which has a particularly well marked content of elastic fibre. The fibrocellular components of these subepicardial and subendocardial layers blend on their mural aspects with the intercellular endomysial and perimysial connective tissue of the myocardium. Each cardiac myocyte is invested by a delicate endomysium consisting of fine reticulin, collagen and elastin fibres embedded in ground substance; this investment is, of course, absent at the specialized desmosomal and gap junction contacts that constitute the intercalated discs (p. 517). Similar considerations apply to Purkinje myocytes and their extensive intercellular contacts. It is widely held that cardiac myocytes are structurally and functionally polarized, forming tracts of cells, with interconnexions laterally with adjacent tracts, and that substantial aggregations of these tracts form bundles, strands or sheets of macroscopic proportions that show a high degree of complex geometric patterning (*see* p. 661). Further, it has been claimed that these larger myocardial aggregates are 'surrounded' or 'separated' by, and perhaps attached to, stronger perimysial condensations of connective tissue. However, much detailed research will still be needed before a comprehensive view of the three-dimensional array of tracts and aggregations of cardiac myocytes becomes available, and this applies even more strongly to the disposition and properties of their associated connective tissues.



Lying approximately in the plane of the coronary sulcus, i.e. at the 'ventricular base' of the heart, and intimately related to the atrioventricular inflow orifices and the arterial trunk outflow orifices and their associated valves, is a complex framework of dense collagen with membranous, tendinous, and fibro-areolar extensions, the whole being sufficiently distinct to be termed the *fibrous skeleton of the heart*. (For early literature on this topic consult Wolff 1781, Henle 1876, Mall 1911, and Walmsley 1929, an excellent modern survey is provided by Walmsley and Watson 1978; for a particularly penetrating structural and functional analysis *see* Zimmerman 1959, Zimmerman and Bailey 1962, and Zimmerman 1966.)

It will have been apparent in the previous pages that the four cardiac valves in fact depart considerably from a single plane, and that the fibrous skeleton is a complicated, deformable, three-dimensional *continuum*. Thus, study (and illustration) of a single section near the ventricular base of the heart (**6.29A**) provides incomplete data, and led some of the earlier anatomists to introduce relatively simple two-dimensional terms such as 'trigones' and 'annuli' which are, in some respects, misleading if taken too literally. The terms, however, are officially recognized and in such widespread use that they will be retained in the present account, but wherever possible, alternatives and additions to the terminology will be provided. Further difficulties are encountered when attempts are made to illustrate such a system, but it is hoped that figure **6.29B** will assist the reader in understanding its main features and interrelationships.

As noted previously, the annuli of the mitral and tricuspid valves are almost coplanar and at 45° to the sagittal plane with

6.29A The base of the ventricles, after removal of the atria and the pericardium. (From Quain's *Elements of Anatomy*, vol. iv, part iii. *The Heart*, by T. Walmsley, 1929.) Contrast with **6.29B**.

6.29B The principal elements of the fibrous skeleton of the heart: *red*—mitral and aortic 'annuli'; *blue*—tricuspid and pulmonary 'annuli'; *green*—tendon of the infundibulum. For clarity the view is from the *right posterosuperior aspect*. Note that due to perspective the pulmonary annulus *appears* smaller than the aortic annulus, whereas, in fact, the reverse obtains. Consult text for an extended discussion. Based in part on the work of Zimmerman and Bailey (1962) and Zimmerman (1966).

an inclination such that they face anterolaterally to the left and also somewhat inferiorly, i.e. towards the cardiac apex. In contrast the aortic valve faces superiorly, to the right and slightly anteriorly; as a whole it lies anterosuperior and to the right of the mitral orifice. Despite these differences in plane and position, however, these *three* valvar orifices, mitral, tricuspid and aortic, are *intimately interconnected* through the medium of their basal collagenous framework. In contrast, the pulmonary valve is considerably removed from the other three, being placed anterior, superior, and virtually at right angles to the aortic valve, its only connexion with the latter being through the relatively lengthy, deformable tendon of the conus arteriosus (infundibulum).

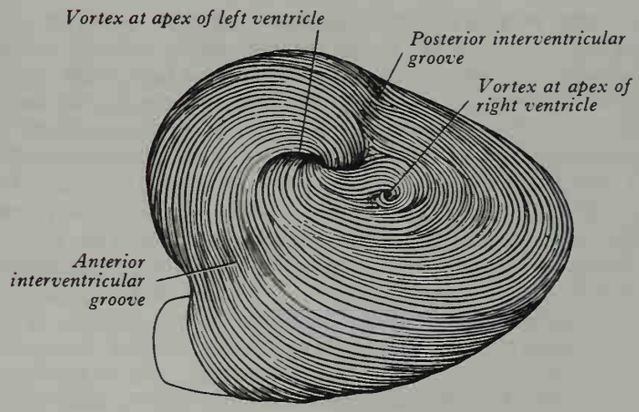
The essential functions of the fibrous skeleton are: (1) to ensure electrophysiological discontinuity between atrial and ventricular myocardium except via the specialized conducting tissues; (2) to provide a strong mechanical attachment for the ventricular

myocardium, and a more tenuous one for the atrial myocardium; (3) to maintain the overall position of the heart within the fibrous pericardium; (4) to establish a stable but dynamically deformable base for the attachments of the fibrous cores of the valve leaflets.

It is apposite to start with a consideration of the specializations of the aortic annulus because it is centrally placed, interconnected with all the surrounding fibrous structures, and the aortic root constantly supports a high-pressure column of blood. Furthermore, it is exposed to the incessant bombardment of the full systolic ejection pressure of the left ventricle with each cardiac cycle, which, as Mall pointed out, without such stout fibrous intermediaries would undoubtedly tear the arterial trunk from the ventricular chamber.

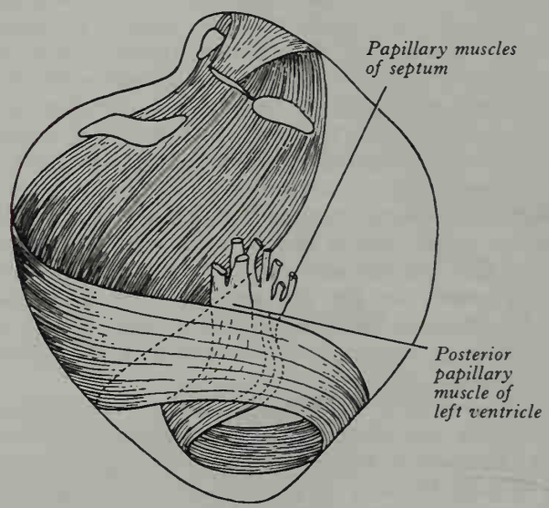
The *aortic fibrous annulus* has been briefly described previously (p. 651); it is constituted by the coaptation of three fibrous scallops which together take the form of a simple three-pronged 'coronet'. Thus, reference to illustration **6**.29B will make it clear that each scallop has two lateral 'high points' or zeniths, and a central 'low point', or nadir, each with its particular specialization. The *distal margin* of each scallop merges with the fibro-elastic wall of an aortic sinus; some myocardial strands have been described as intermixed with the fibro-elastic tissue, and near the annulus collagen predominates but is gradually replaced by increasing quantities of lamellated elastic tissue more distally. The *luminal aspect* of each scallop blends with the lamina fibrosa of a valve cusp or valvule. Adjacent *high points* meet and fuse, with some interchange of collagen fasciculi at the three *intercuspid commissures*. The latter do not reach the upper limit of the sinuses which, as indicated, is marked by a circumferential thickening of the aortic wall, the *supravalvar ridge*. Between the commissures the walls of the sinuses are quite elastic, allowing the commissures to retreat from each other, with concomitant changes in the shape and disposition of the cusps in systolic valve opening, and the converse of these movements in diastolic closure. The *nadirs* of the three scallops show collagenous thickenings to very different degrees. The least prominent is that of the anterior (right coronary) cusp, but its margins blend with the aortic end of the tendon of the infundibulum (*vide infra*). The nadir of the left posterior (left coronary) cusp is thickened to an intermediate extent, and because of its appearance in section in the plane of the atrioventricular valves, it is termed the *left fibrous trigone*. It provides an attachment for part of the anterior leaflet of the mitral valve, and posterolaterally to the left it continues as one of the (mitral) whip-like, tapering, collagenous bundles (the *fila coronaria* of Henle) which partially encircle the atrioventricular orifices. The nadir of the right posterior (non-coronary) scallop is the most massively developed; because of its appearance in section the earlier anatomists termed it the *right fibrous trigone*. In the adult heart it is a dense irregularly ellipsoidal mass about 20 × 10 × 5 mm which provides powerful structural and functional links between the aortic, mitral and tricuspid orifices, and in accord with its site and multiple circumvalvar extensions, it is now termed by many authors the *central fibrous body* of the heart. It continues into the second filum coronarium of the mitral orifice, and provides the base for both fila coronaria of the tricuspid orifice. Anteriorly the central body blends with the *pars membranacea septi* (*vide infra*); posterosuperiorly the *tendon of Todaro*, a palpable subendocardial bundle of collagen about 1 mm in diameter extends into the right atrial wall curving across the *torus aorticus* (p. 644) towards the medial extremity of the valve of the inferior vena cava where its identity is lost. The tendon is one of the boundaries of the *triangle of Koch* (p. 644, **6**.18A) and provides an important surgical guide to the position of the atrioventricular node.

The *proximal* (i.e. ventricular) *aspect* of the triple scalloped fibrous condensation which constitutes the aortic annulus, presents three roughly triangular areas, the *subaortic spans* (*see* Zimmerman 1959; Zimmerman and Bailey 1962). The spans, originally termed *spatia intervalvularia* by Henle (1876), occupy the intervals between adjacent sinuses of Valsalva and their triangular apices correspond to the intercuspid commissures; their walls either consist of collagen, or admixed muscle strands and fibro-elastic tissue, and they encompass the immediately subvalvar recesses of the aortic vestibule. The interval between the right posterior (non-coronary) and left posterior (left coronary) sinuses is filled with the deformable *subaortic curtain* (*intervalvar septum*), which continues into the base of the central part of the anterior leaflet of the mitral valve; down to the leaflet base it is clothed by a thin layer of left atrial myocardium. Its critical functional role as an *aortic baffle* placed between the inflow and outflow tracts of the left ventricle is mentioned on p. 649. The span lying between the right posterior (non-coronary) and anterior (right coronary) sinuses is continuous with the anterior surface of the right fibrous trigone, and is a variably developed collagenous sheet, the *pars membranacea septi*. The latter is an oval area measuring about 1 cm from the aortic annulus to the muscular interventricular septum, about 1.2 cm in the antero-posterior direction, and it is normally some 1 mm in thickness. As far posteriorly as the angulated attachment of the anteroseptal commissure of the tricuspid valve (p. 646) the pars membranacea intervenes between the right and left *ventricles*, whereas posterior to the commissure it separates the left ventricle and right atrium (i.e. here it is an *atrioventricular septum*). After traversing the right fibrous trigone, the atrioventricular bundle of specialized conducting tissue courses along the postero-inferior margins of the membranous septum to reach the muscular interventricular septum where it divides into its initial bundle branches. It will be recalled that this region of the heart has a complex developmental history related to the final stages of septation (p. 185), and it is one of the commonest sites of congenital cardiac anomalies (p. 666). Thus, since it lies at the very centre of the heart interconnecting three valves (aortic, mitral and tricuspid) and three chambers (right and left ventricle and right atrium), and since it is so intimately related to the atrioventricular bundle, and also frequently subject to maldevelopment, the membranous septum is of the greatest interest to the investigative cardiologist and cardiac surgeon.



The third subaortic span, namely that between the anterior (right coronary) and left posterior (left coronary) aortic sinuses, is filled with fibro-elastic tissue which blends along its anterior cusp margin with the *tendon of the infundibulum*; the remainder of the span is clothed with left ventricular myocardium.

The *pulmonary valve fibrous 'annulus'*, situated anterosuperior and almost at right angles to the aortic annulus is, however, of the same general construction as the latter, and although of greater diameter, it is considerably less robust. It is triple scalloped, with commissures at the intercuspid apices, and barely perceptible thickenings at the nadirs of the scallops. The subvalvar spans are filled with fibro-elastic tissue which is well-supported by interlacement with myocardial extensions from the muscular wall of the infundibulum. The *apex* of the subvalvar span nearest to the aorta becomes confluent with the pulmonary end of the tendon of the infundibulum. It has been suggested (Zimmerman and Bailey 1962) that the latter acts as a powerful bond between the two great arterial trunks, and that it "permits a certain degree of torsional movement between them, while preventing them from being torn asunder by the differently directed ejaculatory forces of the ventricles."

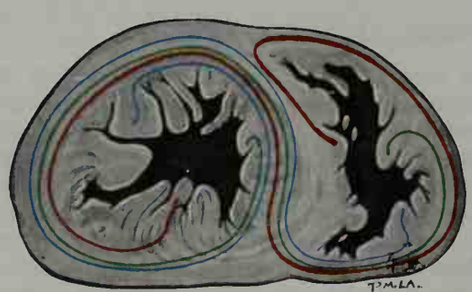


The *mitral* and *tricuspid fibrous annuli* have been adequately described on pp. 649, 645: suffice it to re-emphasize here that they are not simple, rigid, collagenous rings, but dynamic, deformable lines of valve leaflet attachment that vary greatly at different points around their periphery, and also change consderably with increasing age.

MYOCARDIAL ARCHITECTURE

It has long been held that the muscular walls of the cardiac chambers consist of cardiac muscle 'fibres' which are transversely and longitudinally striated (p. 515), and present an exceedingly intricate interlacement. They can be conveniently divided into (*a*) the fibres of the atria, (*b*) the fibres of the ventricles and (*c*) the fibres of the conducting system of the heart (p. 659). It is functionally significant that atrial and ventricular muscle fibres are completely separated by the fibrous 'annuli', the only connexion being by elements of the conducting system (p. 659). (It should be noted that in modern terminology such fibres are presumed to consist of polarized rows, bundles, or other

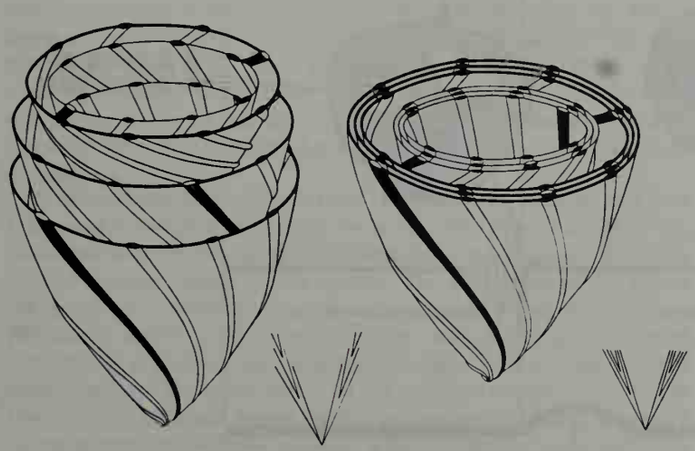
6.30 The two vortices in the myocardium at the apex of the heart. (After Mall.)



6.31 The superficial muscular fibres of the ventricles of the heart originating in the tendon of the infundibulum. (After MacCallum.)

aggregations of cardiac myocytes with their associated connective tissues—*see* p. 654, and below.)

The *atrial fibres* are in two layers, superficial, common to both atria, and deep, proper to each. *Superficial fibres* are most distinct anterior to the atria, crossing their bases transversely as a thin, incomplete layer; some pass into the atrial septum. *Deep fibres* are *looped* and *annular*, the former passing over each atrium to the corresponding atrioventricular ring, in front and behind, while the annular fibres surround the auricles and encircle the vena caval openings and fossa ovalis.

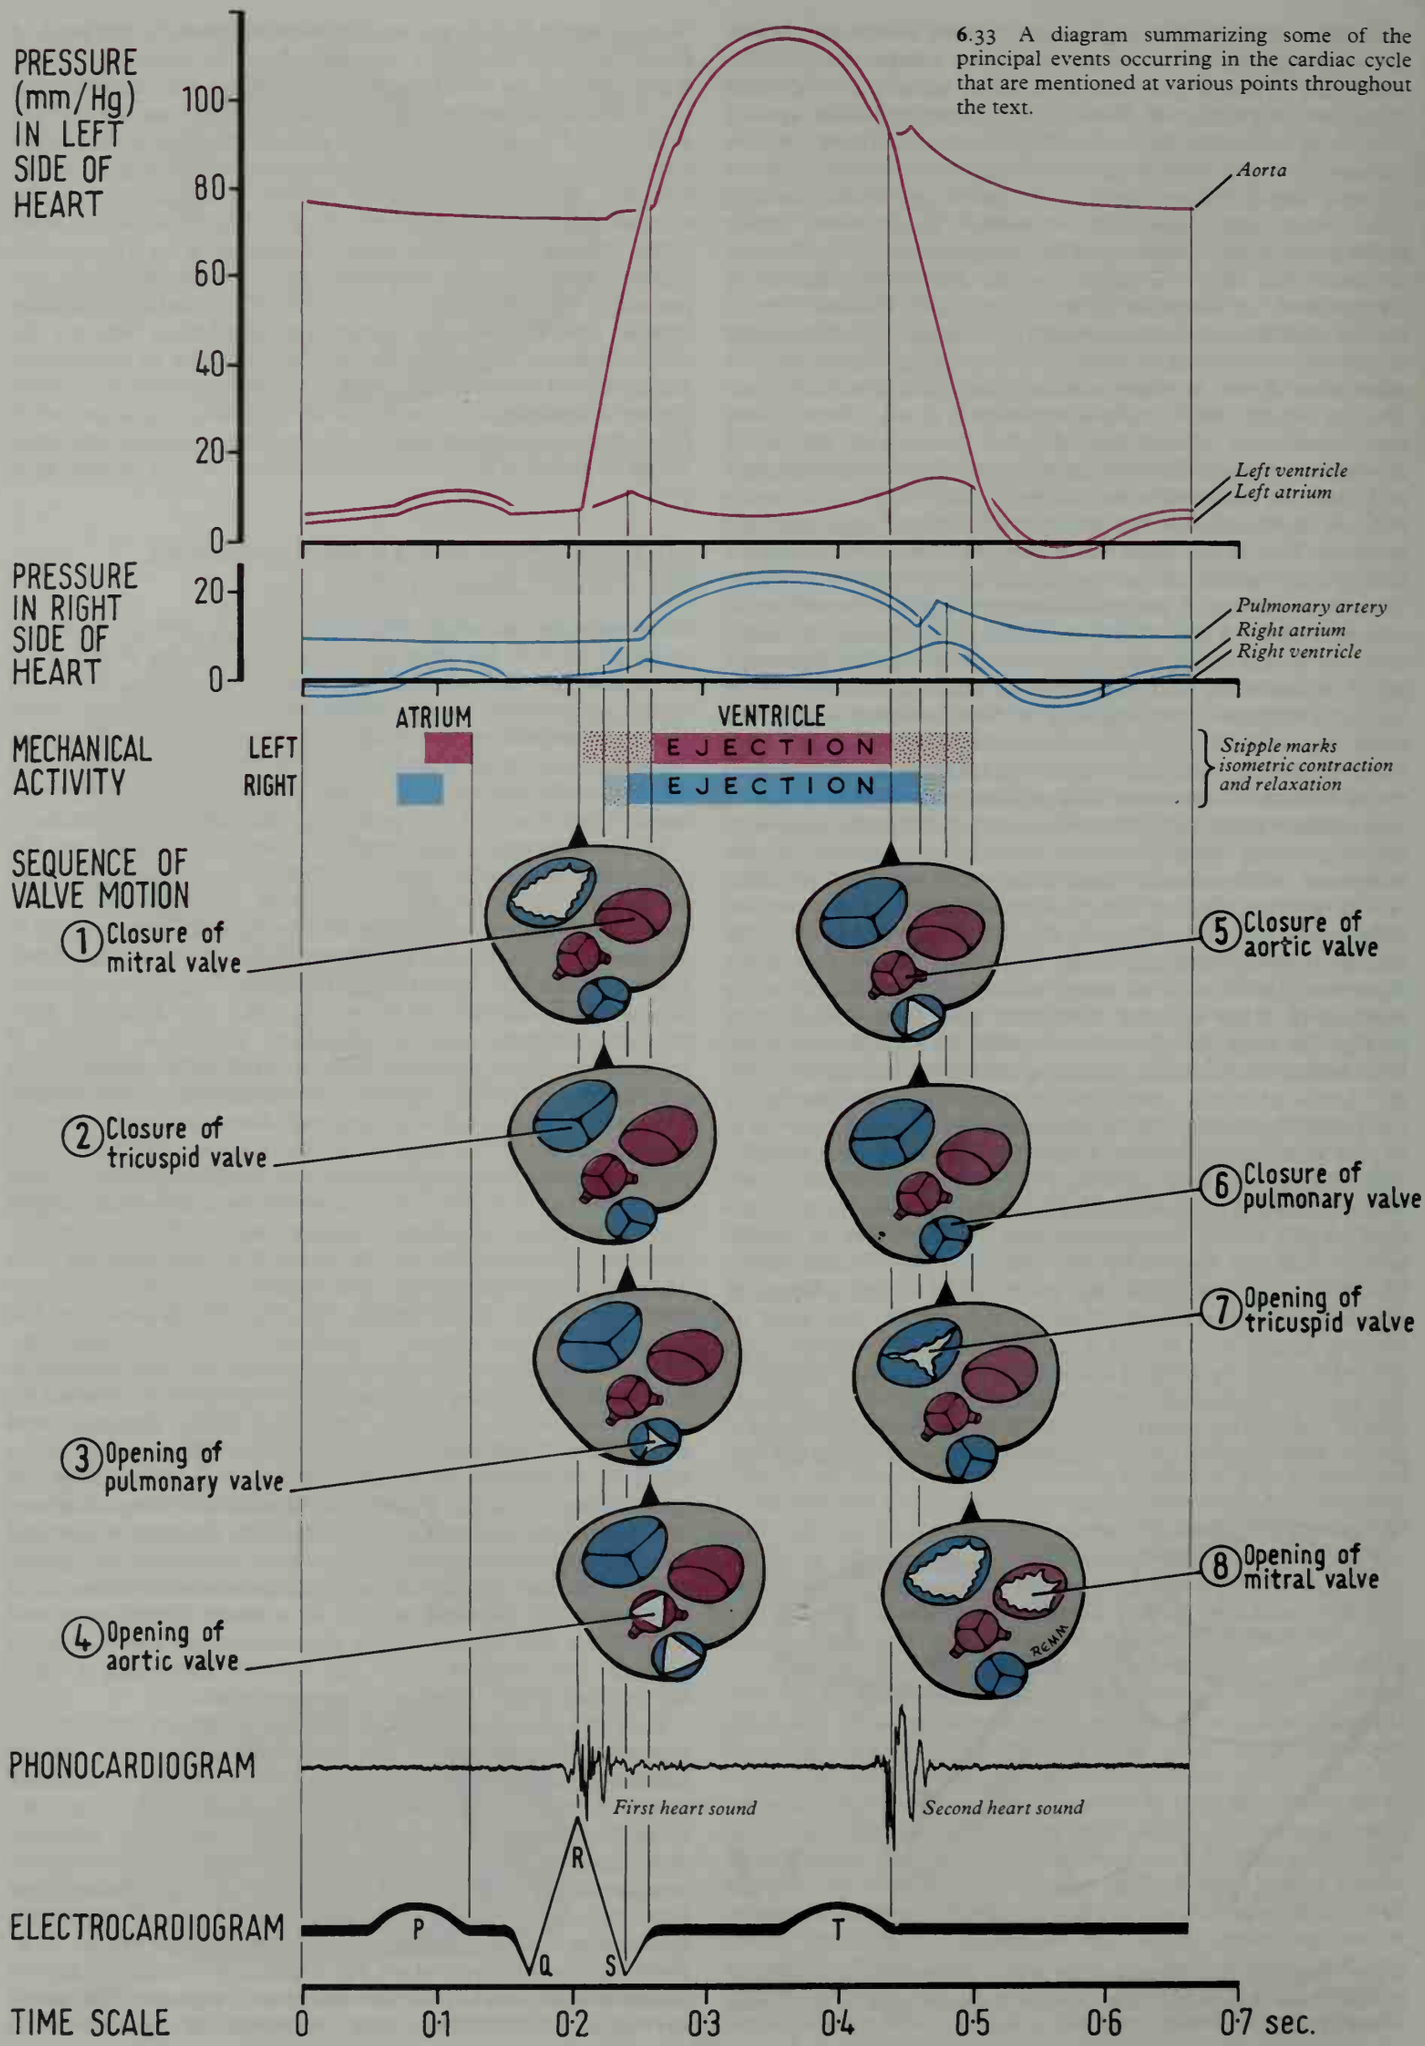


The *ventricular fibres* are complex in arrangement, and few full descriptions except by MacCallum (1897) and Mall (1911, 1912) have been available until recently (*vide infra*). Superficial and deep layers exist, all but two bands of which enter the papillary muscles. In the infundibulum the superficial fibres are transverse to its axis, the deep being longitudinal. Hence, vertical incisions into the infundibulum may be preferable. The *superficial ventricular layers* include: (1) Fibres which start from the infundibular tendon (**6.31**), curve across the diaphragmatic surface, and sweep to the left across the anterior interventricular groove to form a vortex (**6.31**) round the cardiac apex, finally passing up into the papillary muscles of the left ventricle. Fibres from the anterior half of the tendon pass to the anterior and posterior papillary muscles, those from its posterior half to the anterior alone. (2) Fibres from the *right* atrioventricular annulus which cross the diaphragmatic surface of the right ventricle reach its sternocostal surface. There they pass beneath the fibres just described and cross the *anterior* interventricular groove to wind round the apex, ending in the posterior papillary muscle of the left ventricle. (3) Fibres from the *left* atrioventricular annulus, which cross the *posterior* interventricular groove and pass into the right ventricle, end in its papillary muscles. There are three *deep ventricular* layers, starting in the papillary muscles of one ventricle and curving sinuously into the anterior interventricular groove to end in the papillary muscles of the other (**6.32A**). The most superficial layer in the right ventricle is deepest in the left, and *vice versa*. The first layer almost encircles the right ventricle, crosses in the septum to the left, and unites with the superficial fibres from the right atrioventricular ring to form the posterior papillary muscle. The second layer is less extensive in the right ventricular wall and correspondingly greater in the left, where it joins with superficial fibres from the anterior half of the infundibular tendon to form the septal papillary muscles. The third layer almost encircles the left ventricle to unite with superficial fibres from the posterior half of the tendon to form the anterior papillary muscle. The arrangement of these three layers is held to synchronize ventricular systole with atrioventricular valve closure. Two bands of fibres which do not end in the papillary muscles are also described; one, from the *right* atrioventricular ring, crosses the septum (p. 645), encircles the deep left ventricular layers, to end in the *left* ring. The second band is confined to the left ventricle, passing from the *left* atrioventricular ring to encircle the aortic orifice (Mall 1911, 1912). Fibres of the left ventricular musculature and the lower part of the left atrium reach the base of the aorta, close to its valvular cusps. These fibres are said to rotate the aortic base with the general ventricular twist of systole.

The foregoing account of myocardial architecture agrees, in its broadest features, with the views of a majority of the workers in this field, although MacCallum (1900) and Mall (1911) are the most frequently quoted. However, the concepts of obliquely spiralling laminae of fibres, overlapping at differing angles in the ventricular wall, the existence of vortices at the apex of the ventricles through which superficial fascicles spiral inwards to form internal layers—these and some other features were all described in earlier papers by Lower (1669), Borelli (1681), von Haller (1764), Gerdy (1823), and Pettigrew (1864). All these earlier investigators, like their successors, used blunt dissection of hearts which had been boiled (sometimes even roasted!), usually with the addition of varying concentrations of acetic or nitric acid. This is not the place to discuss the validity of this maceration technique, but it is important to realize that, while it is generally assumed that the loosening of myocardial tissue is considered to reside in changes in the endomysial connective tissue, the branching of the cardiac myocytes inevitably entails that a multitude of minute tears of actual muscle cells must occur in such blunt dissection. Theoretically, at least, it might therefore be as easy to tear across the long axis of muscle cells; but all who have used the technique extensively, from Lower to the most recent exponent, Torrent Guasp (1970), appear to have been satisfied that, with careful dissection, they could trace the predominant orientation of a particular layer or fascicle throughout its supposed extent. MacCallum's *tour de force* was the 'unrolling' of the ventricular muscle of a fetal pig's heart; in his short study, accomplished in three weeks, he dissected no human hearts; this aspect of the work was extended by Mall after the former's sadly premature demise. In his much more extensive investigation Mall (1911) particularly emphasized the helical spreading out of superficial fibres after they had plunged deeply into the ventricular walls. In the pig's heart he also described arrangements of deep fibres, which in his illustrations have a rope-like

6.32A The arrangement of the deep layers of the muscular fibres of the ventricles, as seen in cross-section. (After MacCallum.)

appearance and which encircle each ventricle. He regarded these bands as capable of imparting a twisting compression on the ventricles, producing a kind of *wringing* action, as had been suggested long before by Borelli (1681). Although they are not describing exactly the same fascicles, other workers have used the analogy of a rope in their descriptions, and particularly in those of Torrent Guasp, whose extensive studies of human, bovine and other vertebrate hearts are somewhat inaccessible, being published privately as monographs (1959, 1970). It is at this level of detail that many accounts become somewhat difficult to comprehend, as noted by Robb (1934), and Thomas (1957). Robb's brief historical survey points to the difficulties of equating the descriptions of many workers, except in their most general statements. Even in major details there exist contradictions. Thomas (1957), who dissected canine and porcine hearts (and contributed one of the few detailed studies of the *atrial* musculature), states that all tracts of myocardial muscle begin and end by actual attachment to the fibrous rings of the atrioventricular openings, except for those which extend into papillary muscles. This is the usual view, but one denied by Pettigrew (1864), who considered the myocardial 'fibres' to be continuous. This latter view, with certain differences, is also inherent in the descriptions by Torrent Guasp (1970) of continuous arrangements of helical bands, which turn on themselves like 'figures of eight' in encircling both ventricles, an analogy used by Lower (1669). Pettigrew (1864) claimed to have revealed a complex seven-layered structure, whereas most observers are content with a thin superficial layer, an irregular internal layer, concerned in the formation of trabeculae and papillary muscles, and a thick intermediate layer, partly interventricular and partly proper to each ventricle. The potential artificiality inherent in the technique of myocardial unravelling was admitted by Mall (1911), who emphasized that 'the fasciculi and sheets are never fully separated from adjacent fasciculi and sheets'. Torrent Guasp (personal communication, 1978) also admits that in his experience the number of strata which can be dissected out is indefinable. This has not prevented him from contributing perhaps the most complicated account of the arrangement of the myocardium in mammals, including mankind. This elaboration, the details of which cannot be included here, is nevertheless completely justifiable if its architectural details can be shown to accord with the mechanics of cardiac contraction and, equally, with the conducting pathways in the myocardium itself. Unfortunately, a comprehensible harmony between the architectural details of the myocardium and the dynamics of cardiac activity has not been achieved, except in the crudest terms. However, it is significant that in the most recent account of myocardial architectonics (Streeter 1979, 1980) the work of Torrent Guasp is in its major details confirmed. Streeter's own approach to the problem is a searching mathematical analysis of the angular orientation between myocardial 'fibres' at different depths through the ventricular wall. He finds his results much in accord with Torrent Guasp's concept of 'nested' spiral laminae (**6**.32B), which he believes was also foreshadowed by the work of Krehl in 1891. Streeter's account offers the most up-to-date examination of the literature, which is far more extensive than can be cited here. Although it must be stated that all these efforts have so far failed to impart a clear picture of the *total* architectonic arrangement of the myocardium, there is perhaps already sufficient agreement to satisfy physiological concepts. The accepted existence of 'fibre-pathways' of varying obliquity from almost circular to almost longitudinal provides at least the powers required to decrease the ventricular cavities in all dimensions; the passage of very obliquely helical bands of fibres into the papillary muscles also provides an integrating mechanism between the atrioventricular valves and the cyclical changes in longtidunal dimensions of the ventricles. Some outstanding problems require further investigation, in particular the relation or 'attachment' of the ventricular myocardium to the misnamed atrioventricular 'rings' or annuli of the cardiac 'fibrous skeleton' (*see* further on p. 657).



6.32B Diagrammatic representation of one concept of the arrangement of ventricular myocardial 'fibre bundles' from the work of F. Torrent Guasp (1970).

COORDINATION OF CARDIAC ACTIVITIES
THE CONDUCTING SYSTEM

On average the human heart beats ceaselessly at about 60 to 100 cycles per minute for many decades, maintaining a perfusion of blood through the pulmonary and systemic tissues, the most critical maintenance being through the cerebral tissues, where even transient interruption leads to irreversible neuronal changes. The actual rate of the heart beat and the 'stroke volume' of blood delivered with each cycle, of course, fluctuates considerably from time to time in accord with prevailing physiological demands.

In the previous pages emphasis has been placed on the contrasting roles of the 'right' and 'left' hearts, the topography of the cardiac chambers, the construction and operation of the valves, the main elements of the fibrous skeleton, and a review of the general architecture of the myocardium. The principal events in one cardiac cycle, including the electrocardiogram, mechanical sequences of diastole, atrial systole, the isovolumetric contraction, ejection, and isovolumetric relaxation phases of ventricular systole, the main elements of the phonocardiogram, pressure profiles of the right and left hearts and arterial trunks, and the sequences of valve opening and closure are summarized in figure **6**.33. There has now accumulated a vast literature on all aspects of cardiovascular physiology and no attempt will be made to pursue these further in the present volume. However, a brief survey of those structural elements that are involved in the *coordinated sequence* of events in the cardiac cycle, together with some indication of features that remain the subject of much controversy will be attempted. Clearly, the *efficiency* of the pumping action of the heart is heavily dependent upon the precise timing of operation of the interdependent structural complexes. Passive diastolic filling of the atria and ventricles is followed by atrial systole which completes ventricular filling. Excitation and contraction of both atria must therefore be complete before the onset of ventricular contraction and this is effected by the introduction of an *atrioventricular conduction delay*. Further, ventricular contraction is not haphazard but proceeds in a precise pattern; mechanisms exist that ensure the onset of graded papillary muscle contraction and hence control of the atrioventricular valves is followed rapidly by a wave of excitation and contraction that spreads from the ventricular apices, basally towards their outflow tracts and orifices, generating a rapid acceleration of blood during the ejection phase.

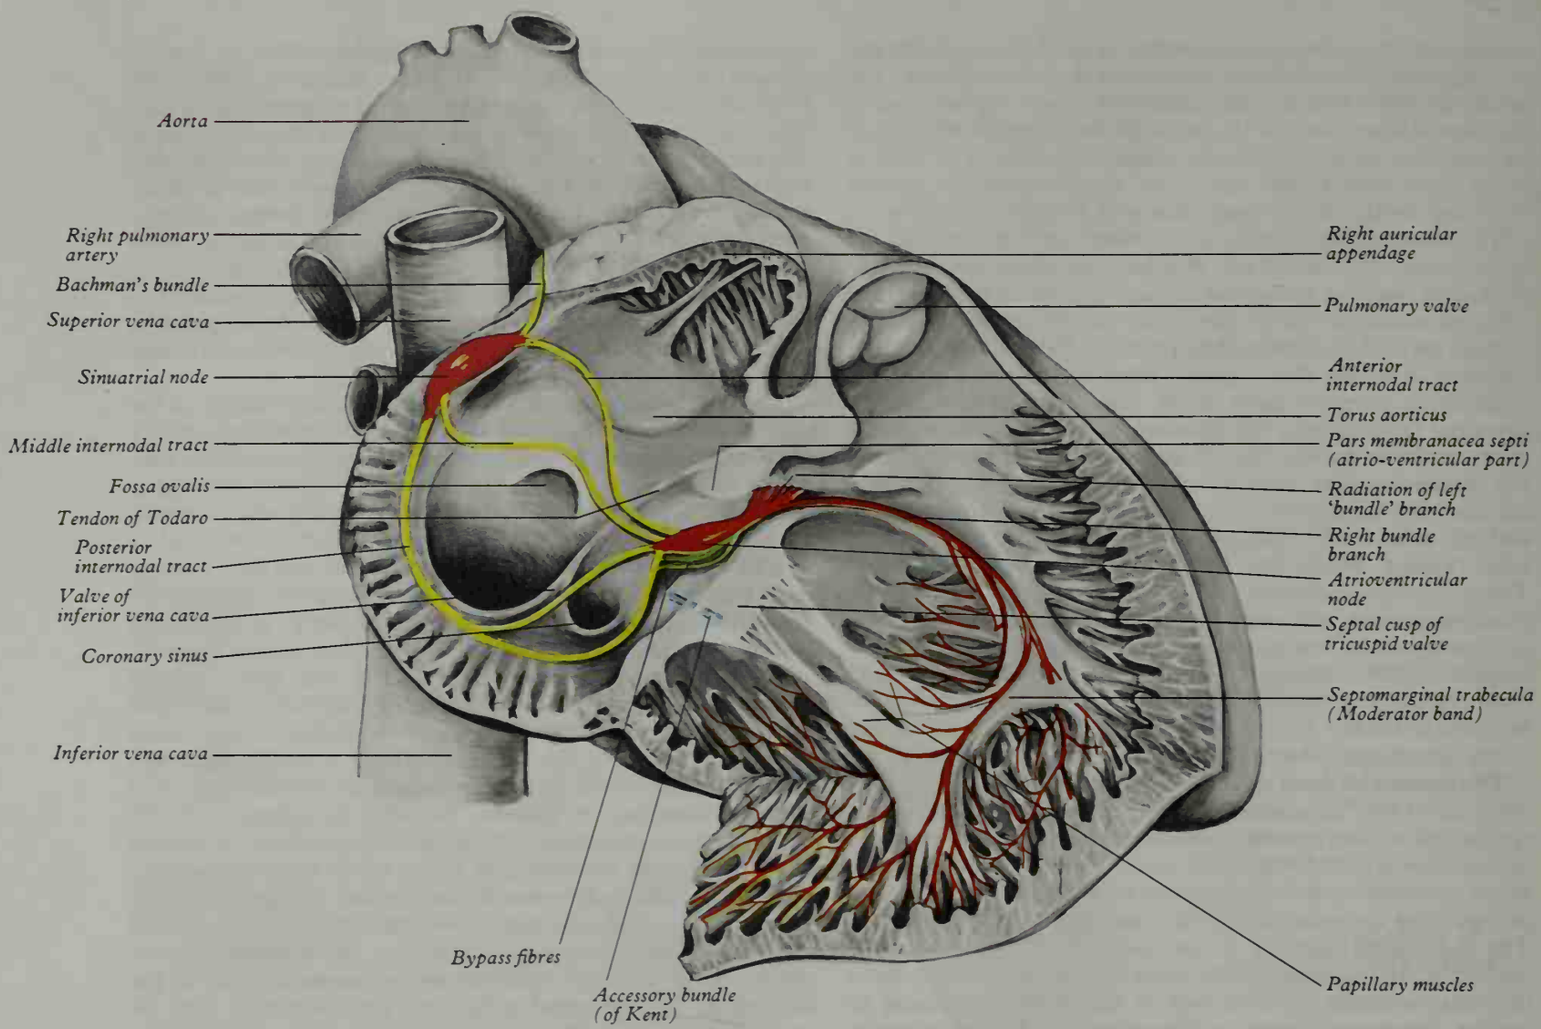
It is now generally accepted that the vertebrate heart beat is *myogenic*, originating in the myocytes themselves, neural influences serving to modify the intrinsic rhythm as functional demands vary. *All* varieties of myocyte in the heart (p. 515) are excitable cells and show the properties of autonomous rhythmic depolarization and repolarization of their cell membranes, conduction of the wave of depolarization via nexuses (gap junctions—p. 8) to neighbouring myocytes, and excitation-contraction coupling to their actomyosin complexes (p. 516). However, these properties are developed to very different degrees in different sites and in the various types of myocyte. The *rate* of rhythmic depolarization and repolarization is slowest in

6.33 A diagram summarizing some of the principal events occurring in the cardiac cycle that are mentioned at various points throughout the text.

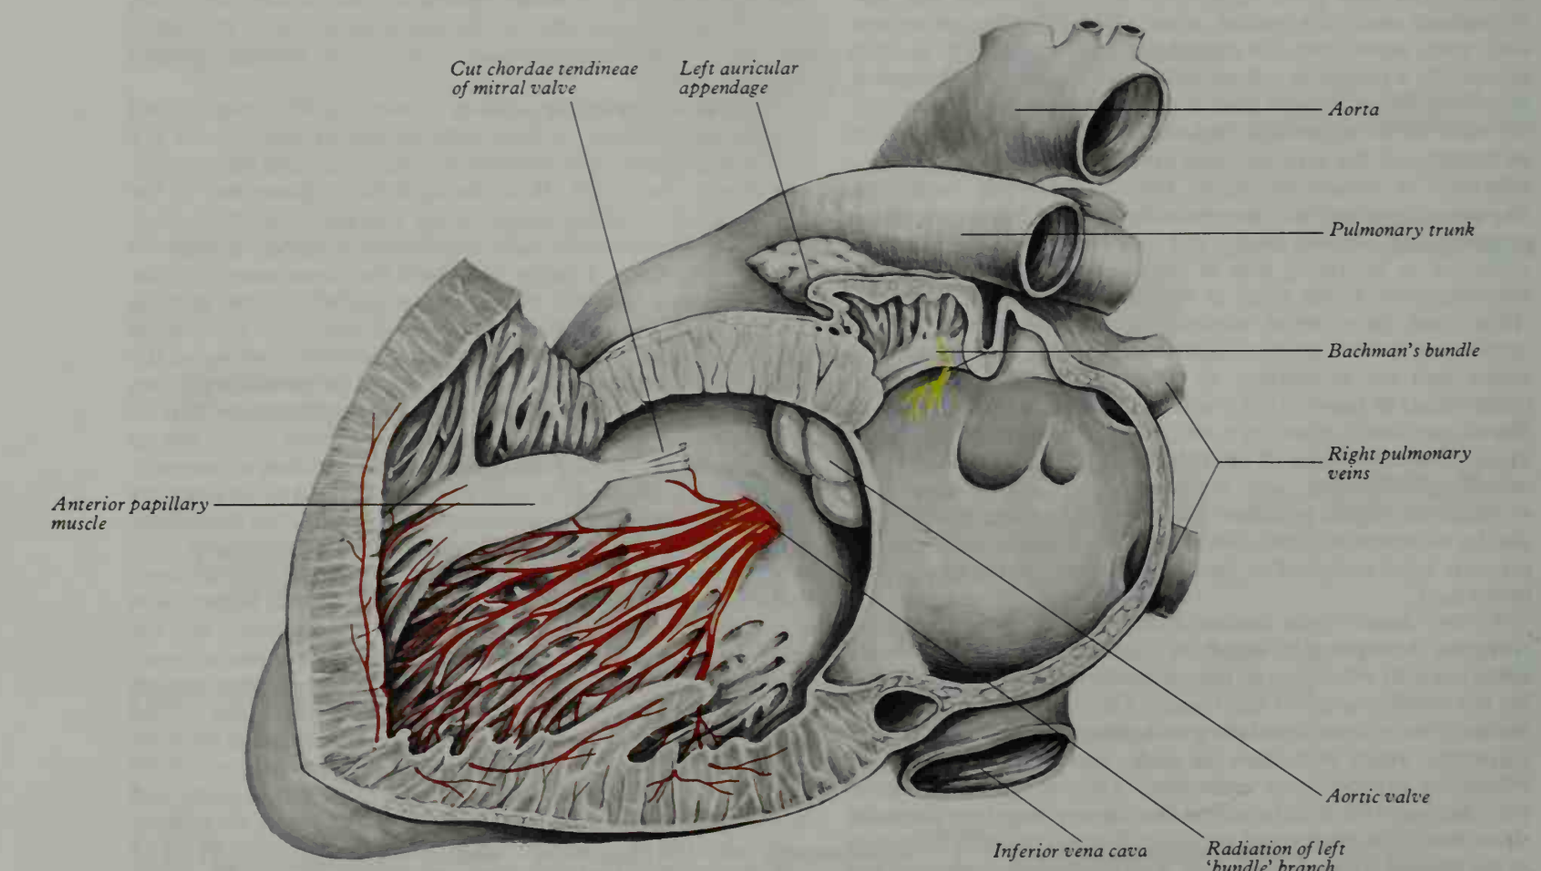
ventricular myocardium, intermediate in atrial myocardium, and fastest in sinuatrial nodal myocytes derived from sinus venosus. The latter, therefore, override the tissues with slower rhythms and, in the normal heart, provide the locus for the repeated initiation of each cardiac cycle. Conversely, conduction *velocity* is slow in nodal and transitional myocytes, intermediate in general 'working' cardiac myocytes and fastest in Purkinje myocytes.

The accumulations, tracts and networks of these various cell types (nodal, transitional and Purkinje myocytes) constitute the *conducting system* or *specialized conducting tissues* of the heart, and while all authorities are in agreement concerning the main constituent parts of the system, their precise cellular makeup and the existence of certain other elements remain debatable.

Generally accepted parts of the conducting system are the sinuatrial (sinus) node, the atrioventricular node, the common atrioventricular bundle, the left and right bundle branches, and the subendocardial network of Purkinje 'fibres'. Strongly advocated by some workers, but rejected by others, are interatrial and internodal tracts of specialized conducting tissue, atrioventricular 'bypass' fibres, and accessory atrioventricular bundles. These various constituents are illustrated in figures **6**.34, 35. For excellent reviews and extensive bibliographies concerning the cardiac cycle the reader should consult Rushmer (1976), and Schlant (1978); similarly, comprehensive (and sometimes controversial) treatments of the cardiac conducting system are to be found in Hudson (1965), Anderson (1974, 1975, 1980), James (1978), James and Scherf (1978).



The sinuatrial node (or sinus node) of Keith and Flack (1907), often called the 'pacemaker' of the heart, because certain of its specialized cells are generally considered to be the site of initiation of excitation in each cardiac cycle, is, as its name suggests, situated at the junctional zone between parts of the mature right atrium derived from the embryonic sinus venosus and primitive atrium. The histological features of the core of the node are quite distinctive, but its periphery is much less obvious and the latter doubtless accounts for some lack of agreement concerning its precise dimensions, shapes and boundaries. Contrary to earlier views the nodal tissue does not extend through the full thickness of the atrial wall from epicardium to endocardium but lies, throughout most of its extent, some 1 mm from the epicardium and rather more from the underlying endocardium. It is often covered by a plaque of subepicardial fat. The node is elongated, extending from the right part of the groove between the root of the right atrial appendage and the anterolateral aspect of the termination of the superior vena cava, then continuing posteroinferiorly to invade the upper part of the crista terminalis. Variously described as a flattened ellipsoid, an 'Indian war club', or possessing a 'head', 'body' and 'tail', in shape, it is generally conceded to be 10–20 mm in length, some 1 mm thick and approximately 3 mm wide at its maximum lateral convexity. (Here, and later, when mentioning the architecture of the conducting tissues, the classification of cardiac cells proposed by James and his co-workers in a series of publications, and summarized in James (1978), will be followed: a brief account of this architecture is given on p. 663. Their classification was based upon exhaustive series of careful dissections, light and electron microscopic studies, and attempts to correlate these with electrophysiological evidence. However, the reader should note that by no means all authorities recognize the full range of cardiac myocyte types proposed by James as being present in all the sites mentioned.)



A most characteristic feature of the sinuatrial node is that it is traversed throughout its length by a centrally placed *artery of the sinuatrial node* which has an unexpectedly large lumen (*see* p. 669 for the variable origin of this vessel). The adventitia of the vessel merges into a dense interlacing collagenous framework, firm to palpation, which permeates the node, and in the interstices of which the myocytes are embedded. Only a few small lateral branches leave the nodal artery as the nutrient supply to the nodal tissue itself; the main vessel continues beyond the node to ramify in the general atrial myocardium. The interesting suggestion has been made that the enlarged adventitia of the nodal artery may subserve a sensory function monitoring aortic pressure and pulsation, and forming part of a feedback loop which stabilizes an appropriate sinus rhythm; pharmacological studies in general support such a view. The myocytes of the node have, on the basis of light microscopy, for long been described as 'primitive' cardiac cells, slender and fusiform or branching, and characteristically pale-staining; the majority of the earlier authors considered that such nodal cells made specialized contacts *directly* with ordinary atrial wall myocytes at the margins of the node. James, however, distinguishes the following cell varieties in the sinuatrial nodal complex and its immediate environment: rounded, polygonal, fusiform or occasionally stellate *nodal myocytes* (pale-staining or P-cells), a heterogeneous and structurally more complex group of short slender *transitional myocytes*, *Purkinje myocytes*, and finally general atrial 'working' *cardiac myocytes*.

The nodal myocytes are confined to the central regions of the node and are circumferentially arranged in the immediate vicinity of the nodal artery, but more irregularly grouped external to this. These cells are now considered to be the origin of pacemaker activities; they make functional contacts with each other and with adjacent transitional cells. The latter are both shorter and of smaller diameter than general myocardial cells and their internal organization varies from the simple almost organelle-free type (as in the P-cell) to one with a well-developed contractile system and complex sarcoplasmic reticulum. They are slow-conducting cells and are interposed between the P-cells and either general myocardium or Purkinje cells. The latter are shorter, and wider than general myocardial cells (their ultrastructure is mentioned on p. 518) and they are thought to have a rapid conduction velocity. It should be noted that in the human heart and the hearts of small mammals in general, the cells in question are not markedly wider than those of the general myocardium (in contrast to the prominent Purkinje cells found in the larger ungulates): accordingly, some authorities do not consider Purkinje cells to be present in the atrial walls and reserve the term for the more distal parts of the ventricular conducting system. James, however, holds the view that Purkinje myocytes are numerous around all the margins of the sinuatrial node (and also extending into the interatrial and internodal tracts—*vide infra*). Thus, he considers that excitation of atrial myocardium follows the sequence: pacemaker activity of nodal myocytes, slow conduction along transitional myocytes, fast conduction along Purkinje myocytes, and finally spreading excitation-contraction between general atrial myocytes.

The atrioventricular node of Tawara (1906) is roughly oval or elliptical in outline, its long (anteroposterior) axis is some 7–8 mm, its maximal vertical dimension being 3 mm, and transversely it is about 1 mm thick. It lies beneath the endocardium of the septal wall of the right atrium in the triangle of Koch (p. 644) immediately dorsal to the basal attachment of the septal leaflet of the tricuspid valve, 1 cm or less above the septal margin of the orifice of the coronary sinus, and encircled by the arching subendocardial collagenous tendon of Todaro. Its right atrial surface is convex whilst its left surface is concave abutting on the base of the mitral valve annulus. Its dorsal extremity projecting into the atrial septum narrows forming the nodal crest whilst its antero-inferior extremity which is closely related to the central fibrous body of the heart continues into the common atrioventricular bundle. The node is everywhere permeated by an irregular collagenous framework enmeshing the myocytes; the framework is, however, much less dense than that of the sinuatrial node. The arterial supply to the node is given on p. 671. *Nodal myocytes* form a relatively small population of cells confined to the deeper parts of the node, particularly near the central fibrous body, and the principal cellular elements are *transitional myocytes*: the latter are irregularly arranged in the dorsal part of the node but become increasingly polarized into longitudinal tracts where they extend into the common atrioventricular bundle. All surfaces of the node are also held to be encrusted with Purkinje myocytes which (1) receive the fine terminals of internodal conduction paths and 'bypass' fibres (*vide infra*) and (2) continue as one of the cellular components of the atrioventricular bundle.

It is probable that the large population of slender, slow-conducting transitional myocytes in the atrioventricular node is responsible for the functionally essential *atrioventricular conduction delay* mentioned above.

6.34, 35 A diagram of the conducting tissues of the heart as seen from the right (**6.34**) and left (**6.35**) aspects. Generally accepted elements are shown in *red*; accessory atrioventricular paths and 'bypass' bundles in *blue*. The internodal and interatrial pathways shown in *yellow* are subject to some controversy. Consult text for further discussion.

The atrioventricular bundle of His (1893) is formed by the convergence of longitudinal tracts of myocytes at the antero-inferior pole of the atrioventricular node. Narrowing rapidly, the bundle, ensheathed in a delicate tunic of vascularized connective tissue, becomes oval, quadrangular, or triangular in transverse section and enters a channel in the central fibrous body (right fibrous trigone—*see* p. 657). Traversing the latter, the undivided (common) bundle reaches the dorsal margin of the pars membranacea septi; thereafter it courses along its postero-inferior margin to reach the crest of the muscular interventricular septum. It is commonly stated that at the crest the common bundle divides into *right* and *left bundle branches* implying a simple bifurcation, but this is misleading in a number of respects. The *right bundle branch* continues as a relatively narrow, discrete rounded aggregation of fascicles which runs at first in a myocardial channel and then subendocardially towards the right ventricular apex; it then enters the septomarginal trabecula which conveys it to the base of the anterior papillary muscle. In its septal course towards the trabecula the bundle gives off relatively few side branches to the ventricular walls, but having reached the papillary muscle it breaks up into a profuse network of fine subendocardial fibres, which first embrace the papillary muscles and then pursue a *recurrent* course towards the ventricular base reaching all parts of the ventricular parieties. The *left bundle branch* is something of a misnomer because numerous fine fascicles, each with its delicate connective tissue sheath, leave the left margin of the common bundle throughout much of its course along the membranous septum: these fascicles form a wide *flattened sheet* which arches over the crest of the muscular septum. The diverging sheet passes apically and subendocardially across the left ventricular aspect of the septum and after 2–3 cm it then separates into anterior and posterior sheets destined for the bases of the papillary muscles bearing the same names. Fine lateral branches leave the margins of the sheaths, but their terminations again form complex subendocardial networks which encompass first the papillary muscles, and then pursue recurrent paths to all parts of the subendocardial ventricular walls.

The common bundle at its outset contains extensions of *transitional myocytes* from the atrioventricular node, but in its distal part, followed by the bundle branches, and terminal subendocardial network, the cells gradually increase in diameter and assume the characteristics of polarized tracts of *Purkinje myocytes*. Between the latter, however, are intermingled tracts of what ultrastructurally appear to be general cardiac myocytes; their conduction characteristics are unknown.

It should be noted that the principal bundle branches are largely insulated from the surrounding myocardium by their sheaths of connective tissue, functional contacts between Purkinje myocytes and the ventricular myocardium first appearing in substantial numbers with the emergence of the profuse subendocardial network. Thus, not only do the papillary muscles contract first followed by a wave of excitation-contraction that proceeds *from* the ventricular *apex* towards the basally situated outflow tract and orifice, but, because of the subendocardial position of the Purkinje network, mural ventricular excitation proceeds from the endocardial to the epicardial surface. However, little is yet known concerning the details of the three-dimensional array of Purkinje myocyte terminals in the ventricular walls; it is even uncertain to what depth they penetrate the walls.

Interatrial and internodal conduction paths. For many years it has been standard teaching in physiological textbooks that sinuatrial pacemaker activity caused *direct* excitation of general atrial cardiac myocytes, and that this spread radially via their intercellular nexuses to encompass both atria, the wave of excitation eventually reaching the atrioventricular node. It was further assumed that the pathways followed by the wave merely reflected the complex topography of the atrial walls and in particular the positions of their orifices. Indeed, a number of modern authorities dismiss the view that any specialized interatrial and internodal conduction pathways exist (*see* for example Anderson *et al.* 1974, 1975; Anderson 1975; Rushmer 1976), or that if they exist they have no demonstrable physiological role in the normal human heart (*see* Marriot and Myerberg 1978).

However, since the earlier years of this century a number of authors have postulated the existence of such specialized routes (e.g. Wenckebach 1908; Thorel 1909, 1910; Bachmann 1916). Further interest was stimulated when electrophysiological studies demonstrated that impulses originating in the sinuatrial node arrived at the atrioventricular node more rapidly than if they had travelled through ordinary myocardium (Hoffman and Cranefield 1960). A strong protagonist of the existence of interatrial and internodal pathways is James (1978) who claims that they may even be demonstrated by careful dissection, and who has examined their histology and ultrastructure. The following pathways have been described, each consisting of an admixture of Purkinje myocytes and ordinary cardiac myocytes.

The *anterior internodal tract* (including the *interatrial bundle of Bachmann*) leaves the anterior extremity of the sinuatrial node, skirts the anterior aspect of the termination of the superior vena cava and passes posteromedially to reach the anterior margin of the interatrial septum. Here, it divides, some fibres penetrating the septum to splay out in the walls of the left atrium (Bachmann's bundle); the remaining fibres descend posteriorly across the right side of the septum behind the torus aorticus to divide into terminal fascicles that approach the atrioventricular node (*vide infra*).

The *middle internodal tract* (of Wenckebach) emerges from the posterosuperior aspect of the sinuatrial node, curving posterior to the orifice of the superior vena cava to reach the interatrial septum, which it crosses, and breaks up in the neighbourhood of the atrioventricular node.

The *posterior internodal tract* (of Thorel) continues from the postero-inferior part of the sinuatrial node, continues through the substance of the crista terminalis and valve of the inferior vena cava, then proceeds to the posterior margin of the atrioventricular node; variable relationships of this tract to the ostium of the coronary sinus have been described.

The fine terminal branches of these internodal pathways are held to enter and make functional contact with transitional myocytes at many levels over the atrioventricular node, including its posterosuperior crest, throughout its convex right atrial surface, and a small number may even reach the root of the common atrioventricular bundle beyond the node. Such radicles thus constitute '*bypass fibres*' circumnavigating much or all of the nodal cells—they provide a possible anatomical basis for a *dual form* of atrioventricular transmission first proposed by Moe *et al.* (1956).

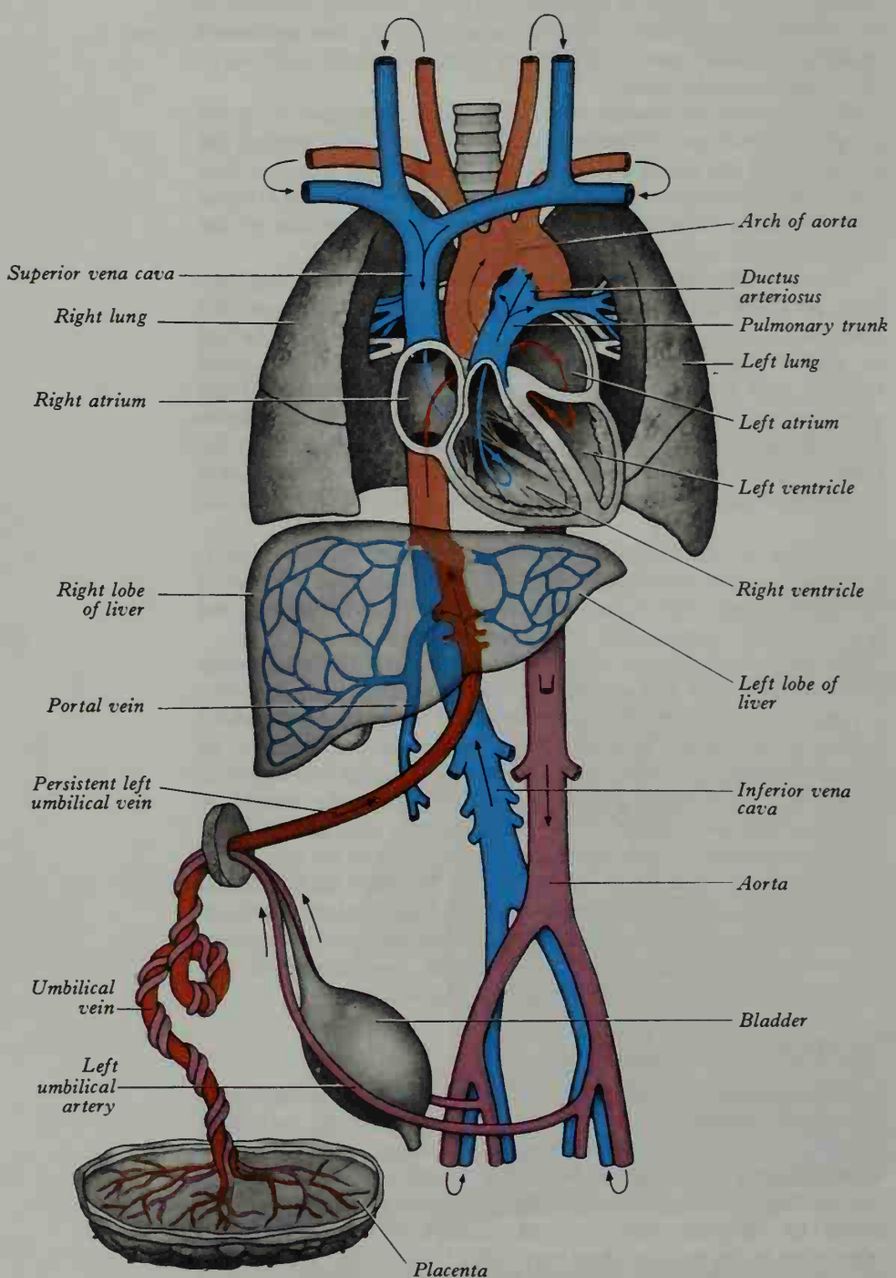
It must be re-emphasized here that the existence, routes, architecture and functional roles of interatrial and internodal conduction pathways remain the subject of vigorous debate; the results of future researches will be awaited with great interest.

Finally, mention must be made of the question of **accessory atrioventricular bundles** the existence of which is often invoked to explain the clinico-pathological background of various cardiac arrhythmias. It is widely held that such bundles may be present near the principal common atrioventricular bundle, or at any point around the circumference of either the mitral or tricuspid fibrous 'annuli'. They are generally thought to be of slender dimensions, of irregular frequency, and of no functional significance in the *normal* cardiac cycle. Whether such bundles consist of specialized conducting tissue or of general myocardium is unresolved; much current research is being directed towards an anatomico-physiological analysis and an assessment of the applied surgical relevance of such connexions.

CARDIAC NERVE SUPPLY

The initiation of each cardiac cycle of activity may be myogenic or neurogenic in invertebrates, but in vertebrates, including mammals, it is myogenic. In the vertebrate heart, with increasing specialization and elaboration of the organ, initiating foci and conducting pathways have become progressively more differentiated to integrate the cycle of successive contraction and relaxation in the cardiac chambers. This 'conducting system' has already been described (p. 659). However, the cardiac cycle is harmonized, in its rate, force, and output, by an extrinsic nerve supply, which operates upon the cardiac nodal tissue and its

fascicular prolongations, upon the coronary vessels, and perhaps upon cardiac muscle. This nerve supply is autonomic and comprises both efferent and afferent fibres. The parasympathetic fibres reach the heart through branches of the vagus (p. 1123) and the sympathetic by rami of the sympathetic trunk (p. 1127). The vagal preganglionic fibres proceed from central origins in the brainstem, particularly the medulla, and these include the nucleus ambiguus (p. 1076), reticular nuclei (p. 946), and possibly the dorsal nucleus of the vagus (p. 1076). These pre-ganglionic axons leave the vagus as its cardiac branches and reach the cardiac plexuses without interruption (*see*, however, p. 1078). The sympathetic pre-ganglionic neurons are situated in the lateral grey column of the thoracic spinal cord, in its cranial five or six segments (Kuntz 1953). The pre-ganglionic fibres from these sources end in the cervical and third and fourth thoracic sympathetic ganglia (Mitchell 1953), from all of which bilateral cardiac nerves, consisting of post-ganglionic fibres, proceed to the heart (pp. 1127, 1132).



The central connexions of the cardiac pre-ganglionic neurons, parasympathetic and sympathetic, are described elsewhere (*see* Reticular System, Hypothalamus, and Cerebral Cortex). The existence and behaviour of these integrating influences is better understood in terms of function, the precise locations of connecting pathways in spinal cord, brainstem, and cranial to this, being in general somewhat uncertain, perhaps because they do not form closely aggregated tracts.

As they reach the heart the sympathetic nerves (post-ganglionic fibres) and the parasympathetic cardiac branches of the vagus (pre-ganglionic fibres) together form a mixed *cardiac plexus* (p. 1132), usually considered divisible into a ventral (superficial) part, inferior to the aortic arch and ventral to the pulmonary artery, and a dorsal (deep) part situated between the aortic arch and the tracheal bifurcation. These plexuses contain ganglia, which also occur in the heart itself, along the distribution of the branches of the cardiac plexus, and their neurons are considered to be largely, if not exclusively, post-ganglionic parasympathetic in nature. With the advent of reliable staining techniques for cholinergic and adrenergic nerve cells, axons, and axon terminals, the intrinsic distribution of autonomic elements in the heart has been subjected to detailed examination, although, of course, methylene blue staining had permitted elucidation of many details prior to this. Even a brief historical review of such contributions is impossible here; Kuntz (1953), Mitchell (1956), and Pick (1970) have all examined earlier reports, and the more recent observations cited here are merely representative of an active field of study.

Cholinergic and adrenergic fibres, originating in or passing through the cardiac plexus, are distributed to the nodal tissue (sinuatrial and atrioventricular), to the atrial and ventricular myocardium, and to the coronary arteries and cardiac veins, in rodents and dogs, according to many observers (*see* Glabella 1976 for references). Whole mounts of the right atrial wall, in pigs, demonstrate the rich supply of cholinergic nerve fibres to this chamber, at least (Bojsen-Møller and Tranum-Jensen 1971); and the same technique shows extensions of the cardiac plexus to the nodes and to the atrioventricular bundle. These cholinergic fibres presumably originate in the small ganglia frequently described in the cardiac plexus and its prolongations. In man a single ganglion in the 'superficial' part of the plexus has been described; but in other mammals numerous small ganglia have been identified in the atrial walls, especially in the vicinity of the sinuatrial and atrioventricular nodes, and along the coronary arteries. No adrenergic neurons have yet been identified in such ganglia, but they contain chromaffin cells of the small intensely-fluorescent type (SIF-cells, *see* p. 1454), according to Nielsen and Owman (1968). Adrenergic fibres occur in all chambers of the heart; both cholinergic and adrenergic axons are said to be more abundant in the atria and adjacent to nodal tissue than elsewhere, but in the cat adrenergic fibres appear to be more densely distributed in the ventricles. According to Chiba and Yamauchi (1970) cholinergic fibres are more numerous in the atrial myocardium of the human heart and adrenergic axons in the ventricular wall.

In most reports nerve fibres are merely described as being in close relation to nodal tissue or myocardial cells; but Thaemart (1969) has reported neuromuscular junctions, with a gap of 78–100 mm, in the atria, ventricles and septa of the murine heart. Such ultrastructural studies have been extensively reviewed by Yamauchi (1973). To summarize, adrenergic and cholinergic terminals occur in the nodes, atrial and ventricular myocardium, the atrioventricular bundle, and the coronary vessels of a wide variety of laboratory mammals. The functional significances of such supplies are only in part understood, but are not difficult to speculate upon. Confirmation of such innervations in the human heart is still awaited, but it seems improbable that similar arrangements do not exist.

Afferent cardiac nerves have attracted less interest in anatomical studies, although their existence is physiologically undeniable. Some of the fibres which accompany the coronary arteries have long been considered to be visceral afferents, and afferents from the atria and the terminations of the caval and pulmonary veins are generally accepted. The precise routes of return of such visceral afferents are not fully established (p. 1136), but the cardiac branches of the vagus and of the middle and inferior cervical sympathetic ganglia probably provide the major pathways. Most recent work has concerned the actual 'terminations' of visceral afferents in the heart. Ultrastructural

6.36 A plan of the fetal circulation. The arrows indicate the direction of blood flow. The placenta is drawn to a greatly reduced scale.

identification of such endings is largely dependent upon mitochondrial accumulations, which are considered to be characteristic. By such criteria Kisch (1958) reported subendothelial afferent terminals in the atria and ventricles of mammals, including man; he considered that these mediated the pain phenomena of *angina pectoris*. Similar endings have been demonstrated also in the pulmonary valve (Chiba and Yamauchi 1970). Further developments in this field are awaited with interest.

The Vessels of the Heart

The arteries supplying the heart, the coronary branches of the aorta, are described on pp. 669–673. The cardiac veins and coronary sinus are described on pp. 737–738. For the lymphatic drainage of the heart *see* p. 860.

The Fetal Circulation

The fetal blood is carried to the placenta by the two umbilical arteries, and returned from the placenta to the early fetus by two umbilical veins, though in later fetal life the right umbilical vein disappears (p. 192). The persisting left vein enters the abdomen at the umbilicus and passes in the free margin of the falciform ligament to the visceral surface of the liver, where it gives off two or three branches to the left lobe, including the quadrate lobe. At the porta hepatis it joins the left branch of the portal vein, from which opposite this point, a large vessel arises and ascends on the posterior aspect of the liver to join the left hepatic vein immediately before that vessel opens into the inferior vena cava. This vessel is termed the *ductus venosus*. During fetal life the portal vein is small compared with the umbilical vein, and the parts of its left branch, proximal and distal to where the umbilical vein joins it, function as branches of the latter vessel carrying oxygenated blood to the right and left parts respectively of the liver (**6**.36). It will be seen therefore that the blood conveyed by the left umbilical vein passes to the inferior vena cava in three different ways. Some enters the liver directly and is carried to the inferior vena cava by the hepatic veins; a considerable quantity circulates through the liver with the portal venous blood, before entering the inferior vena cava by the hepatic veins; the remainder passes into the inferior vena cava through the ductus venosus.

In the inferior vena cava the blood carried by the ductus venosus and hepatic veins mixes with that returning from the lower limbs and from the abdominal wall. It enters the right atrium, and, guided by the valve of the inferior vena cava, passes for the most part through the *foramen ovale* into the left atrium, where it mingles with a small quantity of blood returned from the lungs by the pulmonary veins. A small amount of blood returned to the heart by the inferior vena cava, however, instead of passing through the foramen ovale, goes through the right atrioventricular orifice with the blood from the superior vena cava. From the left atrium blood passes into the left ventricle, and from that cavity into the aorta, through the branches of which it is probably distributed almost entirely to the heart itself and to the head and the upper limbs, only a small quantity being carried into the descending aorta. The blood from the head and the upper limbs is returned by the superior vena cava to the right atrium and all of it passes through the right atrioventricular orifice, carrying with it a small amount of the blood returned by the inferior vena cava. Having reached the right ventricle this blood passes into the pulmonary trunk. The lungs of the fetus being inactive, only a small quantity of the blood conveyed by the pulmonary trunk is distributed to them by the right and left pulmonary arteries, and returned by the pulmonary veins to the left atrium; the greater part passes through the *ductus arteriosus* into the aorta, where it mixes with the small quantity of blood transmitted by the left ventricle into this part of the aorta. It descends through the aorta and is in part distributed to the lower limbs and to the viscera of the abdomen and pelvis, but most of it is conveyed by the umbilical arteries to the placenta.

This account of the circulation of the blood in the fetus has been confirmed by radiographic observations after the injection of radio-opaque substances, and timing the appearance of tracer material in different parts of the circulation after injection of isotopically labelled serum albumin into the bloodstream in fetal sheep (Barclay *et al.* 1944; Dawes 1961). The following points, which are supported by evidence provided by blood-gas analysis can be inferred: (1) The placenta serves the purposes of nutrition and excretion, receiving deoxygenated blood from the fetus and returning it charged with oxygen and nutritive material. (2) Some of the blood of the left umbilical vein traverses the liver before entering the inferior vena cava; this is correlated with the relatively large size of the liver, especially at an early period of fetal life. (3) Only the pulmonary veins open directly into the left atrium, and the volume of blood which enters it from this source is very small. On the other hand, the volume of the blood entering the right atrium is much greater, and the pressure within that chamber is much higher than the pressure in the left atrium. As a result, the flap-like septum primum (p. 184) is thrust over to the left (**2**.103) and the passage of blood from the right to the left side of the heart is effected easily. The valve of the inferior vena cava is placed so as to enable it to direct nearly all the blood which issues from that vessel to the foramen ovale and so to the left atrium, whereas the blood entering the right atrium from the superior vena cava passes directly into the right ventricle. (4) The refreshed blood carried from the placenta to the fetus, mixed with the blood from the portal vein and inferior vena cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and the upper limbs. (5) The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and the upper limbs, together with a small quantity from the left ventricle, is distributed to the abdomen, the lower limbs, and placenta.

The Changes in the Vascular System at Birth

At birth, when pulmonary respiration begins, an increased amount of blood from the pulmonary trunk passes through the pulmonary arteries to the lungs, and a correspondingly increased amount returns by the pulmonary veins to the left atrium. At the same time there is a fall in pressure in the inferior vena cava due to reduction of the venous return by occlusion of the umbilical vein. The pressures within the two atria become equalized, and the foramen ovale, which is valve-like in character, is closed by the apposition, and later by the fusion, of the septum primum to the septum secundum (**2**.103). Possibly, contraction of septum primum musculature, synchronized with that in the wall of the superior vena cava, may play some part in this closure (which occurs some considerable time after *functional* closure of the ductus arteriosus—*vide infra*, and Barclay and Franklin 1938). Not infrequently the fusion is incomplete and a potential communication between the two atria may persist throughout life. Such a communication, unless large, has no functional significance; because of the equality of the intra-atrial pressures and the valve-like arrangement of the opening, no blood can pass from one side to the other.

When the umbilical cord is ligated and the placental circulation is cut off, the umbilical vein becomes thrombosed (*see* p. 764), and is gradually converted into a fibrous vestige, the so-called *ligamentum teres* of the liver. The umbilical vessels have thick muscular walls but are devoid of a nerve supply in their extra-abdominal portions. They constrict in response to a variety of stimuli, such as handling, stretching, cooling and altered oxygen and carbon dioxide tensions in the blood. The ductus venosus also becomes obliterated but the mechanism is not known; there is evidence that it is absent or already closed in about 30 per cent of newborn infants (Rudolph *et al.* 1961). Its fibrous remnant is termed the '*ligamentum' venosum* of the liver. Following ligation of the umbilical cord, the umbilical (hypogastric) arteries become thrombosed from the point at which they give off their last branches—the superior vesical arteries—to the umbilicus. They are subsequently converted into fibrous cords which lie in the extra-peritoneal fatty tissue of the abdominal wall and produce the *medial umbilical folds* of peritoneum.

Obliteration of the ductus arteriosus is also essential. This channel contracts rapidly at first. Blood probably flows

intermittently through it for a week or two after birth. The direction of blood flow in this vessel is reversed, due to a rise in the systemic vascular resistance resulting from exclusion of the placental circulation and a fall in the pulmonary resistance with expansion of the lungs. When blood flows through the narrowed ductus arteriosus loud murmurs may be heard over the left chest (Burnard 1959). Anatomical closure of the ductus arteriosus occurs by proliferation of the lining endothelium but takes some months to complete. The initial constriction of the ductus arteriosus at birth has been attributed to a direct effect of the raised oxygen tension in the blood on its muscular wall. A nervous factor may also be involved, for the muscular wall is provided with both afferent and efferent nerve endings and responds to adrenalin and noradrenalin (Barcroft 1941; Franklin 1939; Barclay *et al.* 1942).

Before birth the ductus arteriosus is the direct continuation of the pulmonary trunk, and has a similar calibre. Ultimately it becomes an impervious cord which connects the left pulmonary artery (near its origin) with the arch of the aorta, the *ligamentum arteriosum*. For a general review of perinatal vascular changes *see* Dawes (1969).

Abnormalities of the Heart

Malformations of the heart are relatively common and probably represent about one-quarter of all developmental abnormalities. Their incidence is estimated at 6 per 1,000 live births and about 2 per cent of stillbirths. Owing to a heavy early mortality, the incidence in older children is about a half of that in live births. A few cardiac anomalies can be attributed to genetic or environmental factors; the majority are believed to be multifactorial and genetic factors may be effective only in certain environmental conditions (Abbot 1936; Brown 1950; Taussig 1961; Hudson and Wendell-Smith 1966).

Complete absence of the heart, *acardia*, is a rare anomaly. The most recent surveys account for 155 cases (Napolitani and Schreiber 1960; Severn and Holyoke 1973), with an estimated incidence of 1 in 34,600 births (Gillian and Hendricks 1957). Afflicted individuals are almost always monochorionic twins, depending for their development upon the other twin's heart.

1. Abnormalities of Position

(*a*) The position of the heart may be completely reversed so that the apex is directed towards the right instead of the left. This condition is associated with mirror image positioning of the great vessels and of the aortic arch. It may be a part of general transposition of the viscera or *situs inversus*, or the condition may affect only the heart (*dextrocardia*).

(*b*) *Ectopia cordis*. The heart may project on the surface of the thorax through a gap in the lower part of the chest wall. This is associated with a breakdown of the thin body wall and anterior part of the pericardium at a very early stage of development.

2. Abnormalities Due to Failure of Normal Developmental Processes

This group includes the majority of anomalies, of which the commonest is a complete or partial failure of division of the common chambers of the heart into right and left. In the complete form there is a persistence of a common atrium or common ventricle or both (*cor triloculare* and *cor biloculare*). When incomplete, the defects involve the interatrial septum, the interventricular septum or both these septa, or failure of division of the bulbus cordis and truncus arteriosus. The defects in each case tend to occur at specific sites.

(*a*) **Atrial septal defects.**

(i) *Defects of the ostium secundum*. The persistence of a slit-like communication between the right and left atria is common and results from failure of fusion, after birth, of the septum primum with the margin of the septum secundum. It is rarely of functional importance. The communication may be large if the septum primum is insufficient to occlude the foramen ovale.

(ii) *Persistence of an ostium primum*. The normal occlusion of the ostium primum by the union of the free edge of the septum primum with the fused atrioventricular cushions fails to occur. This is often associated with malformation of the septal cusp of the tricuspid valve or of the posterior cusp of the mitral valve, and sometimes with underdevelopment of the septum secundum.

(iii) *Other atrial septal defects*. Rarely defects occur dorsal to the fossa ovalis. These may be associated with drainage of pulmonary veins into the right atrium. They are difficult to explain in terms of normal developmental processes.

(*b*) **Ventricular septal defects.**

(i) *Defects of the membranous part*. The commonest defect is situated in the right wall of the outflow channel of the left ventricle, the aortic vestibule, below the commissure between the right and anterior cusps of the aortic valve. Viewed from the right ventricle the defect lies beneath the septal cusp of the tricuspid valve and below the *supraventricular crest* (p. 645). It results from the failure of development of the membranous part of the interventricular septum. This defect rarely occurs alone and is usually associated with an overriding of the muscular part of the interventricular septum by the aortic orifice, pulmonary stenosis or atresia and hypertrophy of the right ventricle (*Fallot's tetralogy*). Rarely the pulmonary trunk is normal or even dilated (*Eisenmenger's complex*). This defect in the interventricular septum may also be associated with transposition of the great vessels (*vide infra*) in which it is the pulmonary trunk which overrides the muscular part of the interventricular septum (*Tausig-Bing syndrome*). In these interventricular septal defects the atrioventricular bundle and its right and left limbs are in most cases found along the postero-inferior margin of the defect; occasionally they lie on the anterior margin (Campbell 1965).

(ii) *Defects of the proximal bulbar septum*. Less commonly a defect occurs in that part of the interventricular septum which is formed from the bulbar ridges. The defect is found below the commissure between left and posterior cusps of the pulmonary valve and between the anterior and right cusps of the aortic valve. It constitutes a communication between the outflow channels of the two ventricles.

(iii) *Defects of the muscular part*. Rarely, a defect occurs in the muscular part of the interventricular septum (*Maladie de Roget*).

(*c*) **Combined atrial and ventricular septal defects.**

These are usually associated with a persistent common atrioventricular orifice with defects in the adjacent parts of the septa. The defect is bounded below and behind by the free margin of the muscular part of the interventricular septum. The atrioventricular valves are abnormal; there is frequently a superior and inferior cusp common to both sides of the heart and draped across the free border of the muscular interventricular septum.

(*d*) **Persistent truncus arteriosus** (Truex and Bishof 1958).

In this condition a large undivided channel lies above and astride the free margin of the muscular interventricular septum and communicates with both ventricles. The right and left pulmonary arteries arise independently from this channel which continues beyond their origin as the ascending aorta. The persistent truncus arteriosus usually possesses a valve with four semilunar cusps. The defect is due to a failure of development of the bulbar ridges and the aorto-pulmonary septum.

3. Abnormalities Resulting from Defective Progress in some Developmental Process (Truex and Bishof 1958).

(*a*) **Abnormal bulbar and truncal septation.**

(i) *Complete transposition*, in which the aorta arises from the right ventricle and the pulmonary trunk from the left ventricle. This may be associated with an incomplete interventricular septum, or with a defective interventricular septum of the type described above (Tausig-Bing syndrome).

(ii) *Varying degrees of partial transposition of the great arteries*, usually associated with a defective interventricular septum of the type described in (2.*b*. i). In the majority of cases in this category the pulmonary trunk arises from the right ventricle but the position of the aorta varies from one in which it arises wholly from the right ventricle to varying degrees of overriding of the ventricular septum.

(*b*) **Anomalous entry of the great veins.**

(i) *A persistent left superior vena cava* may drain into the

coronary sinus or into the superior aspect of the left atrium.

(ii) *The inferior vena cava* may be duplicated.

(iii) *The right pulmonary vein*, or, less frequently, all the pulmonary veins, may drain into the right atrium. Any of the four pulmonary veins may drain into some part of the systemic venous system in the thorax, or less frequently, in the abdomen.

4. Abnormalities of the Visceral Arches

(*a*) Right aortic arch (*see* p. 187).
(*b*) Patent ductus arteriosus (*see* p. 666).
(*c*) Coarctation of the aorta (*see* p. 710).

Congenital malformations of the heart are often multiple, probably occur more frequently in sibs and in children of consanguineous marriages, but there is a rather low concordance between monozygotic twins. About 20 per cent of all cardiac abnormalities are ventricular septal defects; persistent ductus arteriosus, atrial septal defects, coarctation of the aorta, pulmonary stenosis, Fallot's tetralogy and transposition of the great vessels each account for about 10 per cent and aortic stenosis for about 5 per cent. For a discussion of possible causal mechanisms consult Shaner (1962).

THE ARTERIAL SYSTEM

The Pulmonary Trunk

The pulmonary trunk (**6**.37, 38, 41) conveys deoxygenated blood from the right ventricle of the heart to the lungs (*see* Fishman and Hecht 1969). It is about 5 cm in length and 3 cm in diameter, and arises from the base of the right ventricle above and to the left of the supraventricular crest. It runs upwards and backwards, at first in front of the ascending aorta, and then to its left side. In the concavity of the aortic arch it divides, at the level of the fifth thoracic vertebra, into right and left pulmonary arteries, which are of nearly equal size.

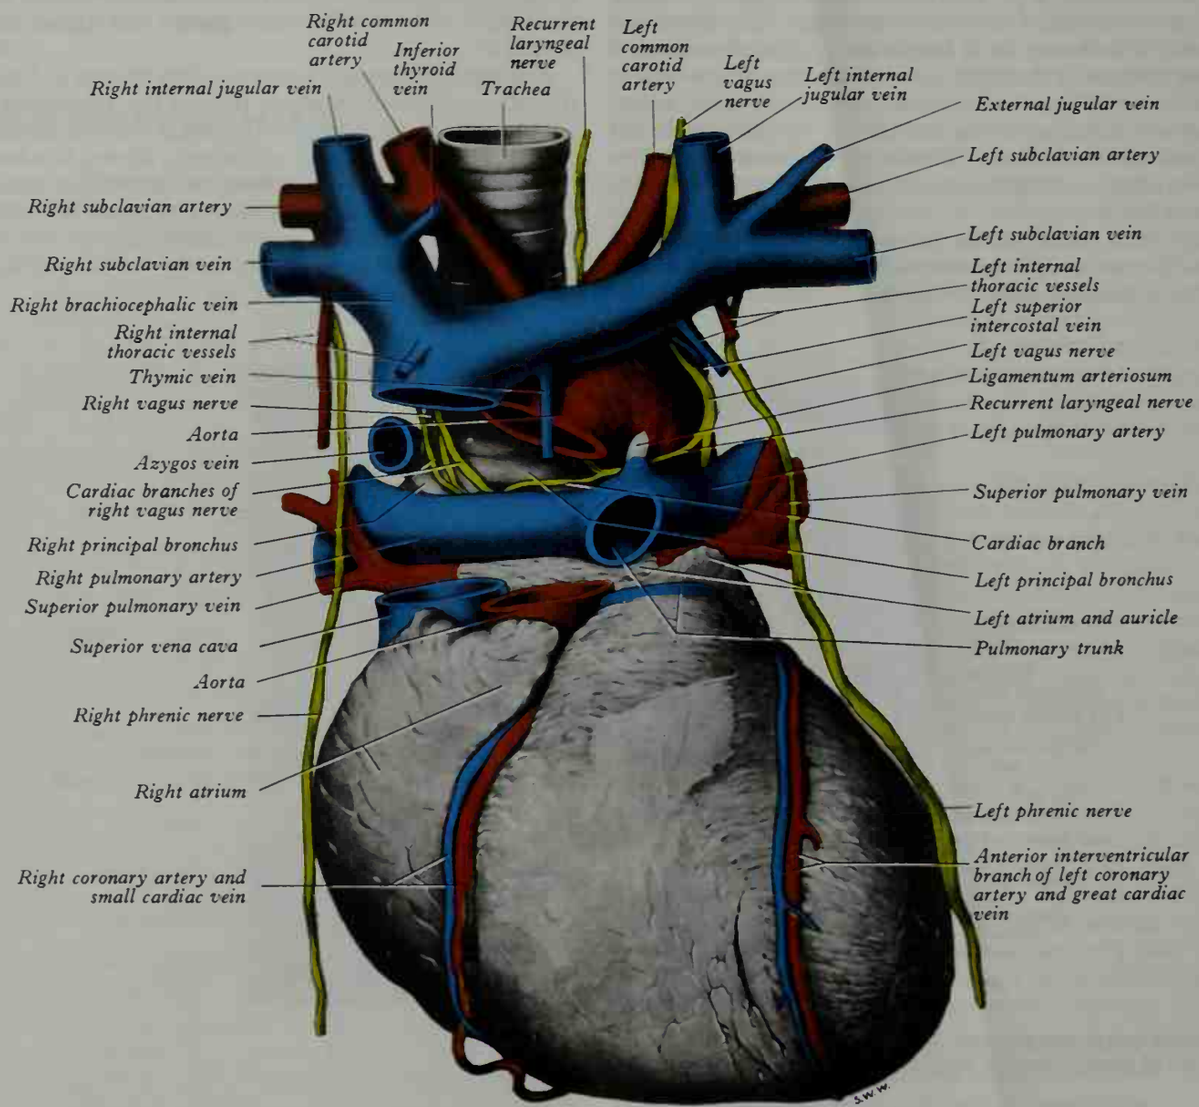
Relations. The whole of the pulmonary trunk is contained within the pericardium. Together with the ascending aorta it is enclosed in a common tube of the visceral layer of the serous pericardium. The fibrous layer of the pericardium is gradually lost upon the external coats of the two pulmonary arteries. *In front*, the pulmonary trunk is separated from the sternal end of the left second intercostal space by the pleura, the left lung and the pericardium. *Behind*, are at first the ascending aorta and the left coronary artery; at a higher level the pulmonary trunk lies in front of the left atrium, and the ascending aorta is on its right side. The auricle of the corresponding atrium and a coronary artery lie on each side of its origin. The superficial part of the cardiac plexus lies between the division of the pulmonary trunk and the arch of the aorta.

The right pulmonary artery, slightly longer and larger than the left, runs horizontally to the right, behind the ascending aorta, superior vena cava and upper right pulmonary vein, and in front of the oesophagus and the right bronchus, to the root of the right lung, where it divides into two branches. The lower and larger of these is distributed to the middle and lower lobes of the lung; the upper and smaller accompanies the upper right lobar bronchus.

The left pulmonary artery, a little shorter and smaller than the right, runs horizontally in front of the descending aorta and left bronchus to the root of the left lung, where it divides into two branches, one for each lobe of the lung. Above, it is connected to the concavity of the aortic arch by the ligamentum arteriosum, on the left of which is the left recurrent laryngeal nerve, and on the right the superficial part of the cardiac plexus. The pericardial fold of the left vena cava (p. 635) passes from its lower border to the upper left pulmonary vein.

6.37 A transverse section through the mediastinum at the level of the upper border of the fifth thoracic vertebra. Superior aspect.

The pattern of branching of the right and left pulmonary arteries shows little variation (except in cases of dextrocardia, where the lobation of the lungs may also be reversed). Cory and Valentine (1959) found the above pattern constant in all 34 right and all 80 left of 114 pulmonary arteries observed at operation (*see* also p. 1265).



The treatment of congenital stenosis of the pulmonary trunk, both with and without an associated 'right to left intracardiac shunt' has advanced rapidly in recent years from the indirect 'systemic/pulmonary vessel anastomosis' (Blalock 1947), to the direct blind approach to the narrow pulmonary orifice and right ventricular outflow tract (Brock 1949), and finally via the open dry heart techniques employing hypothermia or suitable pump/oxygenator circulatory replacement machines.

THE AORTA

The aorta is the main trunk of the system of vessels which convey the oxygenated blood to the tissues of the body. It begins at the upper part of the left ventricle, where it is about 3 cm in diameter, and after passing upwards and to the right for about 5 cm, arches backwards and to the left, over the root of the left lung; it then descends within the thorax on the left side of the vertebral column, gradually inclining towards the median plane, and enters the abdominal cavity through the aortic hiatus in the diaphragm. Considerably diminished in size (about 1·75 cm in diameter), it ends a little to the left of the median plane, at the level of the lower border of the fourth lumbar vertebra, by dividing into the right and left common iliac arteries. For convenience it is described in several portions, viz. *ascending*, the *arch*, and *descending*, the last being divided into *thoracic* and *abdominal* parts.

small dilatations called the *aortic sinuses*. At the continuation of the ascending aorta as the aortic arch the calibre of the vessel is slightly increased, owing to a bulging of its right wall. This dilatation is termed the *bulb of the aorta*, and, on transverse section at this level, the vessel presents a somewhat oval outline.

Relations. The ascending aorta is contained within the fibrous pericardium, and is enclosed in a tube of the serous pericardium, common to it and the pulmonary trunk (**6**.13). *Anteriorly*, its lower part is related to the infundibulum of the right ventricle (p. 640), the commencement of the pulmonary trunk and the auricle of the right atrium; higher up, it is separated from the sternum by the pericardium, the right pleura, the anterior margin of the right lung, some loose areolar tissue and the remains of the thymus; *posteriorly*, it is related successively to the left atrium, the

6.38 The relations of the pulmonary arteries and primary bronchi seen from the front. Parts of the ascending aorta, pulmonary trunk and superior vena cava have been removed in the dissection. The right vagal trunk is uncoloured to avoid confusion.

The Ascending Aorta

The ascending aorta (**6**.14, 37, 38, 40) is about 5 cm long. It begins at the base of the left ventricle, on a level with the lower borders of the third costal cartilage, behind the left half of the sternum; it passes obliquely upwards, forwards and to the right, behind the sternum, as high as the upper border of the second right costal cartilage, describing a slight curve in its course. At its origin, immediately distal to the cusps of the aortic valve, there are three

right pulmonary artery and the right principal bronchus; on its *right side*, to the superior vena cava and right atrium, the former lying partly behind it; on its *left side*, first to the left atrium and, at a higher level, to the pulmonary trunk.

At least two small bodies, believed to be chemoreceptors and similar in structure to the carotid body (p. 1462), lie between the ascending aorta and pulmonary trunk. One, sometimes termed the *inferior aorticopulmonary body*, lies close to the heart and anterior to the aorta; the other, sometimes termed the *middle*

aorticopulmonary body, lies higher up and towards the right side of the ascending aorta (Boyd 1961).

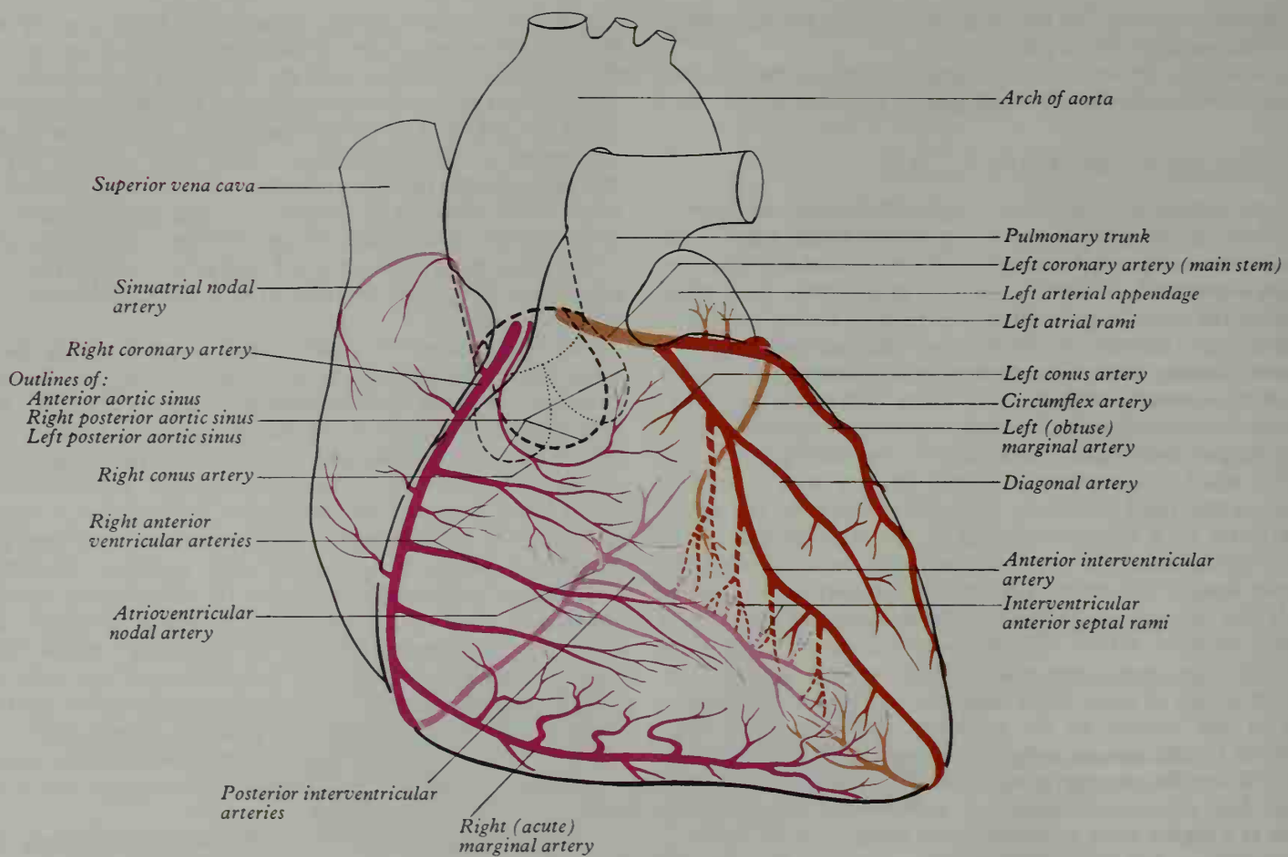
Branches. The branches of the ascending aorta are the right and left coronary arteries (**6**.39), which supply the heart itself.

THE CORONARY ARTERIES (**6**.39A–F)

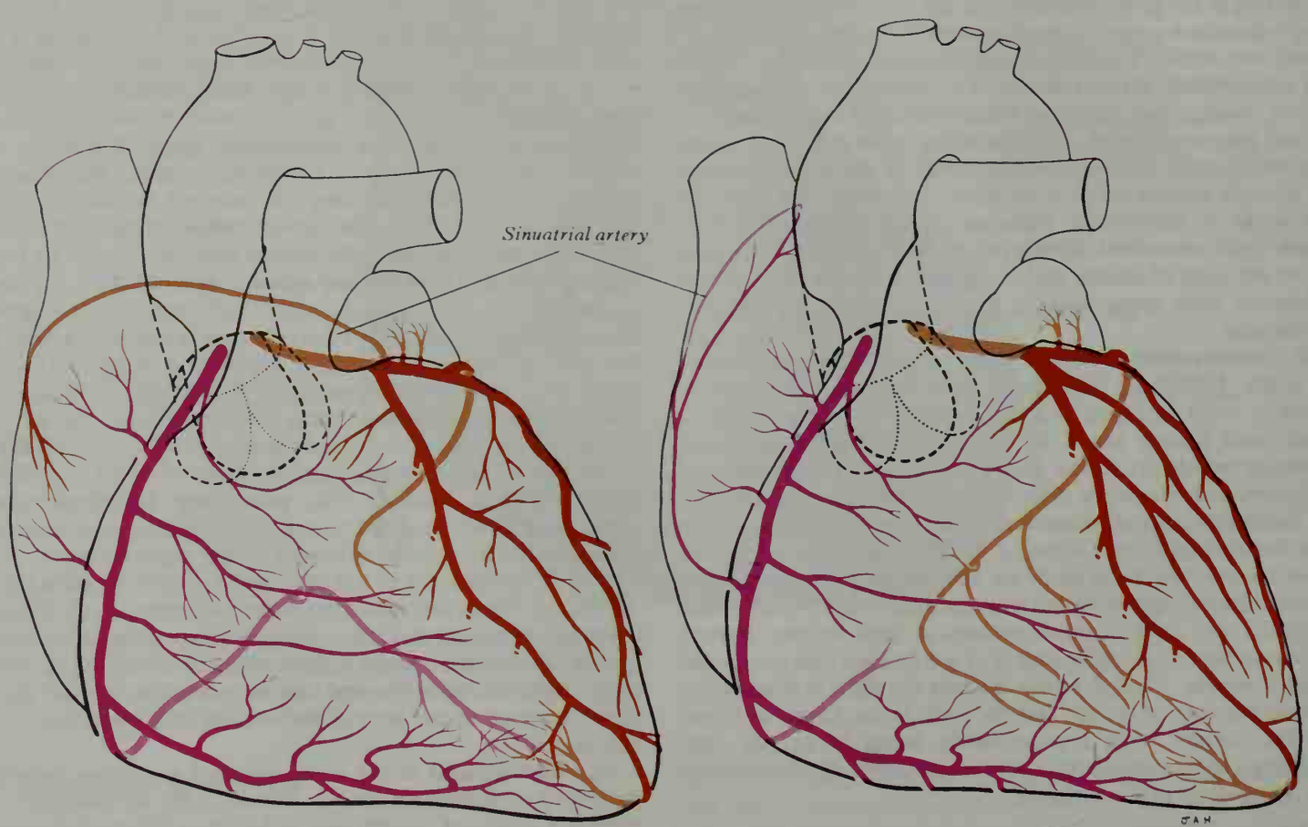
The right and left coronary arteries open off the ascending part of the aorta from the anterior and left posterior aortic sinuses. (In clinical terminology these are called the right and left coronary sinuses, respectively, whilst the official right posterior aortic sinus is termed the non-coronary sinus.) Variations in this pattern of origin are rare, but the two vessels may start, separately or by a common opening, from the same aortic sinus. Sometimes three or even four coronary arteries have been observed. The most common variation concerns the ramus of the right coronary artery which suppies the arterial conus (*arteria coni arteriosi* or 'conus artery'), which in the majority of cases (64 per cent) is the first branch of the right coronary; frequently, however, the conus artery arises by a separate opening in the external wall of the anterior aortic sinus (36 per cent), and thus constitutes a third coronary artery. The opening of the left coronary artery may be double, the two orifices leading into the major initial branches of the left coronary artery, usually the circumflex and anterior interventricular rami, one occasionally leading into a stem common to one of these and a diagonal ventricular ramus. The levels of the orifices of the coronary arteries are variable. Thebesius (1708) appears to have initiated a view that the aortic cusps obstruct the openings when the aortic valve is fully patent in systole; but subsequent observers have found the coronary orifices at a higher level, at or above the margins of the cusps in most specimens, but below in about 10 per cent (right coronary) and 15 per cent (left).

The general arrangement of the two coronary arteries is indicated by their name, for they form an obliquely inverted *crown*, consisting of an anastomotic *circle* in the atrioventricular sulcus connected by marginal and interventricular *loops* intersecting at the apex of the heart (**6**.39). This is, of course, only an approximate description, and the degree of anastomosis is most variable and usually functionally insignificant (*vide infra*). These main arteries and their major rami are usually sub-epicardial in position, but especially those which are placed in the atrioventricular and interventricular sulci are often quite deeply situated, being occasionally hidden by overlapping lips of myocardium and even actually embedded in it. Strands of myocardium may also cross atrial or ventricular branches of the coronary system; Polacek (1961) described them as present in the ventricles of more than 80 per cent of hearts, and Bloor and Lowman (1963) have emphasized their importance in the interpretation of coronary arteriograms.

The diameters of the coronary arteries, both of their main stems and larger branches, have been recorded by a number of observers; even ignoring individual and sexual variations in calibre, such figures are of limited value, since the technique involved is not always stated, physiological state is often ignored as a factor, and observers do not always indicate whether they have measured external diameters (including wall thickness) or actual luminal calibres. Calibre is usually the basis, since most measurements have been made on arterial casts or angiograms. The maximum ranges recorded in major studies are 1·5 to 5·5 mm for the left and right coronary arteries at their origins. Baroldi and Scomazzoni (1967) give means of 4·0 and 3·2 mm for the left and right vessels. The left artery exceeds the right in diameter in about 60 per cent of hearts, and the right is the larger in 17 per cent, the vessels being approximately equal in 23 per cent. Vogelberg (1957) considered that the coronary diameters show some increase up to the 30th year.



The Right Coronary Artery

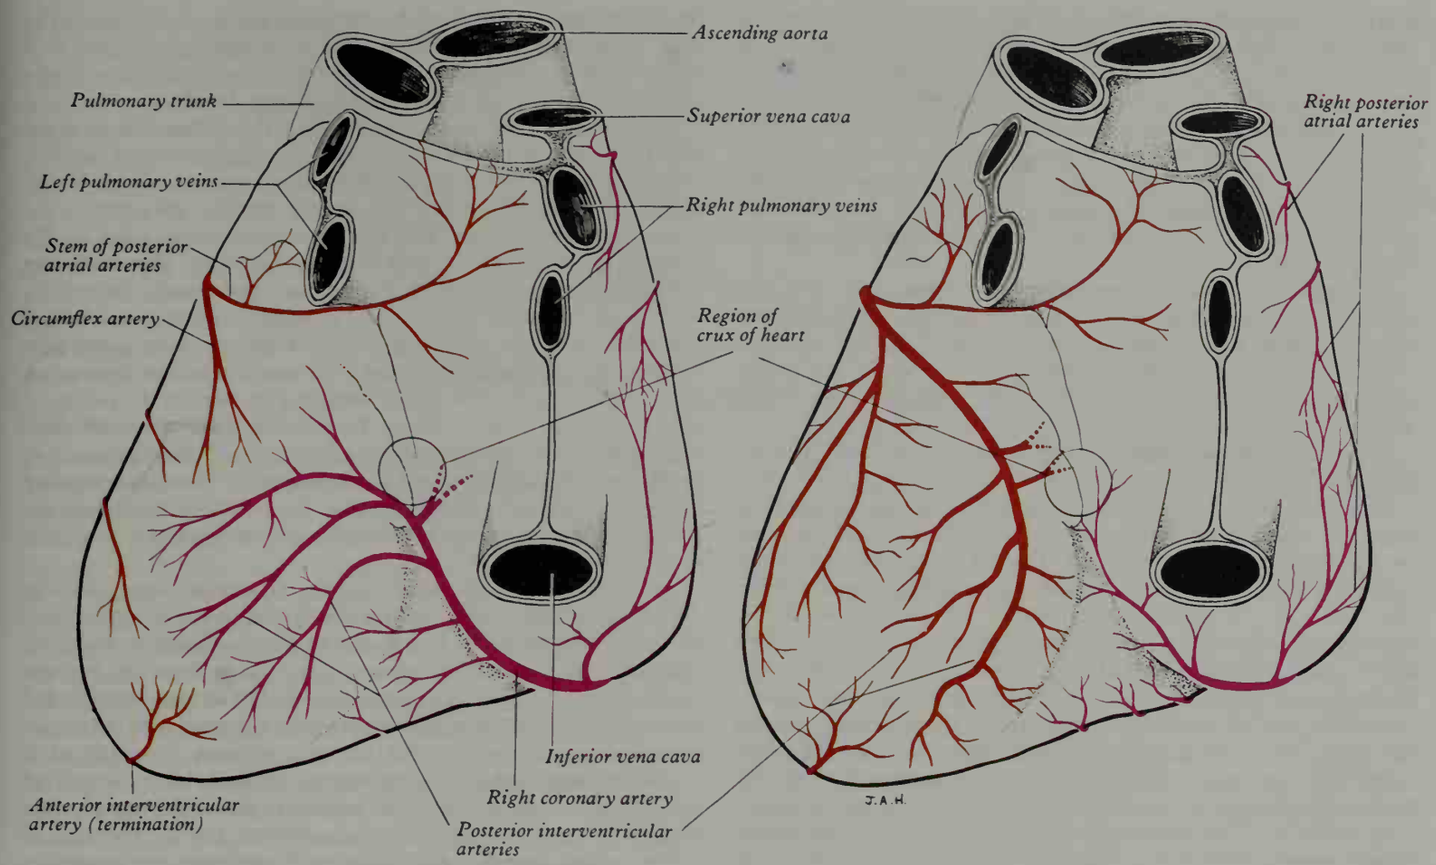


Arising from the anterior ('right coronary') aortic sinus, the right coronary artery passes at first anteriorly and slightly to the right between the right auricular appendage and the pulmonary trunk, between which the sinus usually bulges. Reaching the atrioventricular (coronary) sulcus it descends in this in an almost vertical direction to the right (acute) margin of the heart, curving around this into the posterior part of the sulcus. In this it passes towards the junction of the sulcus with the interatrial and interventricular grooves, a region conveniently named the *crux* of the heart. In about 60 per cent of hearts the artery reaches the crux and terminates a little to the left of this in a variable degree of anastomosis with the circumflex branch of the left coronary. In a minority of instances (*c.* 10 per cent) the right coronary artery ends near the right cardiac margin or between this and the crux (*c.* 10 per cent); more frequently (*c.* 20 per cent) it may even reach the left border of the heart, taking the place of the terminal part of the circumflex artery.

The branches of the right coronary artery supply the right atrium and ventricle and, to a variable extent, parts of the left chambers and the atrioventricular septum. The first branch (which arises separately from the anterior aortic sinus in 36 per cent of cases) is the *conus artery* or 'third coronary artery'; since a similar vessel is derived from the left coronary artery, this branch of the right is more correctly named the *right conus artery*. It ramifies on the anterior aspect of the lowest part of the pulmonary conus and the upper part of the right ventricle. It commonly anastomoses with a similar branch of the left coronary to form the '*annulus of Vieussens*', a somewhat tenuous anastomotic 'circle' around the commencement of the pulmonary trunk. Various observers differ greatly in their descriptions of the conus artery (Baroldi and Scomazzoni 1967), some regarding the right conus artery of particular significance in coronary arterial disease. Some consider it the first ventricular branch of the right coronary, supplying a variable region from the pulmonary conus to the apex.

The anterior atrial and ventricular rami branch from the so-called *first segment of the right coronary*, which extends from its origin to the right margin of the heart. Both sets of vessels diverge from the parent artery at a wide angle, approaching a right angle in the case of the ventricular arteries, in contrast to the more acute origin of the ventricular rami of the left coronary. The **right anterior ventricular rami**, usually 2 or 3 in number, ramify towards the apex, which they rarely reach, unless the **right** ('**acute**') **marginal branch** is included in the group, as it is by some observers. The latter is then the largest anterior ventricular ramus of the right coronary artery, being greater in calibre and long enough to reach the apex in most hearts (93 per cent according to Baroldi and Scomazzoni 1967). When the right ('acute') marginal artery is particularly large, the remaining anterior ventricular rami may be reduced to one or even to complete absence. From the *second segment of the right coronary artery* (i.e. between the right border and the crux) 1 to 3 small **right posterior ventricular rami**, commonly two, supply the diaphragmatic aspect of the right ventricle. Their degree of development is reciprocal to that of the right marginal artery, as in the case of the anterior right ventricular supply, the right marginal usually extending on to the diaphragmatic surface. The posterior right ventricular rami may be absent. As the right coronary approaches the crux of the cardiac sulci, it produces 1 to 3 posterior interventricular rami, only one of which occupies the interventricular sulcus. The **posterior interventricular artery** is singular in about 70 per cent of hearts, otherwise being accompanied by parallel branches of the right coronary, which may occur to the right or left of it, or be present on both sides of the sulcus. When these flanking vessels are present, the branches of the posterior (descending) interventricular artery are small and sparse; when it exists alone it gives off a few branches particularly to the right ventricle but also one or two to the left. Its place is taken in about 10 per cent of individuals by a branch of the left coronary artery.

The **atrial rami** of the right coronary artery are sometimes described as forming anterior, lateral (right or marginal), and posterior *groups* of vessels, but in fact they are most frequently single, small vessels of an average diameter of about 1 mm. The right anterior and lateral atrial arteries are occasionally double and, very rarely, triple; they are distributed chiefly to the right atrium. The posterior ramus is usually single, and is distributed to the right and left atria; but in a large minority of hearts (40 per cent or more) there is also a left posterior atrial branch of the right



6.39A–C Anterior views of the coronary arterial system, with the principal variations.

A The commonest arrangement.

B A common variation in the origin of the sinuatrial nodal artery.

C An example of *left* 'dominance' by the left coronary artery, showing also an uncommon origin of the sinuatrial artery.

Note that in 39A to E the right coronary arterial tree is shown in *magenta*, the left in *full red*. In both cases posterior distribution is shown in a paler shade.

6.39D, E Postero-inferior views of the coronary arterial system.
D An example of the more normal distribution in *right* 'dominance'.
E A less common form of *left* 'dominance'.
N.B. In these 'posterior' views the diaphragmatic (inferior) surface of the ventricular part of the heart has been artificially displaced, and foreshortening ignored, to clarify the details of the so-called posterior (inferior) distribution of the coronary arteries.

coronary. The **artery of the sinuatrial node** may be regarded as an atrial artery, since it is distributed largely to the myocardium of both atria, principally the right. The site of origin of this vessel is variable; it is a branch of the *left* coronary artery in about 35 per cent of hearts (Hutchinson 1978), arising from its circumflex branch (*vide infra*). When a branch of the right coronary, it stems from its anterior, initial segment most frequently, less often from the right lateral part of its course, and with least frequency from the posterior atrioventricular part of its course. Most commonly this 'nodal' artery passes backwards from the proximal trunk of the right coronary in the sulcus between the right auricular appendage and the aorta, a disposition of obvious surgical importance. Whatever its origin the artery of the sinuatrial node usually branches around the base of the superior vena cava, commonly forming an *arterial loop* around the vein, from which small rami branch off to supply the right atrium. A large branch of the vessel, the so-called '*ramus cristae terminalis*' (Spalteholz 1924), passes into the sinuatrial node and transverses it (**6.39**); it is this ramus which should, perhaps, be named the artery of the sinuatrial node, since the rest of the vessel supplies the atria. A more appropriate name, the '*main atrial branch*' of the right coronary, has been suggested by Baroldi and Scomazzoni (1967).

The **septal rami** of the right coronary artery are relatively short vessels, which pass from the posterior interventricular ramus into the posterior region of the interventricular septum. They are numerous, but they do not usually reach the apical part of the septum (which is supplied by the septal branches of the termination of the anterior interventricular artery). The first, and usually the largest of these posterior septal arteries, is the first such branch, commonly arising from the *inverted loop* which is said to characterize the right coronary artery at the crux of the heart, where the posterior interventricular artery is derived from it. It is this **large posterior septal artery** which usually supplies the **atrioventricular node**—in 80 per cent of hearts, according to Hutchinson (1978).

DiDio (1967) has described *atrioventricular rami* of the right coronary artery. These are small recurrent branches from either ventricular arteries, crossing the atrioventricular sulcus to supply the adjoining atrial myocardium, or ventricular twigs from atrial arteries.

The Left Coronary Artery

As stated above, the left coronary artery is distinctly larger in calibre than the right; it supplies a much greater *volume* of myocardium, being distributed to almost the whole of the left ventricle and left atrium, except in those instances of so-called 'right dominance' previously mentioned, where the right coronary supplies a variable part of the posterior region of the left ventricle. Most commonly, also, the left coronary artery supplies most of the interventricular septum.

The initial trunk of the artery, between its opening from the left posterior ('left coronary') aortic sinus and the vessel's first branches, varies from a few millimetres to a few centimetres in length. It lies between the pulmonary trunk and the left auricular appendage, emerging to reach the atrioventricular sulcus, in which it turns to the left. This part of the artery is loosely embedded in subepicardial fat. In general it has no branches, but a small atrial twig sometimes occurs, and very occasionally, according to James (1961), the *artery of the sinuatrial node* may be derived from the left coronary trunk. However, the latter branch, when a ramus of the left coronary, almost always arises from its circumflex branch and will be described with this artery below. As it reaches the atrioventricular or coronary sulcus, the left coronary artery divides into two or three main branches, one of which, the **anterior interventricular (descending) ramus** is commonly described as the continuation of the left coronary

artery. It descends obliquely forward and to the left in the interventricular sulcus, sometimes deeply embedded in it, and crossed by occasional bridges of myocardial tissue and by the great cardiac vein and its tributaries. The artery reaches the apex of the heart almost always, terminating there in about one third of specimens, but most commonly turning around the apex into the posterior (inferior) interventricular sulcus. It passes along the sulcus for a few centimetres, usually for a third to a half of its length, to meet the terminal twigs of the corresponding ramus of the right coronary artery.

The **anterior interventricular artery** produces right and left anterior ventricular and anterior septal branches, and, to a variable extent, corresponding posterior rami. The *right anterior ventricular rami* of the left coronary artery are small, and rarely more than one or two in number, the right ventricle being supplied almost exclusively from the right coronary artery.

The **left anterior ventricular arteries** are large vessels, from 2 to 9 in number, which branch at acute angles from the anterior interventricular to course *diagonally* across the anterior aspect of the left ventricle, their larger terminals reaching the rounded left border of the heart. One of these vessels is often especially large and prominent and it may arise separately from the trunk of the left coronary artery (which then ends by trifurcation rather than the more usual bifurcation), and it is then known as the **left diagonal artery**. A left diagonal artery occurs in 33–50 per cent or more of hearts, according to various observers; very occasionally (20 per cent) it is duplicated. A small *left conus artery* frequently branches from the anterior interventricular artery, near its beginning, and anastomoses on the conus with the conus branch of the right coronary, and with the vasa vasorum of the pulmonary artery and aorta. The **anterior septal rami** of the anterior interventricular artery branch off almost perpendicularly, passing backwards and downwards in the substance of the septum, of which they usually supply about the ventral two-thirds. Small *posterior septal rami* from the same source supply the posterior third or so of the septum for a variable distance from the apex.

The **circumflex artery**, usually comparable with the anterior interventricular artery in calibre, curves to the left border of the heart in the atrioventricular sulcus, continuing round into the posterior part of the sulcus to terminate a little to the left of the crux in the majority of hearts, but sometimes continuing as a posterior interventricular artery. Its proximal part is commonly overlapped by the left auricular appendage. In about 90 per cent of hearts a large ventricular branch, the **left** ('**obtuse**') **marginal artery**, arises perpendicularly from the circumflex and ramifies over the rounded left margin of the heart, supplying much of that region of the left ventricle—it usually reaches the apex of the heart. Smaller anterior and posterior ventricular rami of the circumflex artery also supply the left ventricle. The **anterior ventricular branches** (1 to 5 in number, but usually limited to 2 or 3) course over the left ventricle parallel to the diagonal artery, when present, and replacing it when absent. The **posterior ventricular branches** are somewhat smaller and less numerous, since the left ventricle is partly supplied by rami of the posterior interventricular artery. When the latter is small or absent, it is accompanied by, or replaced by, an interventricular continuation of the circumflex artery. Such a **left posterior interventricular artery** is frequently double or triple. **Atrial rami**, both anterior, lateral, and posterior, spring from the circumflex artery to supply the left atrium.

Three inconstant branches of the circumflex artery require description. The **artery to the sinuatrial node** is a branch of the circumflex in about 35 per cent of hearts (Hutchinson 1978), usually from its anterior segment, less often from its circummarginal part. This artery passes over the left atrium, supplying it and then encircling the termination of the superior vena cava, as in the case of a nodal artery from the right coronary. Similarly, also, it sends a large branch into the sinuatrial node, but is largely an atrial vessel in distribution. The **artery to the atrioventricular node** is a terminal ramus of the circumflex artery in 20 per cent of hearts, arising near the crux, and in such specimens the circumflex usually supplies the posterior interventricular ramus, providing an example of so-called 'left dominance' (*vide infra*). The third branch of the circumflex to be mentioned here is *Kugel's anastomotic artery*, the '*arteria anastomotica auricularis magna*'. Kugel (1927) described this as a constant branch of the circumflex artery, usually from its anterior part, which traverses the interatrial septum (near its ventricular border) to establish some degree of direct or indirect anastomosis with the right coronary artery. The existence of this anastomosis is a matter of controversy, being apparently accepted by James (1974), but denied by Baroldi and Scomazzoni (1967). James regards it as an auxiliary supply to the atrioventricular node.

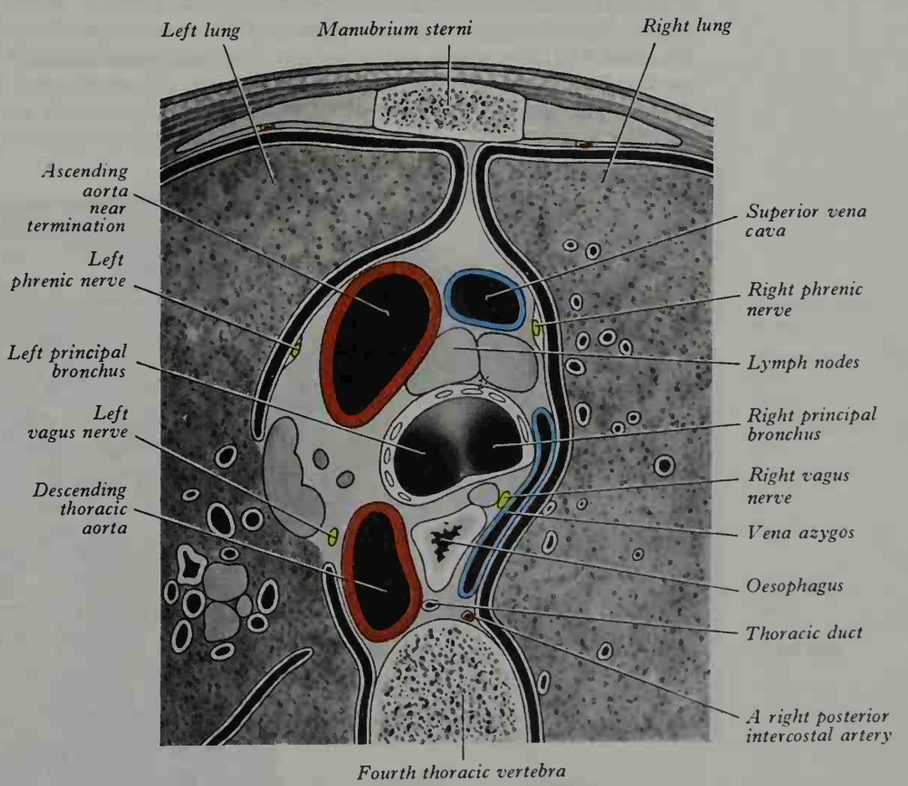
The foregoing details of distribution of the separate coronary arteries require some integration to provide a total concept of cardiac supply. In the commonest arrangement the right coronary artery supplies the whole of the right ventricle (except for a very small region on its own side of the anterior interventricular groove), a variable part on the diaphragmatic aspect of the left ventricle, the postero-inferior third of the intraventricular septum, the right atrium and part of the left, and the conducting system as far as the proximal parts of the right and left bundle branches. The distribution of the left coronary artery is, of course, reciprocal and includes most of the left ventricle (apart from the diaphragmatic region referred to above), a narrow strip of right ventricle (*vide supra*), the anterior two thirds of the interventricular septum, and most of the left atrium. As already mentioned above, and depicted in illustration **6**.39, variations from the distributions just outlined chiefly affect the diaphragmatic aspect of the ventricles; and these reside in the relative '*dominance*' of supply by the left or right coronary artery. The term is, of course, misleading, since it is clear that the left artery almost always supplies a greater *volume* of tissue. In '*right dominance*' the posterior interventricular is derived from the right coronary and in '*left dominance*' from the left. In the so-called '*balanced*' type of pattern branches of both arteries run in or parallel to the interventricular sulcus. Less is known of the variations in atrial supply, because the small vessels involved are not easily preserved and studied in corrosion casts. From Hutchinson's results (1978) it is apparent that in over 50 per cent of hearts the right atrium is supplied by the right coronary alone, the remainder receiving a dual supply. More than 62 per cent of left atria are supplied by the left coronary and about 27 per cent by

6.39F A composite coloured resin cast; in *red* are the aortic root, aortic sinuses, and coronary arteries; in *blue* are the pulmonary trunk and sinuses, and the coronary sinus and its tributaries. Note reduplication of the right coronary artery; the smaller of these vessels is known as the artery of the conus. Note particularly the septal arterial and venous rami. (See text for detailed account.)

the right, but in each group there is a small accessory supply from the other coronary artery, the remainder being supplied almost equally by both arteries. The sinuatrial and atrioventricular nodes also vary in their sources of supply. According to James (1961) the right and left coronary arteries are the source of vessels to the sinuatrial node in 55 per cent and 45 per cent of hearts, the corresponding values from Baroldi and Scomazzoni's study (1967) being 51 per cent and 41 per cent (8 per cent receiving a bilateral supply), whilst figures from Hutchinson (1978) are 65 per cent and 35 per cent. For the atrioventricular node James's values are 90 per cent (right coronary) and 10 per cent (left coronary); Hutchinson's figures are 80 per cent (right coronary) and 20 per cent (left coronary), while Baroldi and Scomazzoni merely state that a right coronary supply is common and a left supply rare.

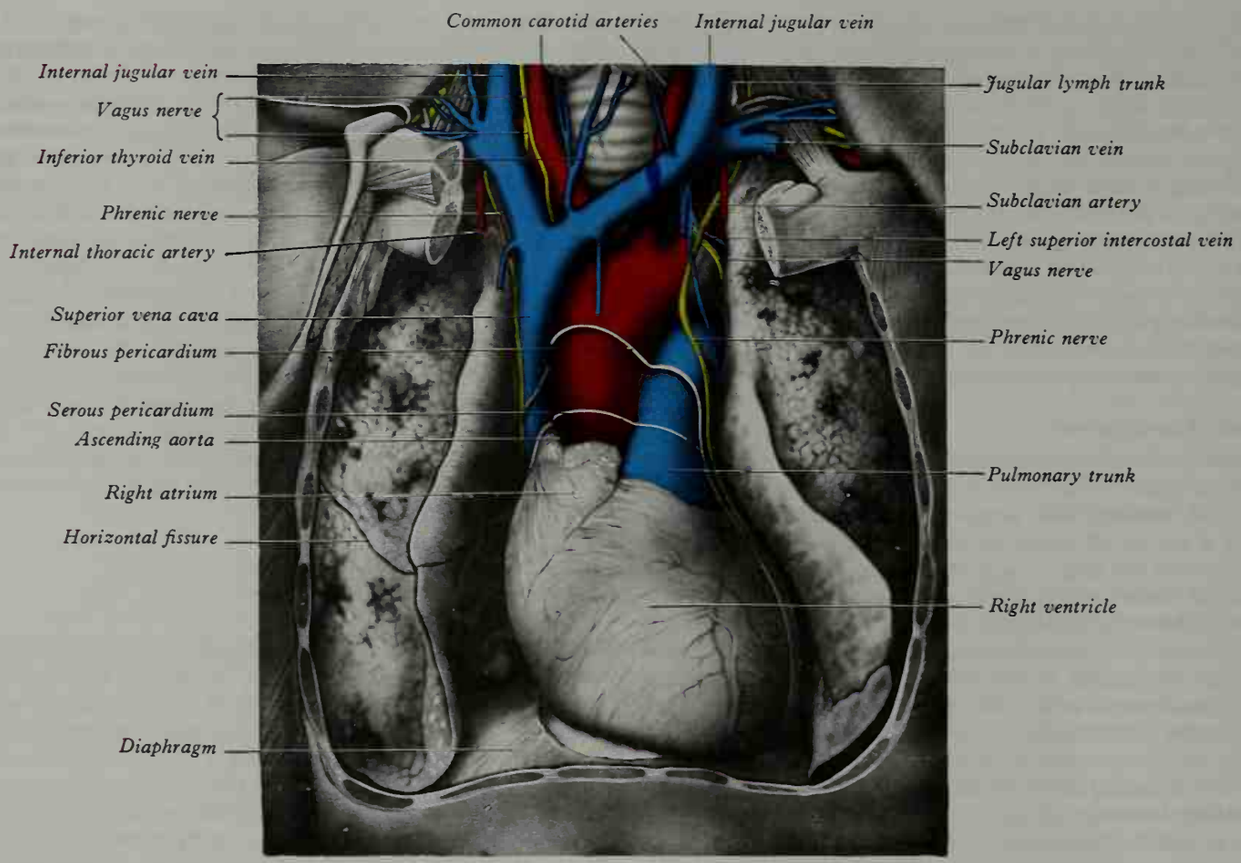
Coronary Anastomosis

The existence of anastomoses between the branches of the two coronary arteries, whether subepicardial or myocardial in location, and between these arteries and extracardiac vessels, is obviously a matter of prime medical importance. Because the clinical evidence has largely suggested that such anastomoses are not of much demonstrable functional value, i.e. in providing rapidly available collateral routes to circumvent relatively sudden coronary obstruction, it has become widely customary to regard the coronary circulation as end-arterial in character. Nevertheless, the existence of anastomoses, particularly between finer branches of the subepicardial rami has long been recognized, and according to Gross (1921), such anastomoses may improve through the advancing life of the individual. Moreover, those who have actually investigated the coronary arteries—whether by injection of radio-opaque perfusants (Vastesueger *et al.* 1957, using post mortem hearts, Laurie and Woods 1958, using *in vivo* coronary radiography), by perfusion with calibrated spherules (Prinzmetal *et al.* 1947), or by injection of plastic resins with subsequent production of corrosion casts (Baroldi *et al.* 1956; James 1961)—have almost all recorded the existence of anastomoses, and in arterial vessels of a calibre as much as 100 to 200 μm. Baroldi and Scomazzoni (1967) have tabulated the results of a large number of investigations carried out since 1880, and it is noticeable in their analysis that no study denying the occurrence of anastomoses has been recorded since 1957. Some workers, however, describe anastomoses as occurring only between the branches of individual coronary arteries; nevertheless, the majority have recorded *intercoronary* anastomoses. James (1974) considers the evidence for anastomoses at all levels, subepicardial (extramural), myocardial (mural), and subendocardial, to be conclusive. He considered the most frequent sites of extramural anastomoses to be the apex, anterior aspect of the right ventricle, the posterior aspect of the left ventricle, the crux, along the interatrial and interventricular sulci, and between the artery of the sinuatrial node and other atrial vessels. It is generally conceded that the functional value of such anastomoses must be extremely variable, though the evidence suggests that they may become more effective in pathological conditions of comparatively slow onset. The precise structure of coronary anastomoses is not fully clarified; most observations depend upon appearances in corrosion casts. These suggest that the anastomotic vessels are relatively straight in normal hearts, but may be much coiled in hearts previously subjected to episodes of coronary occlusion, indicating, perhaps, that they are exposed to greater pressures in pathological states. Little has been recorded of their microscopic structure, but they appear to be little more than endothelial tubes, unsupported by non-striated muscle or elastic tissue.



Extracardiac anastomoses are connexions between various branches of the coronary arteries and other vessels in the thorax, through the medium of pericardial arteries and the arterial vasa vasorum of veins and arteries linking the heart with the systemic and pulmonary circulations. The classic study of Hudson *et al.* (1932) demonstrated that coronary injections of India ink could reach as far as the diaphragm through the aortic vasa vasorum, thus connecting with pericardial, mediastinal, and diaphragmatic arteries. Similar connexions along the pulmonary trunk reach mediastinal and bronchial arteries, and connexions also exist along the pulmonary veins and the venae cavae. These results have been confirmed (Baroldi and Scomazzoni 1967), but in this case also, the effectiveness of these connexions as collateral routes in supplying the heart is unpredictable.

Arteriovenous anastomoses were considered to be present in the coronary circulation by Nussbaum (1912); his evidence was indirect, but Hirsch (1960) described structures like glomera, with a characteristic sphincteric appearance (p. 632), as present in the cardiac sulci. These findings have aroused much controversy and the occurrence of such structures must be regarded as at present uncertain. Various other forms of 'arteriovenous' connexions have been described by many workers. Wearn *et al.* (1933) recorded the existence of numerous connexions through very thin-walled 'arterial' vessels between the coronary circulation and the heart cavities, naming them '*myocardial sinusoids*' and '*arterio-luminal*' vessels. Their existence has been frequently confirmed (*see*, for example, Watanabe 1960), and indirect evidence of them, derived from perfusion experiments, dates back as far as Vieussens (1706). The value of these connexions in coronary disease is uncertain.

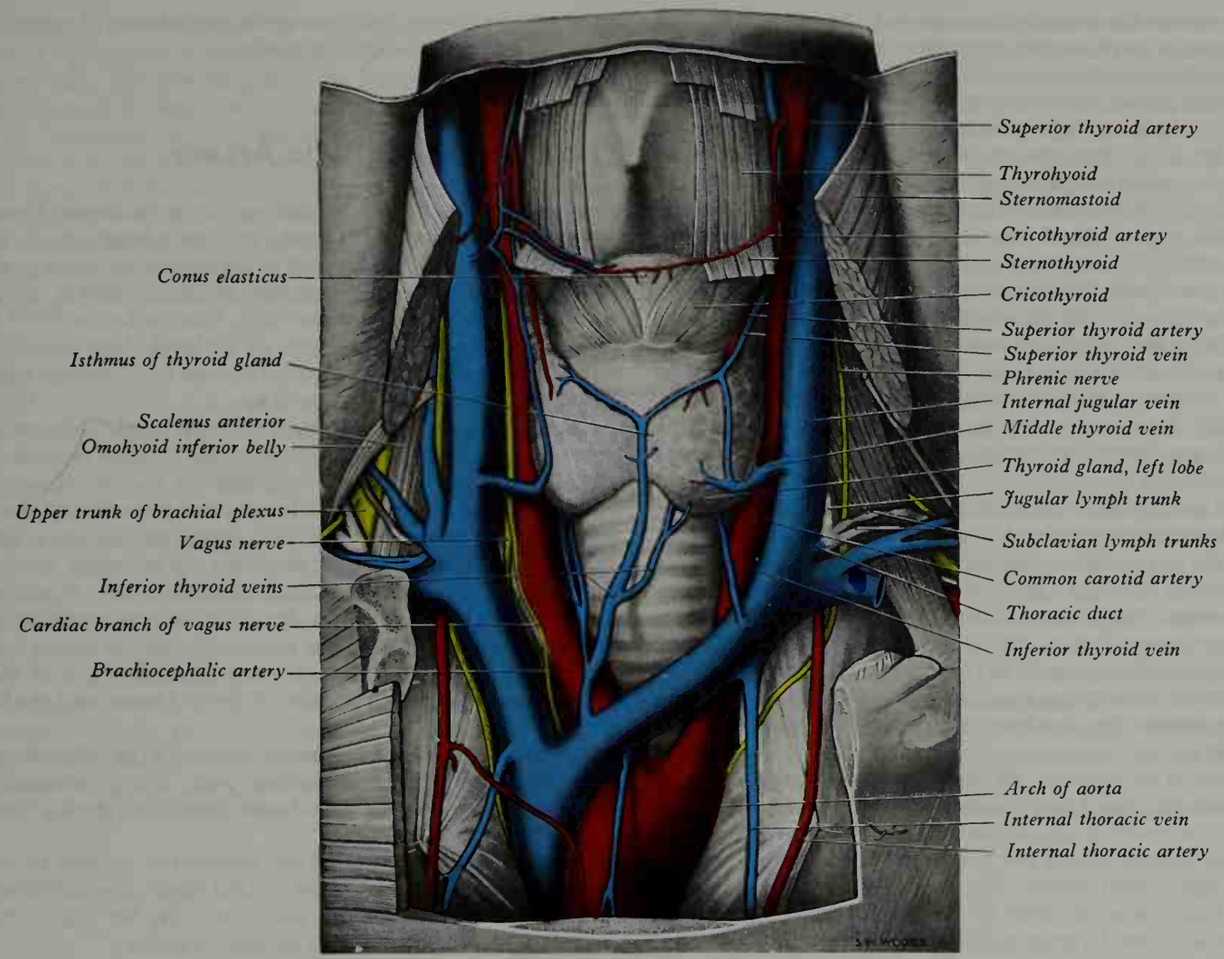


The Arch of the Aorta

The arch of the aorta (**6**.37–42) begins behind the manubrium sterni at the level of the upper border of the second right sternocostal articulation, and runs at first upwards, backwards and to the left in front of the trachea; it is then directed backwards on the left side of the trachea, and finally passes downwards on the left side of the body of the fourth thoracic vertebra, at the lower border of which it is continuous with the descending aorta. Its termination corresponds to the sternal extremity of the second, left costal cartilage (**6**.26). It thus has two curvatures: one with its convexity upwards, the other with its convexity forwards and to the left. Its upper border is usually about the level of the middle of the manubrium sterni.

Relations. Anteriorly and to the left the vessel is covered with the left mediastinal pleura, under cover of which it is crossed by four nerves; in order from before backwards these are: the left phrenic, the lower of the cervical cardiac branches of the left vagus, the

6.40 A transverse section through the mediastinum at the level of the lower part of the body of the fourth thoracic vertebra, viewed from above.



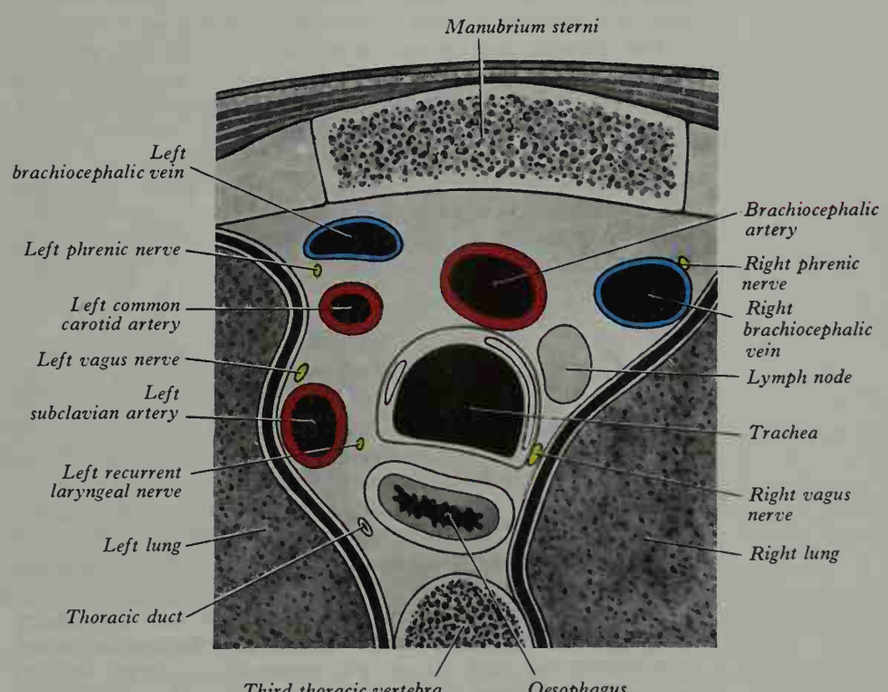
6.41 A dissection to display the heart, great vessels and lungs *in situ*. The sternum and the sternal ends of the costal cartilages, together with the parietal pleura on each side, have been excised, and the mediastinal pleura and parietal layer of the pericardium over the sternocostal surface of the heart have been removed. The lungs have been displaced to expose the heart, and the epicardium dissected off the heart and the great vessels.

superior cervical cardiac branch of the left sympathetic, and the trunk of the left vagus. As the left vagus crosses the arch it gives off its recurrent laryngeal branch, which hooks round below the vessel to the left of the ligamentum arteriosum and then passes upwards on its right side. The left superior intercostal vein runs obliquely upwards and forwards on this surface of the arch, crossing superficial to the vagus but deep to the phrenic nerve (**6.41**). The left lung and pleura separate all these structures from the chest wall. *Posteriorly and to the right*, the trachea and the deep cardiac plexus, the left recurrent laryngeal nerve, the oesophagus, the thoracic duct and the vertebral column are successively in relation to the vessel. *Above*, the brachiocephalic, left common carotid and left subclavian arteries arise from the convexity of the arch and are crossed in front close to their origins by the left brachiocephalic vein. *Below*, the arch is related to the bifurcation of the pulmonary trunk, the left principal bronchus, the ligamentum arteriosum (p. 666), the superficial part of the cardiac plexus and the left recurrent laryngeal nerve.

In the fetus the lumen of the aorta is considerably narrowed between the origin of the left subclavian artery and the attachment of the ductus arteriosus, forming what is termed the *aortic isthmus*, while immediately beyond the ductus arteriosus the vessel presents a fusiform dilatation (*aortic spindle*)—the point of junction of the two parts being marked in the concavity of the arch

6.42 A transverse section through the mediastinum at the level of the upper part of the body of the fourth thoracic vertebra, viewed from above.

6.43 A dissection of the lower part of the front of the neck and of the superior mediastinum. The manubrium sterni and the sternal ends of the clavicles and the first costal cartilages have been removed, and the pleural sac and lung have been retracted on each side. In this specimen each superior thyroid artery arose from the common carotid artery.



by an indentation. These conditions persist, to some extent, in the adult.

Variations. The summit of the arch of the aorta is usually about 2·5 cm below the upper border of the sternum; but it may be considerably higher or lower than this. Sometimes the aorta arches over the root of the right lung (right aortic arch) instead of over that of the left, and passes down on the right side of the vertebral column, a condition which is normal in birds. In such cases there is usually a transposition of the thoracic and of the abdominal viscera. Less frequently the aorta, after arching over the root of the right lung, passes behind the oesophagus to gain its usual position on the left side of the vertebral column; this peculiarity is not accompanied by transposition of the viscera. The aorta occasionally divides, as in some quadrupeds, into an ascending and a descending trunk, the former of which is directed vertically upwards, and subdivides into three branches, to supply the head and upper limbs. Sometimes the aorta subdivides near its origin into two branches, which soon reunite; in these cases the oesophagus and trachea usually pass through the interval between the two branches; this is the normal condition of the vessel in the reptilia and is due to persistence of a part of the right dorsal aorta which usually disappears (p. 187).

Radiological appearances. The shadow cast by the terminal part of the arch is easily seen in anteroposterior radiographs (**6**.27) and is sometimes called the 'aortic knuckle'. The arch may also be seen in left anterior oblique radiographs enclosing a translucent space, 'the aortic window', in which may be seen the shadows of the pulmonary trunk and its left branch.

Branches (**6**.41, 44). Three branches are given off from the upper aspect of the arch of the aorta: the brachiocephalic trunk, the left common carotid and the left subclavian.

Variations. The branches may spring from the commencement of the arch or upper part of the ascending aorta; or the distance between them at their origins may be increased or diminished, the most frequent change in this respect being the approximation of the left common carotid artery to the brachiocephalic trunk (Wright 1969).

6.44 A transverse section through the superior mediastinum at the level of the body of the third thoracic vertebra, viewed from above.

The number of the primary branches may be reduced to one; more commonly there are two, the left common carotid arising from the brachiocephalic trunk (7 per cent), or (more rarely) the common carotid and subclavian arteries of the left side arising from a left brachiocephalic trunk. But the number may be increased to four, through the right common carotid and subclavian arteries arising directly from the aorta; in most of these cases the right subclavian arises from the left end of the arch and passes to the right behind the oesophagus (see also p. 187). Another common variation in which there are four primary branches is that where the left vertebral artery arises from the arch of the aorta between the left common carotid and subclavian arteries. Lastly, the number of trunks may be increased to five or six; very rarely, the external and internal carotid arteries arise separately, the common carotid being absent on one or both sides. In some few cases six branches have been found, and this condition is associated with the origin of both vertebral arteries from the arch.

When the aorta arches over to the right side, the arrangement of the three branches is reversed: there is a left brachiocephalic trunk, and the right common carotid and right subclavian arteries arise separately. In other cases, where the aorta takes its usual course, the two common carotids may be joined in a single trunk, and the subclavians arise separately from the arch, the right subclavian generally arising from the left end of the arch.

Other arteries may spring from the arch of the aorta. Of these the most common are the bronchial (one or both), and the thyroidea ima.

An analysis of variation in the branches of 1,000 aortic arches has been recorded by Anson (1963). In 65 per cent the usual pattern of three major branches was observed; in 27 per cent the left common carotid shared the brachiocephalic trunk (contrast the percentage quoted above). The four large arteries branched separately from the aortic arch in 2·5 per cent. The remaining 5 per cent also showed a great variety of forms of branching, the commonest (1·2 per cent) being the occurrence of symmetrical right and left brachiocephalic trunks.

The Brachiocephalic Artery

The brachiocephalic (innominate) artery is the largest branch of the arch of the aorta, and is from 4 to 5 cm in length (**6**.41, 43, 44, 118). It arises from the convexity of the arch of the aorta, posterior to the centre of the manubrium sterni; it passes obliquely upwards, backwards and to the right, lying at first in front of the trachea and then on its right side. At the level of the upper border of the right sternoclavicular joint it divides into the right common carotid and right subclavian arteries.

Relations. It is separated *anteriorly* from the manubrium sterni by the sternohyoid and sternothyroid, the remains of the thymus, the left brachiocephalic and right inferior thyroid veins, which cross its root, and sometimes the cardiac branches of the right vagus nerve. *Posteriorly* it is related to the trachea below, and the right pleura above, where also the right vagus nerve lies posterolateral to the vessel before leaving it to pass on to the side of the trachea; on the *right side*, are the right brachiocephalic vein, the upper part of the superior vena cava, and the pleura; and on the *left side*, the remains of the thymus, the origin of the left common carotid artery, the inferior thyroid veins, and at a higher level the trachea.

Branches. The brachiocephalic artery is usually devoid of branches other than its terminal ones, but occasionally the *thyroidea ima* arises from it, and sometimes it gives off a *thymic* or a *bronchial branch*.

The thyroidea ima, small and inconstant, ascends in front of the trachea to the isthmus of the thyroid gland, in which it ends. It occasionally arises from the aorta, or from the right common carotid, subclavian or internal thoracic arteries.

THE CAROTID SYSTEM OF ARTERIES

The principal arteries of the head and neck are the two common carotids; they ascend in the neck as far as the level of the upper border of the thyroid cartilage, where each divides into two branches: (1) the external carotid, supplying the exterior of the head, the face and the greater part of the neck; (2) the internal carotid, supplying the parts within the cranial and orbital cavities.

The common and internal carotid arteries, together with the veins and nerves which accompany them, are situated in a cleft on each side of the neck. This cleft may be said to possess three walls: a posterior, formed mainly by the transverse processes of the cervical vertebrae with their attached muscles; a medial, consisting of the trachea, oesophagus, thyroid gland, larynx and the constrictor muscles of the pharynx; and an anterolateral, made up of the sternocleidomastoid with, at different levels, the omohyoid, sternohyoid, sternothyroid, and the digastric and stylohyoid.

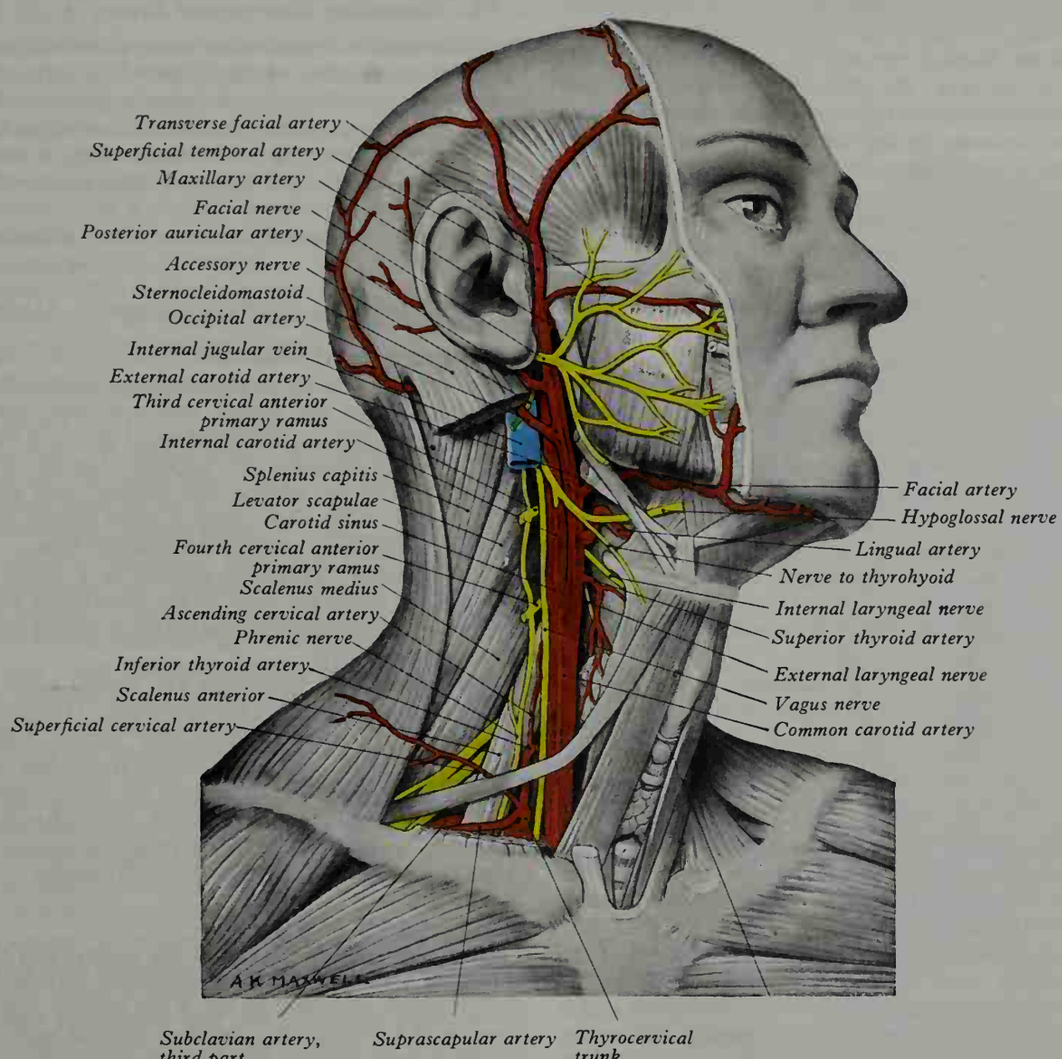
The Common Carotid Arteries

The common carotid arteries differ in length and in their mode of origin. The *right* artery begins at the bifurcation of the brachiocephalic trunk behind the right sternoclavicular joint and is confined to the neck. The *left* artery springs from the highest part of the arch of the aorta immediately behind and to the left of the brachiocephalic trunk, and therefore consists of a thoracic and a cervical portion.

The thoracic part of the left common carotid artery (**6**.43, 44) ascends from the arch of the aorta to the level of the left sternoclavicular joint, where it is continuous with the cervical portion. It lies at first in front of the trachea, but later inclines to its left side.

Relations. It is separated *in front* from the manubrium sterni by the sternohyoid and sternothyroid, the anterior portions of the left pleura and lung, the left brachiocephalic vein and the remains of the thymus; *behind*, it is related first to the trachea, then to the left subclavian artery, the left edge of the oesophagus, the left recurrent laryngeal nerve and the thoracic duct. On its *right side* it is related below to the brachiocephalic trunk, and above to the trachea, the inferior thyroid veins and the remains of the thymus; at its *left side* are the left vagus and phrenic nerves, the left pleura and lung.

The cervical parts of the common carotid arteries have similar courses (**6**.43, 44, 46). Each passes obliquely upwards and slightly laterally, from behind the sternoclavicular joint, to the level of the upper border of the thyroid cartilage, where it divides into the external and internal carotid arteries (**6**.47). At its point of division the vessel shows a dilatation, termed the *carotid sinus*, which usually involves, and may be restricted to, the proximal part of the internal carotid artery. In this situation the tunica media is thinner than elsewhere and the tunica adventitia, which is relatively thick, contains a large number of sensory nerve endings, derived from the glossopharyngeal nerve (p. 1075). The nerve fibres and terminals show evidence of degeneration and regeneration, suggesting a continuous turnover which may be more marked in the elderly (Rüsager and Weddell 1962). The structure of the walls of the sinus enables it to react readily to changes in the arterial blood pressure and to bring about appropriate modifications reflexly. Owing to its situation on the main artery of supply to the brain, its function as a baroreceptor mechanism enables it to exercise control over intracranial pressure. The *carotid body*, which lies behind the point of division of the common carotid artery, is a small, reddish-brown structure; it acts as a 'chemoreceptor' (*see* Adams 1958 for an earlier comparative account, and p. 1462 for modern views concerning its fine structure and possible modes of operation).



At the lower part of the neck the two arteries are separated from each other by a narrow interval which contains the trachea; but at the upper part, the thyroid gland, the larynx, and the pharynx project forwards between the two vessels. The common carotid artery is contained in the carotid sheath (p. 537), which is continuous with the deep cervical fascia, and is composed of loose cellular tissue, but the part surrounding the artery is thicker and denser than the rest. This sheath encloses also the internal jugular vein and vagus nerve, the vein lying lateral to the artery, and the nerve between the artery and vein on a plane posterior to both. The superior root of the ansa cervicalis is embedded in its anterior wall.

Relations. The common carotid artery is crossed *anterolaterally*, at the level of the cricoid cartilage,by the superior belly of the omohyoid. Below this muscle the artery is very deeply seated, being covered with the skin, superficial fascia, platysma, deep cervical fascia, sternocleidomastoid, sternohyoid and sternothyroid. Above the omohyoid it is more superficial, being covered merely by the skin, the superficial fascia, platysma, deep cervical fascia and the medial margin of the sternocleidomastoid; this part of the artery is crossed obliquely, from its medial to its lateral side, by the sternocleidomastoid branch of the superior thyroid artery. In front of, or embedded in, its sheath is the superior root of the ansa cervicalis, this branch being joined by the inferior root of the ansa, from the second and third cervical nerves, which crosses the vessel obliquely. The superior thyroid vein usually crosses the artery near its termination, and the middle thyroid vein a little below the level of the cricoid cartilage; each anterior jugular vein crosses the artery just above the clavicle, but is separated from it by the sternohyoid and sternothyroid. *Behind*, the artery is separated from the transverse processes of the fourth, fifth and sixth cervical vertebrae by the longus colli and longus capitis and the origin of the scalenus anterior, the sympathetic trunk and the ascending cervical artery being interposed between the artery and the muscles. Below the level of the sixth cervical vertebra the common carotid artery lies in the angle between the scalenus anterior and the longus colli (**6**.118), anterior to the vertebral vessels, the inferior thyroid and subclavian arteries, the sympathetic trunk, and, on the left side, the thoracic duct. *Medial* to it are the oesophagus, trachea, the inferior thyroid artery and recurrent laryngeal nerve; at a higher level, the larynx and pharnyx are medial to the artery; the lobe of the thyroid gland overlaps it anteromedially. *Lateral* to the artery is the internal jugular vein; *posterolaterally*, in the angle between it and the internal jugular vein is the vagus nerve.

On the right side, at the lower part of the neck, the recurrent laryngeal nerve crosses obliquely behind the artery; the right internal jugular vein diverges from the artery below, but the left vein approaches and often overlaps the lower part of the vessel.

Variations. In about 12 per cent of subjects the *right* common carotid artery arises above the level of the upper border of the sternoclavicular joint. It may arise as a separate branch from the arch of the aorta, or in conjunction with the left common carotid. The *left* common carotid artery varies in its origin more frequently than the right. In the majority of abnormal cases it arises in common with the brachiocephalic artery; if that artery be absent, the two common carotids arise usually by a single trunk. It is rarely joined with the left subclavian, except in cases of transposition of the aortic arch.

Division of the common carotid artery may occur higher than

6.45 A dissection of the right side of the neck, showing the carotid and subclavian arteries and their branches. The parotid and submandibular glands have been removed together with the lower part of the internal jugular vein, most of the sternocleidomastoid, and the upper parts of the stylohyoid and posterior belly of the digastric.

usual, at or about the level of the hyoid bone; more rarely it occurs below the usual level, opposite the middle of the larynx, or the lower border of the cricoid cartilage. Very rarely the artery ascends in the neck without undergoing division, either the external or the internal carotid being absent. In a few instances the artery has been found absent, the external and internal carotid arteries arising directly from the arch of the aorta; this perculiarity exists on both sides in some instances, on one side in others.

The common carotid artery usually has no branches; but it may give origin to the vertebral, the superior thyroid (**6**.43) or its laryngeal branch, the ascending pharyngeal, the inferior thyroid, or the occipital.

The External Carotid Artery

The external carotid artery (**6**.45, 53) begins opposite the upper border of the thyroid cartilage, at the level of the disc between the third and fourth cervical vertebrae, and, taking a slightly curved course, passes upwards and forwards, and then inclines backwards to a point behind the neck of the mandible midway between the tip of the mastoid process and the angle of the jaw, where, in the substance of the parotid gland, it divides into the superficial temporal and maxillary arteries. It diminishes rapidly in size, owing to the number and large size of its branches. In the child, it is a little smaller than the internal carotid artery; but in the adult, the two vessels are of nearly equal size. At its origin, where its pulsations are easily felt, it is contained within the carotid triangle (p. 585), and lies anterior to and nearer the median plane than the internal carotid artery; higher up it is situated lateral to this artery.

Relations. Within the carotid triangle the external carotid artery is covered by the skin, the superficial fascia, the loop between the cervical branch of the facial nerve and the transverse (anterior) cutaneous nerve of the neck, the deep fascia, and the anterior margin of the sternocleidomastoid; it is crossed by the hypoglossal nerve and its vena comitans, by the lingual and (common) facial veins and sometimes by the superior thyroid vein. Leaving the carotid triangle it is crossed by the posterior belly of the digastric and the stylohyoid and then ascends between the latter muscle and the posteromedial surface of the parotid gland. Finally, it enters the gland, where it lies deep to the facial nerve and the junction of the superficial temporal and maxillary veins. Deeply, it is related at first to the wall of the pharynx, the superior laryngeal nerve, and the ascending pharyngeal artery. At a higher level the internal carotid artery is deep to it, but is separated from it by the styloid process, the styloglossus and stylopharyngeus, the glossopharyngeal nerve, the pharyngeal branch of the vagus nerve, and a part of the parotid gland (**6**.46). The relation of the external carotid artery to the parotid gland is, in fact, a matter of some controversy, many clinicians asserting that it is often medial to, rather than within the gland. The most recent study (Guffarth and Graumann 1975), based on a short series of dissections, suggests that both relationships occur and at about equal frequency.

Branches. The branches of the external carotid artery (**6**.45, 49) are:

1. Superior thyroid.
2. Ascending pharyngeal.
3. Lingual.
4. Facial.
5. Occipital.
6. Posterior auricular.
7. Superficial temporal.
8. Maxillary.

1. The Superior Thyroid Artery (**6**.45)

This arises from the front of the external carotid artery just below the level of the greater cornu of the hyoid bone and divides into terminal branches at the apex of the lobe of the gland. It may arise from the common carotid artery (**6**.43).

Relations. From its origin beneath the anterior border of the sternocleidomastoid it runs downwards and forwards in the carotid triangle along the lateral border of the thyrohyoid, and is covered by the skin, platysma and fasciae; it then passes under cover of the omohyoid, sternohyoid and sternothyroid. To its medial side are the constrictor pharyngis inferior and the external branch of the superior laryngeal nerve, but the nerve frequently lies on a more posterior plane.

Branches. It supplies the adjacent muscles and the thyroid gland; it anastomoses with its fellow of the opposite side and the inferior thyroid arteries. The branches to the gland are: the anterior branch, which follows the medial border of the upper pole of the lobe and supplies principally the anterior surface, sending a branch across the upper border of the isthmus to anastomose with the artery of the opposite side; the posterior branch descends on the posterior border of the gland, supplying its medial and lateral surfaces, and anastomoses with the inferior thyroid artery. Sometimes a lateral branch is distributed to the lateral surface of the gland.

Besides arteries to muscles and the thyroid gland, the superior thyroid artery has the following branches:

Infrahyoid.	Superior laryngeal.
Sternocleidomastoid.	Cricothyroid.

The infrahyoid artery is small, runs along the lower border of the hyoid bone deep to the thyrohyoid, and anastomoses with the opposite vessel.

The sternocleidomastoid branch, which frequently arises from the external carotid artery, runs down and laterally across the carotid sheath.

The superior laryngeal artery accompanies the internal laryngeal nerve and passes deep to the thyrohyoid; it pierces the lower part of the thyrohyoid membrane, and supplies the larynx, anastomosing with the opposite artery and with the inferior laryngeal artery, a branch of the inferior thyroid.

The cricothyroid branch is small and runs transversely across the upper part of the cricothyroid ligament communicating with the artery of the opposite side.

2. The Ascending Pharyngeal Artery (**6**.56)

This, the smallest branch of the external carotid, is a long, slender vessel. It arises close to the origin of the external carotid, and ascends vertically between the internal carotid and the side of the pharynx to the base of the skull, being crossed by the styloglossus and the stylopharyngeus, with longus capitis posterior to it; it anastomoses freely with the ascending palatine branch of the facial artery.

Branches. The named branches of the ascending pharyngeal artery are:

Pharyngeal. Inferior tympanic. Meningeal.

The pharyngeal branches, three or four in number, supply the constrictors and the stylopharyngeus. A branch of variable size is distributed to the palate, and may take the place of the ascending palatine branch of the facial artery; it runs downwards and forwards between the superior border of the superior constrictor and the levator veli palatini, and accompanies the latter muscle to the soft palate; it gives minute branches to the tonsil, and supplies a twig to the auditory tube.

The inferior tympanic artery is a small branch which traverses the temporal bone, in the canaliculus for the tympanic branch of the glossopharyngeal nerve, to supply the medial wall of the tympanic cavity.

The meningeal branches are several small vessels which supply the dura mater and adjacent bone. They enter the cranium through the foramen lacerum, the jugular foramen and the hypoglossal canal, and supply nerves traversing them.

Numerous small vessels supply the longi capitis et colli, the sympathetic trunk, the hypoglossal, glossopharyngeal and vagus nerves, and cervical lymph nodes; they anastomose with branches of the ascending cervical and vertebral arteries.

3. The Lingual Artery (**6**.45)

This is the principal supply to the tongue and the floor of the mouth. It arises from the anteromedial surface of the external carotid artery opposite the tip of the greater cornu of the hyoid bone, and between the superior thyroid and facial arteries. Running obliquely upwards and medially at first, it then curves downwards and forwards to the greater cornu of the hyoid bone, forming a characteristic loop; it passes medial to the posterior border of the hyoglossus, runs horizontally forwards under cover

of that muscle, and finally, ascending almost perpendicularly, courses tortuously forwards on the under surface of the tongue as far as its tip (**6**.48).

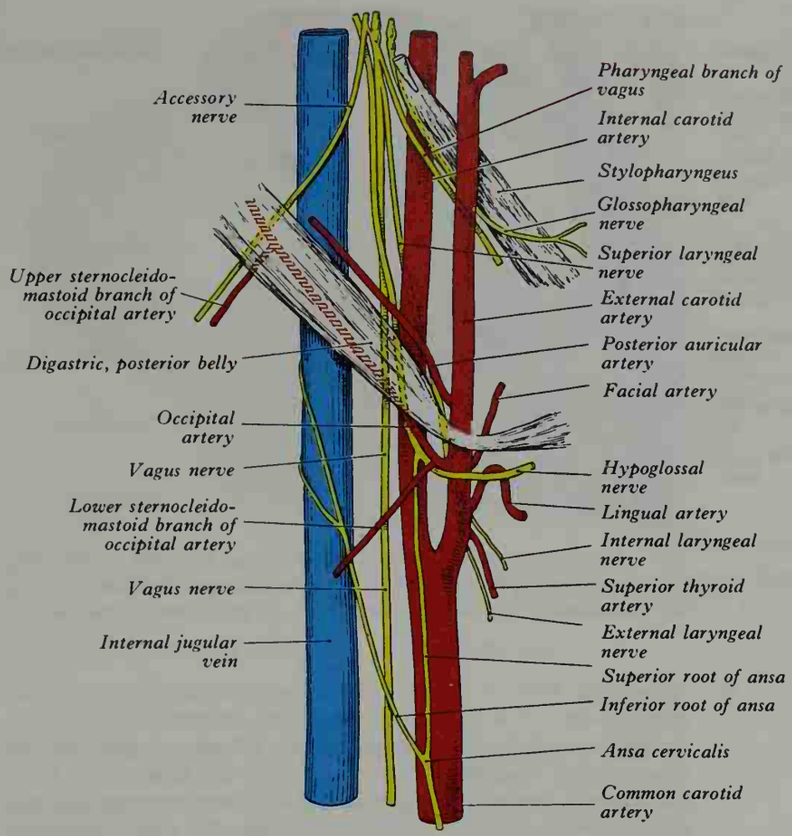
Course and relations. The *first part* of the lingual artery is in the carotid triangle; superficial to it are the skin, fascia and platysma; medial to it, the middle constrictor. It runs upwards and medially for a short distance, and then descends to the level of the hyoid bone, forming a loop, which is crossed by the hypoglossal nerve. The *second part* of the artery traverses the upper border of the hyoid bone, deep to the hyoglossus, the tendon of the digastric or its fascial retinaculum, the stylohyoid, the lower part of the submandibular gland and the posterior part of the mylohyoid; the hyoglossus separates the artery from the hypoglossal nerve and its vena comitans; in this part of its course it lies on the middle constrictor and crosses the stylohyoid ligament. It is accompanied by the lingual veins (p. 742). The *third part* of the artery is named the *arteria profunda linguae*. It bends sharply upwards near the anterior border of the hyoglossus, and then runs forwards close to the inferior surface of the tongue near the frenulum, accompanied by the lingual nerve. Medially, it is related to the genioglossus, laterally, to the longitudinalis linguae inferior, below, to the mucous membrane of the tongue. At the tip of the tongue it anastomoses with the lingual artery of the opposite side.

Branches. The branches of the lingual artery are:

The suprahyoid branch, which is very small; it runs along the upper border of the hyoid bone, and anastomoses with the contralateral artery.

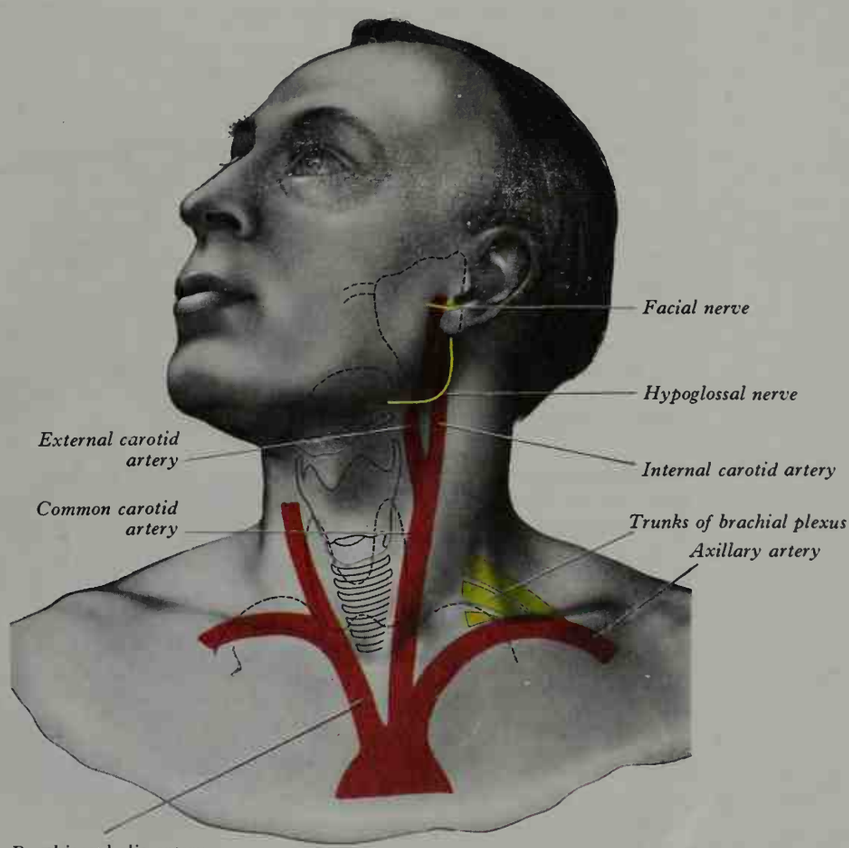
The dorsal lingual branches, consisting usually of two or three small vessels, arise medial to the hyoglossus muscle, ascend to the posterior part of the dorsum of the tongue, and supply its mucous membrane, the palatoglossal arch, the tonsil, soft palate and epiglottis; they anastomose with the vessels of the opposite side.

The sublingual artery which arises at the anterior margin of the hyoglossus, travels forward between the genioglossus and mylohyoid to the sublingual gland. It supplies the gland and gives branches to the mylohyoid and neighbouring muscles, and to the mucous membrane of the mouth and gums. One branch runs behind the alveolar part of the mandible in the substance of the gum to anastomose with a similar artery from the other side; another pierces the mylohyoid and anastomoses with the submental branches of the facial artery.



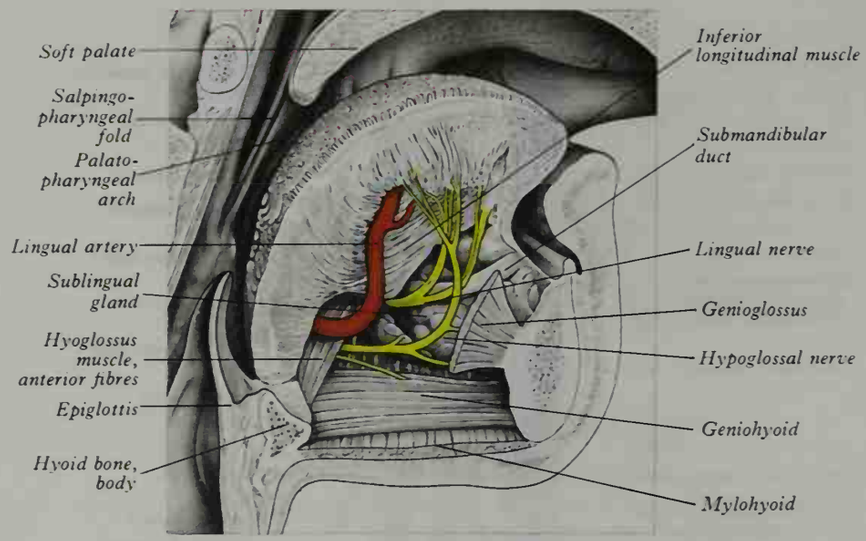
The lingual artery often shares a common trunk with the facial or, less frequently, with the superior thyroid artery. It may be replaced by a branch of the maxillary artery.

4. The Facial Artery (6.49, 56)



This arises from the front of the external carotid artery in the carotid triangle above the lingual artery, and immediately above the greater cornu of the hyoid bone. Medial to the ramus of the mandible, it arches upwards and grooves the posterior border of the submandibular gland. It next turns downwards and forwards between the gland and the medial pterygoid, and, reaching the lower border of the mandible, hooks round it at the anterior edge of the masseter, and enters the face. On the face it passes forwards and upwards across the mandible and buccinator almost to the angle of the mouth where its pulsations can be felt if the cheek be grasped lightly between finger and thumb. It then ascends the side of the nose, and ends at the medial palpebral commissure, to supply the lacrimal sac and anastomose with the dorsal nasal branch of the ophthalmic artery. The facial artery is remarkably tortuous—in the neck to accommodate itself perhaps to the movements of the pharynx during deglutition and on the face to the movements of the mandible, lips and cheeks.

Distal to its superior branch (**6**.49) the facial artery is occasionally termed the *angular artery*.



Relations. In the neck, at its origin the artery is superficial, being covered merely by skin, platysma, and fasciae, and is often crossed by the hypoglossal nerve. It runs upwards and forwards, deep to the digastric and stylohyoid and the posterior part of the submandibular gland. At first on the surface of the middle constrictor of the pharynx, it may reach as high as the lateral surface of the styloglossus, and it is then separated from the tonsil only by that muscle and the lingual fibres of origin of the superior

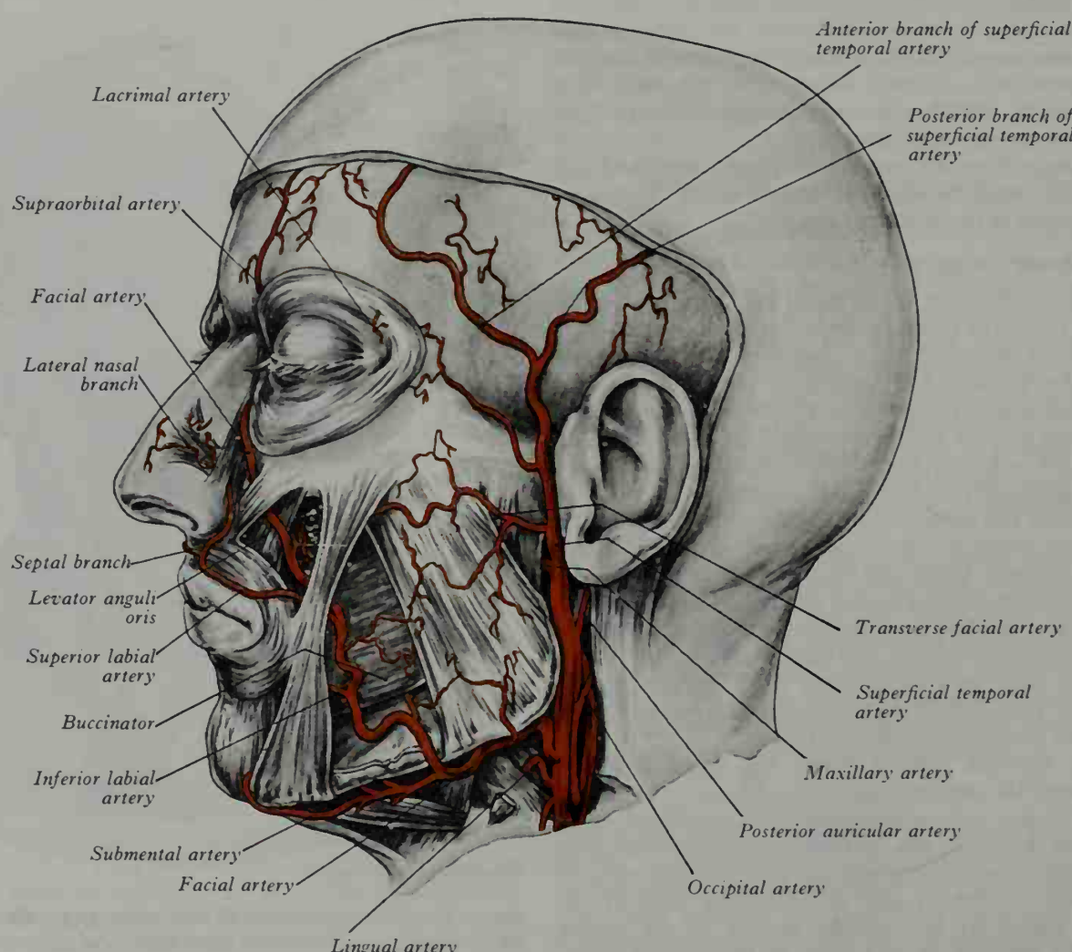
6.47 The surface projection of some of the larger structures in the face and neck. *Note.*—The parotid gland and its duct, the submandibular and thyroid glands, and the apices of the lungs are shown as interrupted outlines. The hyoid bone and the thyroid, cricoid and tracheal cartilages are indicated by continuous outlines.

6.48 A dissection of the left half of the tongue from the medial side, exposing the end of the second part and the beginning of the third part of the left lingual artery and adjoining structures, in an edentulous subject.

constrictor. Next, it descends to the lower border of the mandible, lying in a groove on the lateral aspect of the submandibular gland. *In the face*, where its pulsations can be felt as it passes over the base of the mandible, it is comparatively superficial, lying immediately beneath the platysma. In its course over the face, it is under cover of the skin, the fat of the cheek, and, near the angle of the mouth, the platysma, risorius and zygomaticus major. It rests on the buccinator and levator anguli oris, and passes either over or through the levator labii superioris. Its terminal part is embedded in the fibres of the levator labii superioris alaeque nasi. The facial vein lies posterior to the artery, and, taking a more direct course across the face, is at some distance from the artery. At the anterior border of the masseter the two vessels are in contact; in the neck the vein is superficial to the artery. The branches of the facial nerve cross the artery from behind forwards.

The facial artery supplies the muscles and tissues of the face, the submandibular gland, the tonsil and the soft palate. Its branches can be divided into cervical and facial groups.



Cervical Branches

The ascending palatine artery (**6**.56) arises close to the origin of the facial artery and passes up between the styloglossus and stylopharyngeus to the side of the pharynx, along which it ascends between the superior constrictor and the medial pterygoid towards the base of the skull. Near the levator veli palatini it divides into two branches: one follows this muscle, and, winding over the upper border of the superior constrictor, supplies the soft palate, anastomosing with its fellow of the opposite side and with the greater palatine branch of the maxillary artery; the other pierces the superior constrictor and supplies the tonsils and the auditory tube, anastomosing with the tonsillar and ascending pharyngeal arteries.

The tonsillar artery is the principal supply to the tonsil. Sometimes derived from the ascending palatine artery, though usually a separate branch, it ascends between the medial pterygoid and styloglossus, and at the upper border of the latter muscle it perforates the superior constrictor and ramifies in the tonsil and the root of the tongue.

The glandular branches, three or four large vessels, supply the submandibular salivary gland and lymph nodes, the neighbouring muscles and overlying skin.

The submental artery, the largest cervical branch of the facial artery, branches off as it quits the submandibular gland: it

6.49 The arteries of the left side of the face and their main branches. Note the less usual origin of the lateral nasal branch in this specimen.

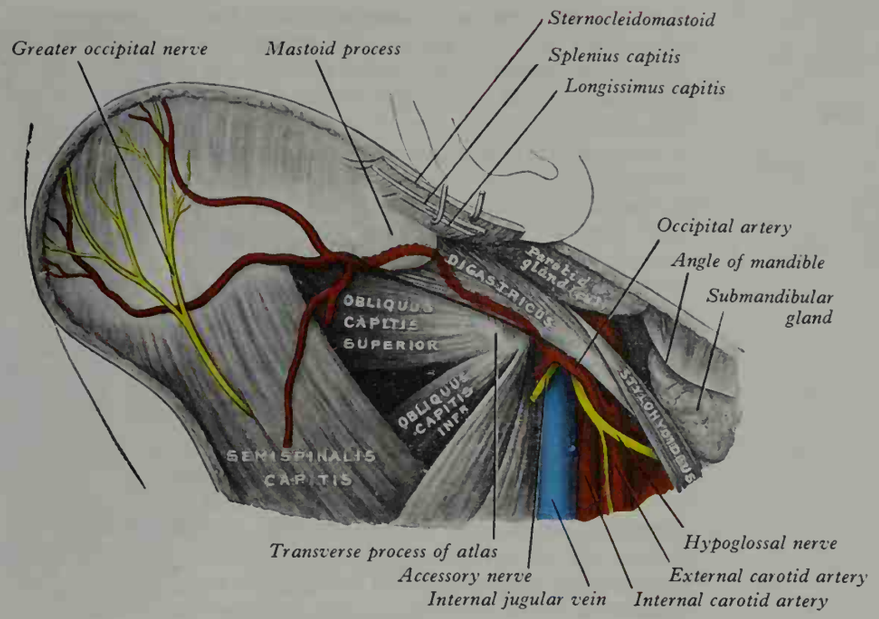
runs forwards upon the mylohyoid (**6**.49), below the body of the mandible. It supplies the surrounding muscles, and anastomoses with the sublingual branch of the lingual artery and the mylohyoid branch of the inferior alveolar artery; at the chin it turns upwards over the base of the mandible and divides into superficial and deep branches which anastomose with the inferior labial and mental arteries, supplying the chin and lower lip.

Facial Branches

The inferior labial artery (**6**.49) arises near the angle of the mouth; it passes upwards and forwards under cover of the depressor anguli oris and, penetrating the orbicularis oris, runs in a tortuous course near the edge of the lower lip between this muscle and the mucous membrane. It supplies the glands, mucous membrane and muscles of the lower lip and anastomoses with the artery of the opposite side, and with the mental branch of the inferior alveolar artery.

The superior labial artery (**6**.49) is larger and more tortuous than the inferior. It follows a similar course near the edge of the upper lip, lying between the mucous membrane and the orbicularis oris, and anastomoses with the artery of the opposite side. It supplies the upper lip, and gives off a *septal branch*, which ramifies on the lower and front part of the nasal septum, and an *alar branch*, to the ala of the nose.

The lateral nasal branch (**6**.49) is derived from the facial artery as that vessel ascends along the side of the nose. It supplies the ala and dorsum of the nose, anastomosing with its fellow, with the septal and alar branches of the superior labial artery, with the dorsal nasal ramus of the ophthalmic artery, and with the infraorbital branch of the maxillary artery. The lateral nasal artery may be represented by several small rami; it may alternatively arise from the superior labial artery, diverging from its septal branch (as in **6**.49).



The anastomoses of the facial artery are very numerous, not only with the branches of the vessel of the opposite side, but, *in the neck*, with the sublingual branch of the lingual, with the ascending pharyngeal and with the palatine branch of the maxillary; *on the face*, with the mental branch of the inferior alveolar, the transverse facial branch of the superficial temporal, the infraorbital branch of the maxillary and the dorsal nasal branch of the ophthalmic artery. The anastomoses across the midline between the superior and inferior labial arteries are by their main trunks, an important fact in the treatment of split lip.

Variations. The facial artery not infrequently arises in common with the lingual artery, constituting the *linguo-facial trunk*. It varies in size, and in the extent to which it supplies the face: it occasionally ends by forming the submental artery, and not infrequently extends only as high as the angle of the mouth or nose. The deficiency is then compensated for by enlargement of one of the neighbouring arteries. In a series of 110 human fetuses a common linguo-facial trunk occurred in 43 per cent. In 42 per cent it did not reach the medial orbital angle, terminating as the superior (20 per cent) or inferior (22 per cent) labial artery (Kozielec and Jożwa 1977).

5. The Occipital Artery (**6**.50)

This artery arises from the back of the external carotid artery, opposite to the facial artery and, running at first on the medial surface of the posterior belly of the digastric, ends in the posterior part of the scalp.

Course and relations. At its origin, it is crossed superficially by the hypoglossal nerve, which winds round it from behind forwards. The artery passes backwards and upwards deep to the lower border of the posterior belly of the digastric, crossing in its course the internal carotid artery, the internal jugular vein, and the hypoglossal, vagus and accessory nerves (**6**.50). Reaching the interval between the transverse process of the atlas and the mastoid process of the temporal bone, it comes into contact with the lateral border of the rectus capitis lateralis. It then runs in the occipital groove on the temporal bone, and here is medial to the mastoid process and the attachments to it of the sternocleidomastoid, splenius capitis, longissimus capitis and digastric, and lies successively on the rectus capitis lateralis, obliquus superior and semispinalis capitis. Finally, it turns upwards and pierces the

6.50 A dissection to show the course of the occipital artery.

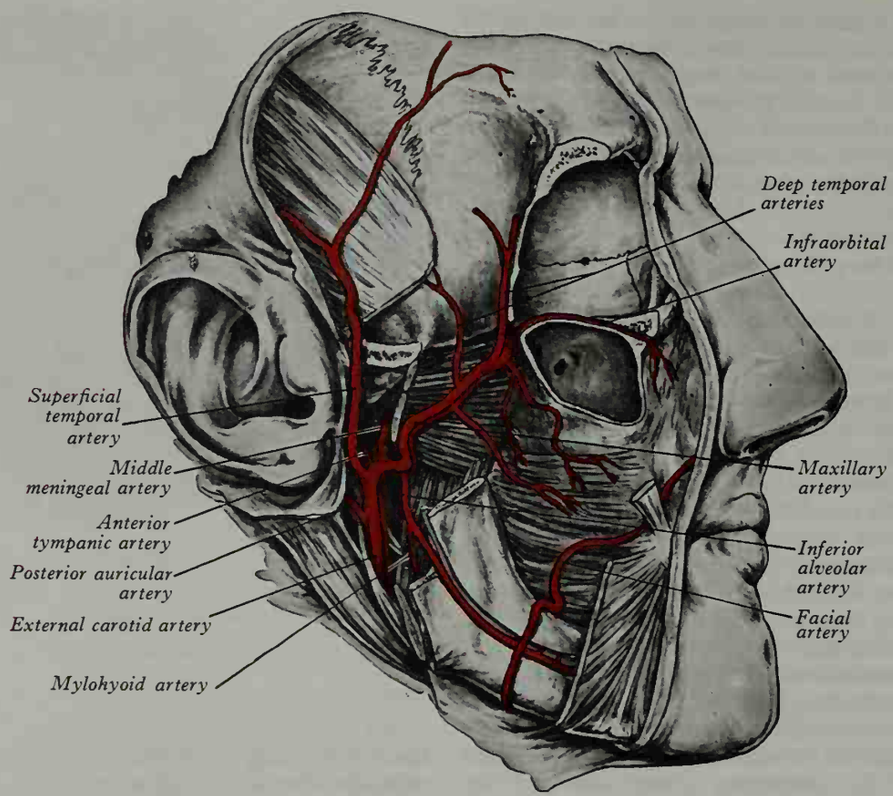
fascia connecting the cranial attachments of the trapezius and the sternocleidomastoid, and ascends in a tortuous course in the superficial fascia of the scalp, where it divides into numerous branches. The terminal portion of the occipital artery is accompanied by the greater occipital nerve.

Branches. The following branches arise from the occipital artery:

The sternocleidomastoid branches are usually two in number. The *lower branch* usually arises from the beginning of the occipital artery, but sometimes comes directly from the external carotid. It passes downwards and backwards over the hypoglossal nerve and the internal jugular vein, and enters the substance of the sternocleidomastoid; it anastomoses with the sternocleidomastoid branch of the superior thyroid artery. The *upper branch* arises from the occipital artery as it crosses the accessory nerve, and runs downwards and backwards superficial to the internal jugular vein. It enters the deep surface of the sternocleidomastoid in company with the accessory nerve.

The mastoid branch, small in size and sometimes absent, enters the cranial cavity through the mastoid foramen; it gives branches to the mastoid air cells and ramifies in the dura mater.

The stylomastoid artery in two thirds of subjects (*see* p. 682).



The auricular branch supplies the back of the auricle and anastomoses with the posterior auricular artery.

Unnamed **muscular branches** supply the digastric, stylohyoid, splenius and longissimus capitis.

The descending branch (**6**.50) arises from the occipital artery as the latter lies on the obliquus superior, and divides into superficial and deep branches. The *superficial branch* passes deep to the splenius, and anastomoses with the superficial branch of the transverse cervical artery; the *deep branch* descends between the semispinales capitis et cervicis, and anastomoses with the vertebral artery, and with the deep cervical artery, a branch of the costocervical trunk (**6**.56).

The meningeal branches enter the skull through the jugular foramen and the condylar canal, to supply the dura mater and bone in the posterior fossa, and the caudal four cranial nerves.

The occipital branches, which are the terminal rami, are distributed to the scalp, and reach as high as the vertex of the skull; they are very tortuous, and lie between the skin and the occipital belly of the occipitofrontalis, anastomosing with the artery of the opposite side and with the posterior auricular and temporal arteries, and supplying the occipital belly of the occipitofrontalis, the skin and the pericranium. One of the terminal branches may give off a meningeal twig, which passes through the parietal foramen.

6.51 The right maxillary artery. An extensive dissection has been carried out, involving the removal of the parotid gland, the zygomatic arch, part of the ramus of the mandible, the lateral walls of the orbit and maxillary sinus and the orbital contents.

6. The Posterior Auricular Artery (6.49)

This is small and branches from the posterior aspect of the external carotid immediately above the digastric and stylohoid. It ascends between the parotid gland and the styloid process of the temporal bone to the groove between the cartilage of the auricle and the mastoid process, where it divides into auricular and occipital branches.

Branches. As well as supplying the digastric, stylohyoid, sternocleidomastoid, and parotid gland, the posterior auricular artery gives off:

The stylomastoid artery, an indirect branch of the posterior auricular in about a third of subjects (Blunt 1954), enters the stylomastoid foramen to supply the facial nerve, tympanic cavity, mastoid antrum and air cells, and semicircular canals. In the young its posterior tympanic ramus forms an encircling anastomosis to supply the tympanic membrane with the anterior tympanic artery (p. 683).

The auricular branch, which ascends under cover of the auricularis posterior, ramifies on the cranial surface of the auricle; some of its branches pierce the auricle, and others curve round its margin to supply its lateral surface.

The occipital branch, which passes laterally across the front of the mastoid process, then turns backwards over the sternocleidomastoid to the occipital belly of the occipitofrontalis and to the scalp above and behind the ear; it anastomoses with the occipital artery.

7. The Superficial Temporal Artery (6.45)

This, the smaller terminal branch of the external carotid, begins in the parotid gland, behind the neck of the mandible, and crosses over the posterior root of the zygomatic process of the temporal bone; about 5 cm above this process it divides into anterior and posterior branches.

Relations. As it crosses the zygoma, it is covered by the auricularis anterior; it is crossed in the substance of the parotid gland by the temporal and zygomatic branches of the facial nerve, and is accompanied in the scalp by the corresponding veins and by the auriculotemporal nerve, which lies immediately behind it.

Branches. The superficial temporal artery supplies the parotid gland, the temporomandibular joint, the masseter, and certain named branches:

The transverse facial artery (6.49) arises from the superficial temporal artery before that vessel emerges from the parotid gland; it runs forwards through the gland, passes across the masseter between the parotid duct and the zygomatic arch, accompanied by one or two branches of the facial nerve. It divides into numerous branches, which supply the parotid gland and duct, the masseter, and the skin, and anastomose with the facial, masseteric, buccal, lacrimal, and infraorbital arteries.

The anterior auricular branches are distributed to the lobule and anterior portion of the auricle, and to the external acoustic meatus.

The zygomatico-orbital artery, sometimes a branch of the middle temporal artery, runs along the upper border of the zygomatic arch between the two layers of the temporal fascia to the lateral angle of the orbit. It supplies branches to the orbicularis oculi, and anastomoses with the lacrimal and palpebral branches of the ophthalmic artery.

The middle temporal artery arises immediately above the zygomatic arch, and, perforating the temporal fascia, gives branches to the temporalis; it anastomoses with the deep temporal branches of the maxillary artery.

The frontal (anterior) branch runs tortuously upwards and forwards towards the tuberosity of the frontal bone; it supplies the muscles, skin and pericranium in this region, and anastomoses with its fellow of the opposite side, and with the supraorbital and supratrochlear arteries.

The parietal (posterior) branch, larger than the preceding vessel, curves upwards and backwards on the side of the head, lying superficial to the temporal fascia, and anastomosing with the opposite artery and with the posterior auricular and occipital arteries.

Variation in the superficial temporal artery is largely limited to the relative sizes of its frontal, parietal, and transverse facial branches; either of the first two may be absent, while the transverse facial may be large enough to replace a shortened facial artery. Variations in fetal material have been described by Kozielec and Jóźwa (1976).

Applied Anatomy. As the superficial temporal artery crosses the zygomatic process it lies beneath the skin and fascia, and its pulsations may be readily felt, for example, during an anaesthetic, or in circumstances where the radial pulse is not available; it may be compressed easily against the bone in order to check bleeding from the temporal region of the scalp. It should be noted that this vessel and the other arteries to the scalp enter from below and are well protected by dense tissue. It is rarely found that they are all implicated in scalping injuries and their anastomoses are so free that so long as one is intact the detached scalp may be replaced with reasonable hope of its survival. When a flap is raised from this part of the head, for craniotomy, the incision should be shaped like a horseshoe, with its convexity upwards, so that the flap shall contain the superficial temporal artery, which ensures a sufficient supply of blood.

In angiograms of the external carotid artery the branches of the superficial temporal and middle meningeal arteries are superimposed. They may be distinguished by the straighter courses, lack of anastomoses, and narrower calibre of the meningeal rami (Domnić-Stošić and Jeličić 1974).

8. The Maxillary (Internal Maxillary) Artery (6.51)

This, the larger terminal branch of the external carotid, arises behind the neck of the mandible and is at first embedded in the parotid gland; it passes forwards medial to the neck of the mandible and then runs either superficial or deep to the lower head of the lateral pterygoid to enter the pterygopalatine fossa between the two heads of that muscle. It may be divided into mandibular, pterygoid and pterygopalatine portions associated successively with bone, muscle, and bone, a useful indication of the branches of each part.

The *first* or *mandibular part* passes horizontally forwards, between the neck of the mandible and the sphenomandibular ligament, where it lies parallel with and a little below the auriculotemporal nerve; it crosses the inferior alveolar nerve, and runs along the lower border of the lateral pterygoid.

The *second* or *pterygoid part* runs obliquely forwards and upwards medial to temporalis, and superficial to the lower head of the lateral pterygoid; very frequently it lies deep to the latter, between it and the branches of the mandibular nerve, and in this case, before entering on the third part of its course, it often forms a wide loop which projects laterally between the two heads of the lateral pterygoid.

The *third* or *pterygopalatine part* passes between the upper and lower heads of the lateral pterygoid, and through the pterygomaxillary fissure into the pterygopalatine fossa, where it lies in front of the pterygopalatine ganglion.

Branches. The maxillary artery is distributed to the upper and lower jaws, the teeth, muscles of mastication, palate, nose and cranial dura mater. Its branches may be divided into three groups, corresponding with its three parts.

Branches of the First Part (6.51)

The deep auricular artery, a small branch, often arises with the anterior tympanic. It ascends in the substance of the parotid gland, behind the temporomandibular joint, pierces the cartilaginous or bony wall of the external acoustic meatus, and supplies its cuticular lining and the outer surface of the tympanic membrane; it gives a branch to the temporomandibular joint.

The anterior tympanic artery, a small branch, ascends behind the temporomandibular joint, and enters the tympanic cavity through the petrotympanic fissure; it ramifies upon the medial aspect of the tympanic membrane, and forms a vascular circle around it with the posterior tympanic branch of the stylomastoid artery; it anastomoses with small branches of the artery of the pterygoid canal and with caroticotympanic branches from the internal carotid artery in the tympanic cavity.

The middle meningeal artery is the largest of the meningeal artery of the pterygoid canal and with caroticotympanic branches the lateral pterygoid, and, passing between the two roots of the auriculotemporal nerve, may lie on the lateral surface of the tensor veli palatini just before it enters the cranial cavity through the foramen spinosum of the sphenoid bone; it then runs forwards and laterally for a variable distance in a groove on the anterior part of the squamous part of the temporal bone, and divides into a frontal and a parietal branch. The *frontal (anterior) branch*, the larger, crosses the greater wing of the sphenoid bone, reaches the groove, or canal, in the sphenoidal angle of the parietal bone, and then divides into branches which spread out between the dura mater and internal surface of the cranium, some passing upwards as far as the vertex, and others backwards to the occipital region. One branch runs upwards, grooving the parietal bone about 1·5 cm behind the coronal suture. It corresponds, in a general way, to the line of the precentral sulcus of the brain. The *parietal (posterior) branch* curves backwards on the squamous part of the temporal bone, and, reaching the lower border of the parietal bone some distance in front of its mastoid angle, divides into branches which supply the posterior part of the dura mater and cranium. The branches of the middle meningeal artery anastomose with the arteries of the opposite side, and with the anterior and posterior meningeal arteries.

The middle meningeal artery gives off the following branches within the cranial cavity: (1) Numerous small *ganglionic branches* supply the trigeminal ganglion and the roots of the trigeminal nerve. (2) A *petrosal branch* enters the hiatus for the greater petrosal nerve, gives twigs to the facial nerve and the tympanic cavity, and anastomoses with the stylomastoid artery (of variable origin—*see* pp. 681, 682). (3) A *superior tympanic artery* runs in the canal for the tensor tympani, and supplies this muscle and the lining membrane of the canal. (4) *Temporal branches* pass through minute foramina in the greater wing of the sphenoid, and anastomose in the temporal fossa with the deep temporal arteries. (5) An *anastomotic branch* with the lacrimal artery (p. 688) runs forwards and enters the orbit through the lateral part of the superior orbital fissure. It anastomoses with a recurrent meningeal branch of the lacrimal artery, and an enlargement of this anastomosis explains the occasional origin of the lacrimal from the middle meningeal artery. Apart from these small branches and a supply to the dura mater, the middle meningeal artery is predominantly a periosteal artery supplying bone and red bone marrow.

Surface Anatomy (**6**.119). The *middle meningeal artery* enters the skull opposite a point immediately above the middle of the zygoma (**6**.119) and divides 2 cm above this. From this situation the frontal branch runs first upwards and slightly forwards to the pterion (**3**.126) and then turns upwards and backwards towards the mid-point between the inion (**3**.69) and the nasion (**3**.126). The parietal branch runs upwards and backwards towards the lambda (**3**.61).

Applied Anatomy. The middle meningeal artery is of considerable surgical importance, for it may be torn in fractures of the temporal region of the skull, or, indeed, by injuries causing separation of the dura mater from the bone without fracture. The injury may be followed by considerable haemorrhage between the bone and dura mater, which produces symptoms of compression of the brain, and requires trephining for its relief. As the compression implicates the motor region of the cortex, paralysis on the opposite side of the body forms the prominent phenomenon of the lesion.

The accessory meningeal branch may arise from the maxillary artery or from the middle meningeal artery. It enters the cranial cavity through the foramen ovale, and supplies branches to the trigeminal ganglion, dura mater and bone. Its main distribution, however, is *extracranial* (Baumel and Beard 1961), passing principally to the medial pterygoid, lateral pterygoid (upper head), tensor veli palatini, parts of the sphenoid bone (greater wing and pterygoid processes), the mandibular nerve and the otic ganglion, and it is sometimes represented by a number of separate small arteries.

The inferior alveolar (dental) artery descends posterior to the inferior alveolar nerve to the mandibular foramen on the medial surface of the ramus of the mandible. Here the artery lies between the bone on the lateral side, and the sphenomandibular ligament on the medial side. Before it enters the mandibular foramen, it gives off a *mylohyoid branch*, which pierces the sphenomandibular ligament, and descends with the mylohyoid nerve in the mylohyoid groove on the ramus of the mandible; it ramifies on the superficial surface of the mylohyoid and

anastomoses with the submental branch of the facial artery. The inferior alveolar artery then runs in the mandibular canal, accompanied by the inferior alveolar nerve, and, opposite the first premolar tooth, divides into two branches, incisor and mental. The *incisor* branch is continued forwards below the incisor teeth as far as the median plane, where it anastomoses with the artery of the opposite side. Within the canal the inferior alveolar artery and its incisor branch supply the mandible, tooth sockets, and a series of branches which correspond in number to the roots of the teeth; these enter the minute apertures at the extremities of the roots, and supply the pulp of the teeth. The *mental branch* escapes at the mental foramen, supplies the chin, and anastomoses with the submental and inferior labial arteries. Near its origin the inferior alveolar artery gives off a *lingual* branch, which descends with the lingual nerve and helps to supply the mucous membrane of the mouth.

Branches of the Second Part (6.51)

The deep temporal branches, an anterior and a posterior, ascend between the temporalis and the skull; they supply the muscle, and anastomose with the middle temporal artery; the anterior communicates with the lacrimal artery by means of small branches which perforate the zygomatic bone and greater wing of the sphenoid bone.

The pterygoid branches, irregular in their number and origin, supply the pterygoid muscles.

The masseteric artery is small and passes with the corresponding nerve behind the tendon of the temporalis and through the mandibular notch to the deep surface of the masseter. In the substance of that muscle it anastomoses with the masseteric branches of the facial and with branches of the transverse facial artery.

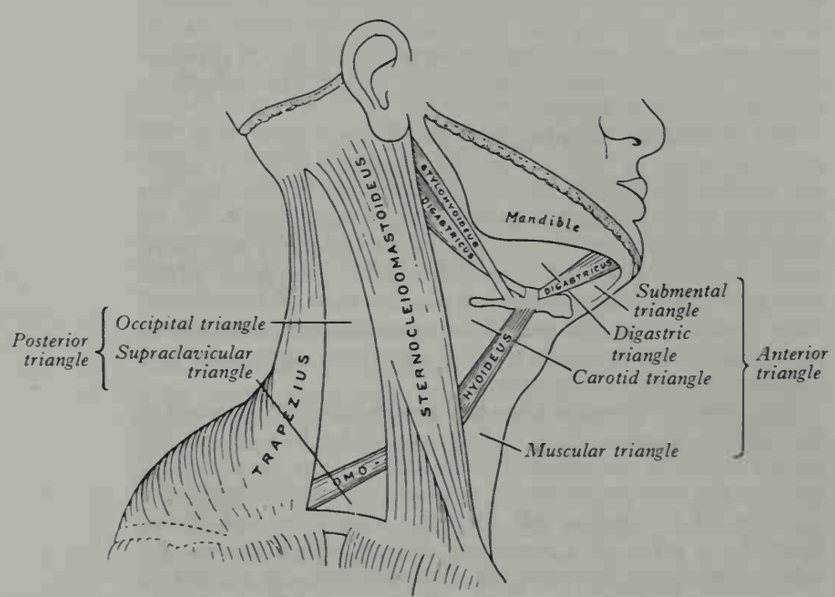
The buccal artery is small and runs obliquely forwards with the buccal nerve, between the medial pterygoid and the insertion of the temporalis, to the outer surface of the buccinator, to which it is distributed, anastomosing with branches of the facial and infraorbital arteries.

Branches of the Third Part

The posterior superior alveolar (dental) artery is given off from the maxillary artery as that vessel enters the pterygopalatine fossa. Descending upon the infratemporal surface of the maxilla, it divides into branches, some of which enter the alveolar canals, and supply the molar and premolar teeth and the lining of the maxillary sinus, while others are continued forwards on the alveolar process to supply the gums.

The infraorbital artery often arises in conjunction with the posterior superior alveolar artery. It enters the orbital cavity through the posterior part of the inferior orbital fissure, runs along the infraorbital groove and canal with the infraorbital nerve, and emerges with the nerve on the face through the infraorbital foramen, deep to the levator labii superioris. In the canal, it gives off (*a*) *orbital branches*, which assist in supplying the rectus inferior, the obliquus inferior and the lacrimal sac, and (*b*) *anterior superior alveolar (dental) branches*, which descend through the anterior alveolar canals to supply the upper incisor and canine teeth and the mucous membrane of the maxillary sinus. On the face, some branches ascend to the medial angle of the eye and the lacrimal sac, anastomosing with the terminal branches of the facial artery; others run towards the nose, anastomosing with the dorsal nasal branch of the ophthalmic artery; others descend between the levator labii superioris and the levator anguli oris, and anastomose with the facial, transverse facial and buccal arteries.

The remaining branches of the maxillary artery arise in the pterygopalatine fossa.



The greater palatine artery descends through the greater palatine canal with the greater palatine nerve from the pterygopalatine ganglion, and gives off two or three *lesser palatine arteries*, which are transmitted through the lesser palatine canals to supply the soft palate and tonsil, and to anastomose with the ascending palatine artery. The greater palatine artery emerges on the oral surface of the palate through the greater palatine foramen, runs forwards, in a groove near the alveolar border of the hard palate, to the incisive canal; its terminal part passes upwards through this canal, and anastomoses with a branch of the sphenopalatine artery. Branches are distributed to the gums, the palatine glands and the mucous membrane of the roof of the mouth.

The pharyngeal branch is very small; it runs backwards through the pharyngeal (palatovaginal) canal with the pharyngeal branch of the pterygopalatine ganglion, and is distributed to the mucosa of the roof of the nose, pharynx, sphenoidal air sinus and auditory tube.

The artery of the pterygoid canal, frequently a branch of the greater palatine artery, passes backwards along the pterygoid canal with the corresponding nerve supplying its walls and contents. It is also distributed to the mucous membrane of the upper part of the pharynx, the auditory tube and the tympanic cavity.

The pharyngeal branch is medial, and the artery of the pterygoid canal lateral, to the pterygopalatine ganglion, while the trunk of the maxillary artery is anterior to it.

The sphenopalatine artery, the terminal part of the maxillary artery, passes through the sphenopalatine foramen into the cavity of the nose at the posterior part of the superior meatus. Here arise its *posterior lateral nasal branches*, which ramify over the conchae and meatuses, anastomose with the ethmoidal arteries and the nasal branches of the greater palatine artery, and assist in supplying the frontal, maxillary, ethmoidal and sphenoidal sinuses. Crossing the anterior part of the inferior surface of the sphenoid bone, the sphenopalatine artery ends on the nasal septum as the *posterior septal branches*, which anastomose with the ethmoidal arteries; one branch descends in a groove on the vomer to the incisive canal and anastomoses with the terminal ascending branch of the greater palatine artery, and with the septal branch of the superior labial artery.

6.52 The triangles of the right side of the neck.

Collateral Circulation. After ligature of the common carotid, the collateral circulation can be established in many instances by the free communication which exists between the carotid arteries of opposite sides, both outside and inside the cranium, and by enlargement of the branches of the subclavian artery. The chief communications outside the skull take place between the superior and inferior thyroid arteries, and between the deep cervical and descending branch of the occipital; the vertebral takes the place of the internal carotid within the cranium.

Nevertheless, wounds of the common carotid should be treated by suture whenever possible, because, after ligature of the vessel, symptoms of cerebral disturbance supervene in about 25 per cent of cases.

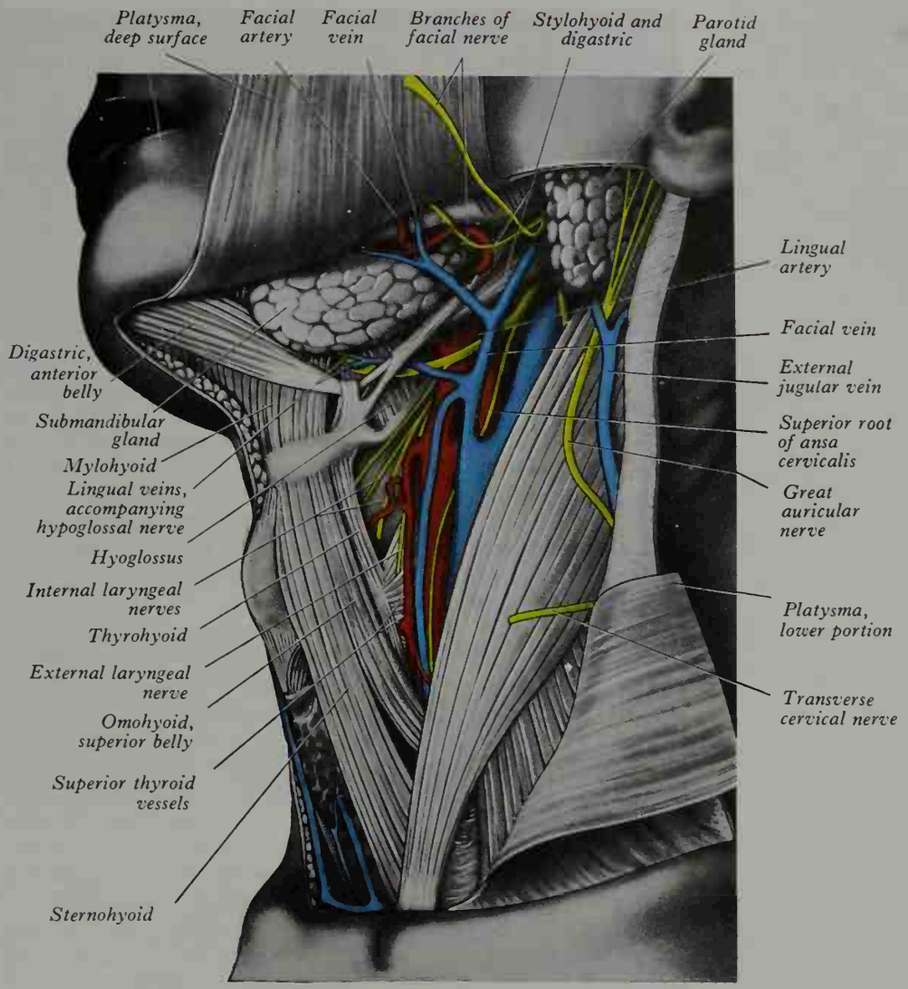
After ligature of the external carotid artery the circulation is re-

established by the free communication between most of the large branches of the artery (facial, lingual, superior thyroid, occipital) and the corresponding arteries of the opposite side, and by the anastomosis of its branches with those of the internal carotid artery, and of the occipital artery with branches of the subclavian, etc.

The Triangles of the Neck

The side of the neck (**6**.52) presents a somewhat quadrilateral outline, limited above by the base of the mandible, and a line drawn from the angle of the mandible to the mastoid process, below, by the upper border of the clavicle, in front, by the anterior median line of the neck, behind, by the anterior margin of the trapezius. This space is subdivided by the sternocleidomastoid, which passes obliquely across the neck, from the sternum and clavicle below, to the mastoid process and occipital bone above. The area in front of this muscle is called the *anterior triangle* of the neck, that behind it, the *posterior triangle*. While these and their subdivisions are purely arbitrary topographical regions, they have a certain value in description and as surface landmarks.

THE ANTERIOR CERVICAL TRIANGLE



The anterior triangle of the neck is bounded anteriorly by the anterior median line of the neck, posteriorly, by the anterior margin of the sternocleidomastoid; its base, directed upwards, as the inferior border of the mandible, and a line from the angle of the mandible to the mastoid process: its apex is below, at the sternum. This triangle may be subdivided into muscular, carotid, digastric and submental triangles.

The muscular triangle is bounded, in front, by the median line of the neck from the hyoid bone to the sternum, behind and below, by the anterior margin of the sternocleidomastoid, behind and above, but the superior belly of the omohyoid.

The carotid triangle is limited, behind, by the sternocleidomastoid, in front and below, by the superior belly of the omohyoid, above, by the stylohyoid and the posterior belly of the digastric. (It should be noted here that in the living non-obese neck, the carotid triangle is usually an obvious *surface feature*, presenting as a relatively small triangular depression, best seen with the head and cervical vertebral column slightly extended, and the head rotated a little to the contralateral side.)

It is covered by the skin, superficial fascia, platysma and deep fascia, ramifying in which are branches of the facial and the cutaneous cervical nerves. Its floor is formed by parts of the thyrohyoid, hyoglossus, and the inferior and middle constrictor muscles of the pharynx. When this space is dissected it is seen to contain the upper part of the common carotid artery, which divides opposite the superior border of the thyroid cartilage into the external and internal carotid arteries. These vessels are overlapped by the anterior margin of the sternocleidomastoid. The external and internal carotid arteries lie side by side, the external being the more anterior. The following branches of the external carotid artery are also encountered: the superior thyroid, running forwards and downwards, the lingual, forwards with an upward loop, the facial, forwards and upwards, the occipital, upwards and backwards and the ascending pharyngeal, directly upwards on the medial side of the internal carotid. The veins encountered are those corresponding to the above-mentioned branches of the external carotid artery—viz. the superior thyroid, the lingual, facial, ascending pharyngeal, and sometimes the occipital—all of which end in the internal jugular vein. The hypoglossal nerve crosses both the internal and external carotid arteries, curving round the origin of the lower sternocleidomastoid branch of the occipital artery; in this position it gives off the superior root of the ansa cervicalis, and this small nerve runs down in the anterior part of the carotid sheath. On the medial side of the external carotid artery, below the hyoid bone, is the internal laryngeal nerve and, still more inferiorly, the external laryngeal nerve.

It should be noted that many important structures in this region, such as the internal jugular vein, the vagus nerve, etc., lie entirely subjacent to the sternocleidomastoid and are therefore excluded from the triangle.

6.53 A dissection of the left anterior triangle. The platysma has been divided transversely; its upper part has been turned upwards on to the face, its lower part turned backwards, exposing the lower part of the sternocleidomastoid.

The digastric triangle is bounded, above, by the base of the mandible and a line drawn from its angle to the mastoid process, below and behind, by the posterior belly of the digastric and the stylohyoid, below and in front, by the anterior belly of the digastric.

It is covered by the skin, superficial fascia, platysma and deep fascia, ramifying in which are branches of the facial and transverse cutaneous cervical nerves. Its floor is formed by the mylohyoid and hyoglossus. The anterior part contains the submandibular gland, superficial to which is the facial vein, while deep to it is the facial artery, which crosses the lower border of the mandible at the anterior edge of the masseter; on the surface of the mylohyoid are the submental artery and the mylohyoid artery and nerve. The posterior part of this triangle contains the lower part of the parotid gland; the external carotid artery, having passed deep to the stylohyoid, curves over the upper border of the muscle so as to overlap to some extent its superficial surface where it ascends deep to the parotid gland before entering its substance. In this triangle the external carotid artery lies superficial to the internal carotid and crosses lateral to it; more deeply placed, and separated from the external carotid artery by the styloglossus, the stylopharyngeus and the glossopharyngeal nerve, are the internal carotid artery, the internal jugular vein and the vagus nerve.

The submental triangle is limited on each side by the anterior belly of the digastric; its apex is at the mandible; its base is formed by the body of the hyoid bone, and its floor by the mylohyoid. It contains one or two lymph nodes and some small veins; the latter unite to form the anterior jugular vein.

THE POSTERIOR CERVICAL TRIANGLE

The posterior triangle of the neck is bounded, in front, by the sternocleidomastoid, behind, by the anterior margin of the trapezius, its base is formed by the middle one-third of the clavicle; its apex is at the occipital bone between the attachments of the sternocleidomastoid and the trapezius. The 'apex' is often blunted by considerable separation between the occipital attachments of the latter two muscles, in which case the triangle is more of an elongated parallelogram between them. The triangle is crossed, about 2·5 cm above the clavicle, by the inferior belly of the omohyoid, which divides the triangle into an occipital and a supraclavicular triangle.

The occipital triangle, the upper and larger division of the posterior triangle, is bounded in front by the sternocleidomastoid, behind, by the trapezius, below, by the inferior belly of the omohyoid. Its floor is formed from above downwards by the splenius capitis, levator scapulae, and the scaleni medius et posterior; sometimes a small part of the semispinalis capitis is seen at the apex of the triangle. It is covered by the skin, the superficial and deep fasciae, and below by the platysma. The accessory nerve pierces the sternocleidomastoid and courses on the levator scapulae obliquely backwards across the space to reach the deep surface of the trapezius; the cutaneous and muscular branches of the cervical plexus become more superficial at the posterior border of the sternocleidomastoid; below, the supraclavicular nerves, the transverse cervical vessels and the upper part of the brachial plexus cross the space. A chain of lymph nodes is also arranged along the posterior border of the sternocleidomastoid, from the mastoid process to the root of the neck.

The supraclavicular triangle, the lower and smaller division of the posterior triangle, is bounded, above, by the inferior belly of the omohyoid, below, by the clavicle; its base is formed by the lower part of the posterior border of the sternocleidomastoid. Its floor consists of the first rib, the insertion of the scalenus medius and the first digitation of the serratus anterior. The size of this triangle varies with the extent of attachment of the clavicular portions of the sternocleidomastoid and trapezius, and also with the level at which the inferior belly of the omohyoid crosses the neck; this level is lowered when the arm is raised, and raised when the arm is depressed. The triangle is covered by the skin, the superficial and deep fasciae, and the platysma, and crossed by the supraclavicular nerves. Just above the level of the clavicle, the third portion of the subclavian artery curves laterally and downwards from the lateral margin of the scalenus anterior, across the first rib, to the axilla. The subclavian vein lies behind the clavicle, and is not usually seen in this space; but in some cases it rises as high as the artery, and has even been seen to accompany that vessel behind the scalenus anterior. The brachial plexus of nerves lies partly above and partly behind the artery, and in close contact with it. The suprascapular vessels pass transversely behind the clavicle and are not, strictly speaking, in the triangle; running in the same direction, but at a slightly higher level, are the transverse cervical artery and vein. The external jugular vein descends behind the posterior border of the sternocleidomastoid to terminate in the subclavian vein; it receives the transverse cervical and suprascapular veins, which form a plexus in front of the third part of the subclavian artery, and occasionally it is joined by a small vein which crosses the clavicle from the cephalic vein. The small nerve to the subclavius also crosses this triangle about its middle, and some lymph nodes are contained within the space.

The Internal Carotid Artery

The internal carotid artery (**6**.54, 55, 56) supplies the greater part of the cerebral hemisphere, the eye and its accessory organs, and sends branches to the forehead and nose. It begins at the bifurcation of the common carotid artery, where it usually presents a localized dilatation, termed the carotid sinus (p. 676). It ascends to the base of the skull, and enters the cranial cavity through the carotid canal of the temporal bone. It then runs forward through the cavernous sinus, lying in the carotid groove on the side of the body of the sphenoid bone, and ends below the anterior perforated substance of the brain by dividing into anterior and middle cerebral arteries.

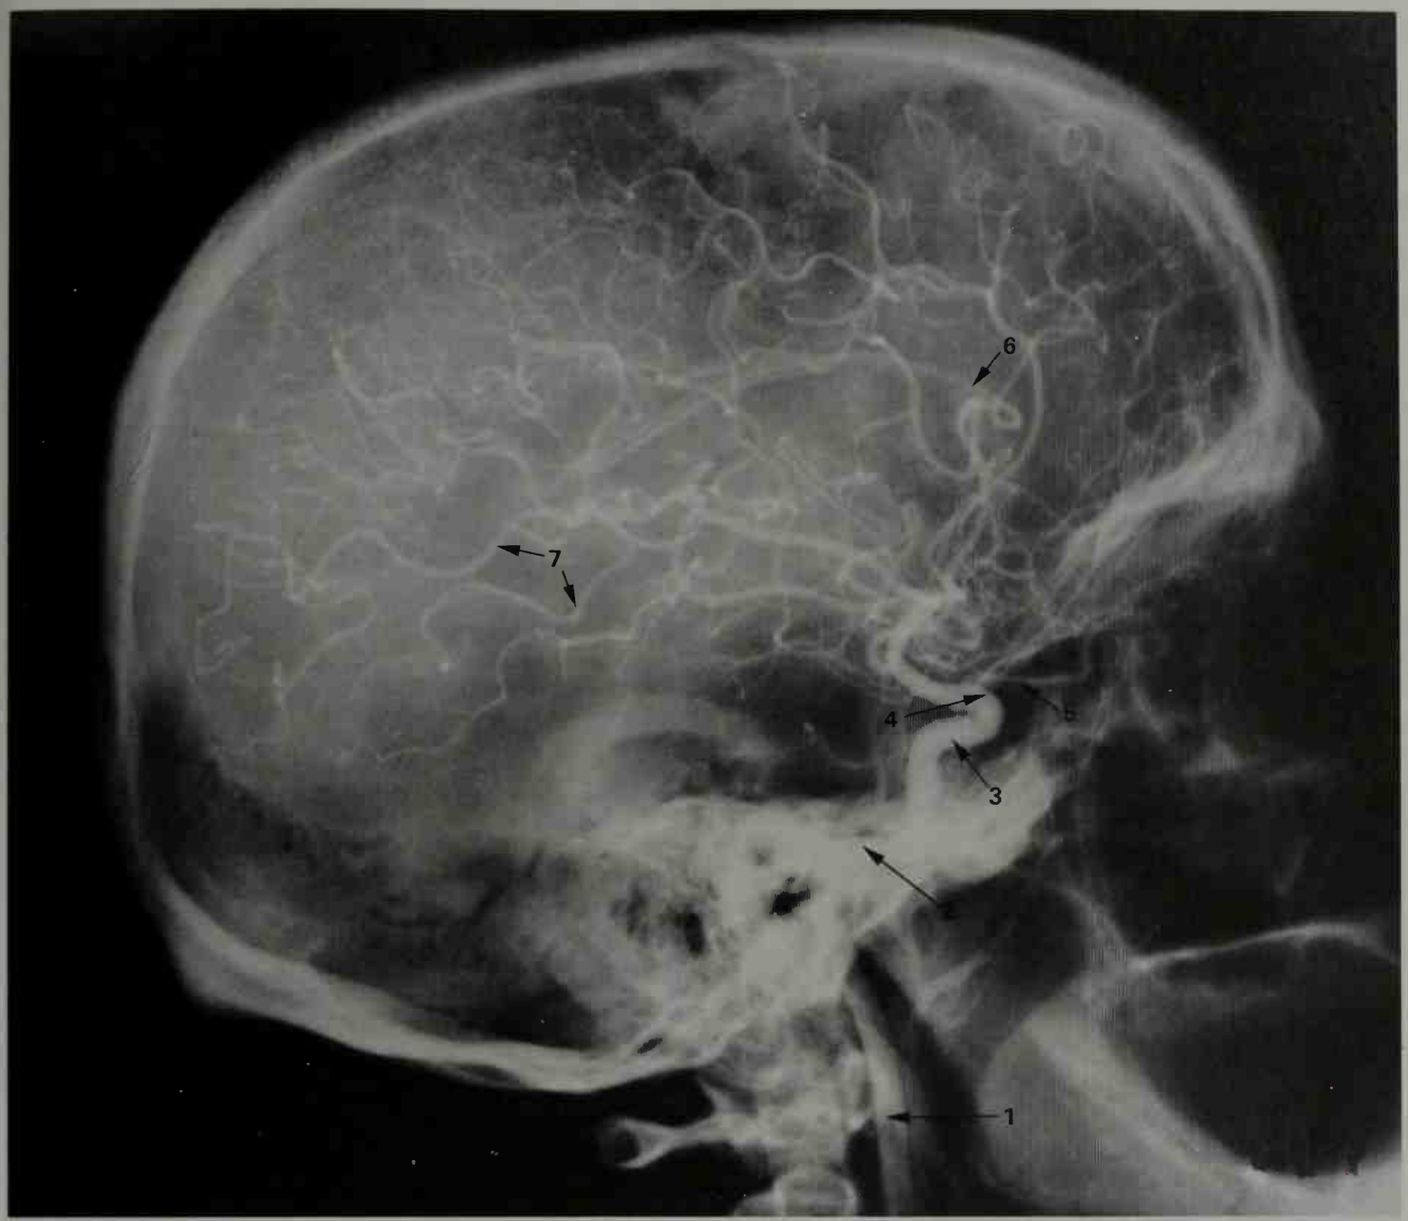
The internal carotid artery may for convenience be divided into four parts: cervical, petrous, cavernous and cerebral.

The Cervical Part

This section of the internal carotid artery begins at the carotid bifurcation, at the upper border of the thyroid cartilage, and ascends in front of the transverse processes of the upper three cervical vertebrae to the lower end of the carotid canal in the petrous portion of the temporal bone. Comparatively superficial at its commencement, it is contained in the carotid triangle, but after passing medial to the posterior belly of the digastric it lies on a much deeper plane. Except at the base of the skull, the internal jugular vein and the vagus nerve lie on its lateral side; the external carotid artery is at first anterior and medial to the internal carotid but on leaving the carotid triangle it curves backwards so as to lie superficial to it.

The cervical part of the internal carotid artery has many additional relations. *Posteriorly*, it adjoins the longus capitis, but the superior cervical sympathetic ganglion intervenes and the superior laryngeal nerve crosses obliquely behind the vessel. *Medially*, the artery is related to the wall of the pharynx, from which it is separated by an interval containing some fat, connective tissue and the pharyngeal veins, the ascending pharyngeal artery and the superior laryngeal nerve. *Anterolaterally*, the internal carotid artery is covered throughout by the sternocleidomastoid. In addition, *below the digastric*, the hypoglossal nerve and the superior root of the ansa cervicalis, the lingual and facial veins are superficial to the artery. *At the level of the digastric* the vessel is crossed by the stylohyoid and by the occipital and posterior auricular arteries. *Above the digastric*, it is separated from the external carotid artery by the styloid process, the styloglossus and stylopharyngeus, the glossopharyngeal nerve, the pharyngeal branch of the vagus and the deeper part of the parotid gland. At the base of the skull the glossopharyngeal, vagus, accessory and hypoglossal nerves are between the internal carotid artery and the internal jugular vein, which here lies posterior to the artery.

The Petrous Part



The internal carotid artery at first ascends in the carotid canal in the petrous temporal bone, and then curves forwards and medially. As it leaves the canal to enter the cranial cavity, it runs upwards and medially above the fibrocartilage which in life fills the foramen lacerum. Finally, it passes between the lingula and petrosal process of the sphenoid bone. The artery is at first in front of the cochlea and tympanic cavity; it is separated from the latter and from the auditory tube by a thin, bony lamella, cribriform in the young subject, often partly absorbed in old age. Further forwards it is separated from the trigeminal ganglion by a thin plate of bone, the floor of the trigeminal impression and the roof of the horizontal portion of the carotid canal; frequently this bony plate is more or less deficient. The artery is surrounded by a plexus of small veins and the carotid plexus of nerves, which is derived from the internal carotid branch of the superior cervical ganglion of the sympathetic trunk.

The Cavernous Part

When the internal carotid artery is in the cavernous sinus, it is covered by the lining endothelium of the sinus. It at first ascends towards the posterior clinoid process, then passes, forwards on the side of the body of the sphenoid, and again curves upwards on the medial side of the anterior clinoid process, traversing the dura mater forming the roof of the sinus; occasionally the anterior and middle clinoid processes form a bony ring round the artery. The cavernous portion of the artery is surrounded by a sympathetic plexus, and the oculomotor, trochlear, ophthalmic and abducent nerves (**6**.127) are lateral to it.

The Cerebral Part

After perforating the dura mater medial to the anterior clinoid process, the internal carotid artery turns backwards below the

6.54 Internal carotid arteriogram (right). Lateral view. (Adult male of 33 years.) The following can be identified: Parts of internal carotid artery and individual vessels—1. Cervical. 2. Intrapetrous. 3. Cavernous. 4. Terminal. 5. Ophthalmic artery. 6. Anterior cerebral artery. 7. Branches of middle cerebral artery. Note absence of radio-opaque injectant from cerebellar vessels.

optic nerve, and then passes between the optic and oculomotor nerves to the anterior perforated substance at the medial end of the lateral cerebral sulcus, where it divides into the anterior and middle cerebral arteries.

Variations. The length of the internal carotid artery naturally varies with the length of the neck, and with the point of carotid bifurcation. It arises occasionally from the arch of the aorta, and then has been found medial to the external carotid as far as the larynx, where it crosses behind the latter vessel to reach its usual position. The course of the cervical part of the artery, instead of being straight, may be very tortuous. When this occurs the vessel approaches nearer to the pharynx than usual, and may lie very close to the tonsil. Its absence has been occasionally recorded.

Surface Anatomy. The internal carotid corresponds to a broad line drawn upwards from the termination of the common carotid to the posterior border of the neck of the mandible (**6**.47).

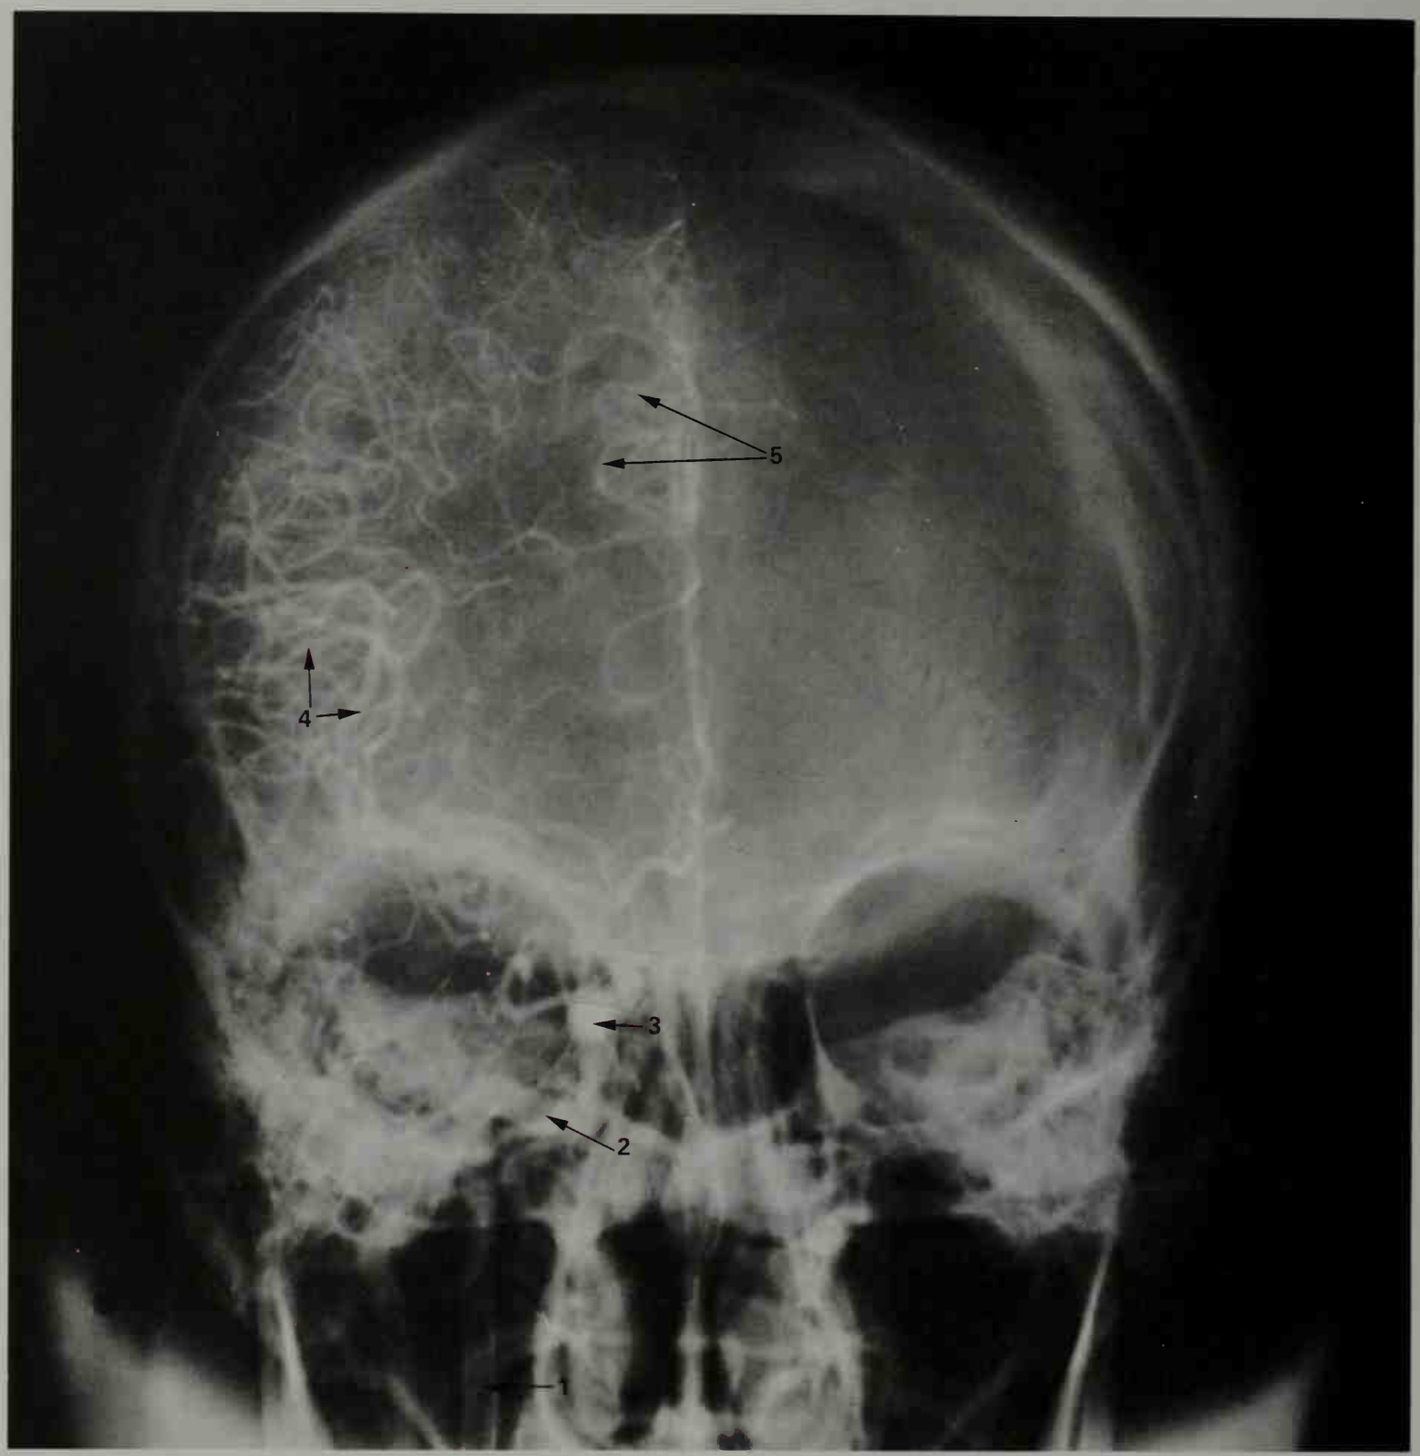
Branches. The cervical portion of the internal carotid has no branches. Those from the other parts are:

From the petrous part
1. Caroticotympanic.
2. Pterygoid.

From the cavernous part
3. Cavernous.
4. Hypophysial.
5. Meningeal.

From the cerebral part
6. Ophthalmic.
7. Anterior cerebral.
8. Middle cerebral.
9. Posterior communicating.
10. Anterior choroid.

1. The caroticotympanic branch (or branches) is small; it enters the tympanic cavity through a foramen in the wall of the carotid canal, and anastomoses with the anterior tympanic branch of the maxillary artery, and with the stylomastoid artery.



2. The pterygoid branch, small and inconstant, enters the pterygoid canal with the nerve of that name, and anastomoses with a branch of the greater palatine artery.

3. The cavernous branches are numerous small vessels which supply the trigeminal ganglion, the walls of the cavernous and inferior petrosal sinuses and their contained nerves. Some anastomose with middle meningeal rami.

4. The hypophysial branches are a group of small but important vessels; for details *see* p. 1443.

5. The meningeal branch is a minute branch which passes over the lesser wing of the sphenoid to supply the dura mater and bone of the anterior cranial fossa; it anastomoses with the meningeal branch from the posterior ethmoidal artery.

6. The ophthalmic artery (**6**.57) is a branch from the internal

6.55 Internal carotid arteriogram (right). Anteroposterior view. (Same subject as **6**.54.) Parts of internal carotid artery—1. Cervical. 2. Intrapetrous. 3. Cavernous. 4. Branches of middle cerebral artery. 5. Branches of anterior cerebral artery. Note lack of contrast medium on left side.

carotid as it emerges from the cavernous sinus medial to the anterior clinoid process; it enters the orbital cavity through the optic canal, inferolateral to the optic nerve. In the orbital cavity it runs for a short distance lateral to the optic nerve and medial to the oculomotor and abducent nerves, the ciliary ganglion and the rectus lateralis. It next crosses obliquely above the optic nerve and below the rectus superior to reach the medial wall of the orbit. It then runs forwards between the obliquus superior and the rectus medialis, and, at the medial end of the upper eyelid, divides into two branches, named *supratrochlear* and *dorsal nasal*. As the artery crosses the optic nerve it is accompanied by the nasociliary nerve, and is separated from the frontal nerve by the rectus superior and levator palpebrae superioris; the terminal part of the artery is accompanied by the infratrochlear nerve. In about 15 per cent of subjects the ophthalmic artery crosses below the optic nerve. Its branches are as follows.

The *central artery of the retina*, the first and one of the smallest branches of the ophthalmic artery, commences below the optic nerve. It runs for a short distance within the dural sheath of the optic nerve, and about 1·25 cm behind the eyeball it pierces the inferomedial surface of the nerve, and runs forward to the retina along the centre of it. Its distribution is described elsewhere with the eye (p. 1175).

The *lacrimal artery* arises from the ophthalmic artery close to its exit from the optic canal, and is one of its largest branches; sometimes it is given off before the ophthalmic artery enters the orbit; occasionally its place is taken by a branch of the middle meningeal artery (p. 683). It accompanies the lacrimal nerve along the upper border of the rectus lateralis, and supplies the lacrimal gland. Its terminal branches, after traversing the gland, are distributed to the eyelids and conjunctiva: of those supplying the eyelids, two are of considerable size and are named the *lateral*

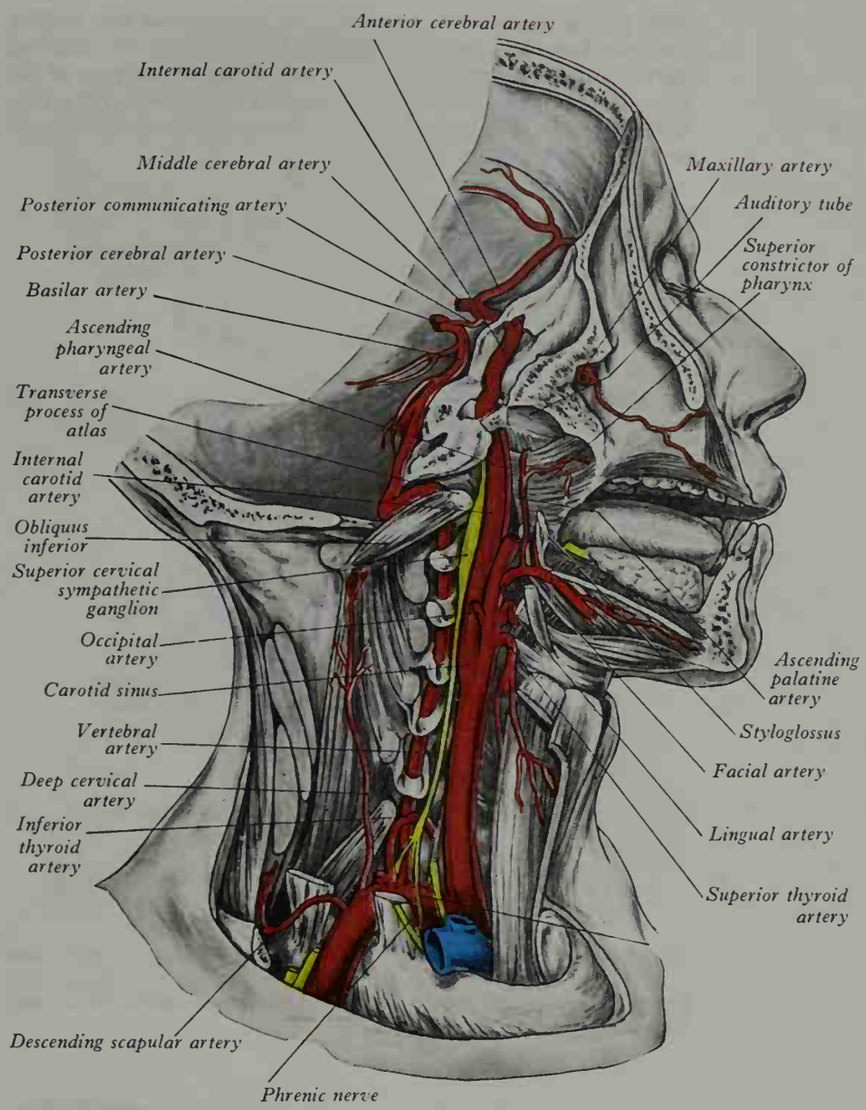
palpebral arteries; they run medially in the upper and lower lids respectively and anastomose with the medial palpebral arteries. The lacrimal artery gives off one or two *zygomatic branches*, one of which passes through the zygomaticotemporal foramen to the temporal fossa, and anastomoses with the deep temporal arteries; another appears on the cheek through the zygomaticofacial foramen and anastomoses with the transverse facial and zygomatico-orbital arteries. A *recurrent meningeal branch* passes backwards through the lateral part of the superior orbital fissure and anastomoses with a branch of the middle meningeal artery. It is enlargement of this anastomosis which may provide an alternative origin of the lacrimal artery.

The *muscular branches* frequently spring from a common trunk. They consist of a superior and an inferior group, and most of them accompany the branches of the oculomotor nerve. The inferior group, more constantly present, gives off most of the anterior ciliary arteries. Additional muscular branches are derived from the lacrimal and supraorbital arteries, or from the trunk of the ophthalmic artery.

The *ciliary arteries* are divisible into three groups, long and short posterior, and anterior.

The *long posterior ciliary arteries*, two in number, pierce the posterior part of the sclera a short distance from the entrance of the optic nerve. Their distribution is described on p. 1162.

The *short posterior ciliary arteries*, about seven in number, pass forwards around the optic nerve to the posterior part of the eyeball, and, after dividing into from fifteen to twenty branches, pierce the sclera around the entrance of the nerve, and supply the choroid coat and the ciliary processes. At the entrance of the optic nerve they anastomose with twigs of the central artery of the retina, and at the ora serrata with branches of the long posterior and anterior ciliary arteries.



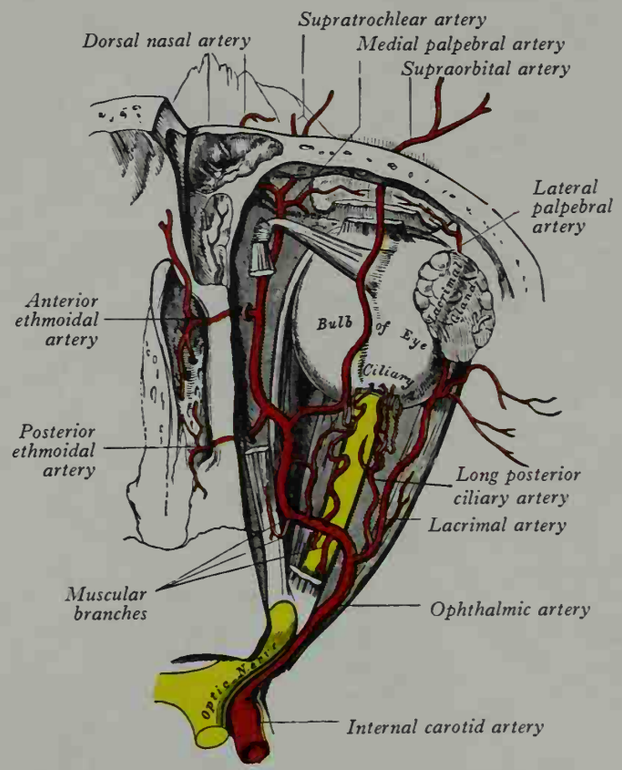
The *anterior ciliary arteries* are derived from the muscular branches of the ophthalmic artery; they run to the front of the eyeball on the tendons of the recti, form a circumcorneal vascular zone beneath the conjunctiva, and then pierce the sclera a short distance from the sclerocorneal junction and end in the greater arterial circle of the iris (p. 1162).

The *supraorbital artery* leaves the ophthalmic artery as the vessel crosses the optic nerve. It ascends medial to the rectus superior and levator palpebrae superioris and, meeting the supraorbital nerve, accompanies it between the periosteum and levator palpebrae superioris to the supraorbital foramen or notch; passing through this it divides into superficial and deep branches, which supply the skin, muscles and pericranium of the forehead, anastomosing with the supratrochlear artery, the frontal branch of the superficial temporal artery, and the artery of the opposite side. In the orbit it supplies twigs to the rectus superior and the levator palpebrae, and sends a branch across the trochlea of the obliquus superior, to the parts at the medial angle of the eye. At the supraorbital margin it frequently sends a branch to the diploë of the frontal bone, which may supply the mucoperiosteum of the frontal sinus.

The *posterior ethmoidal artery* runs through the posterior ethmoidal canal, supplies the posterior ethmoidal air sinuses, and, entering the cranium, gives off a meningeal branch to the dura mater and nasal branches which descend into the nasal cavity through the cribriform plate of the ethmoid bone, to anastomose with branches of the sphenopalatine artery supplying bone.

The *anterior ethmoidal artery* accompanies the anterior ethmoidal nerve through the anterior ethmoidal canal, supplies the anterior and middle ethmoidal and frontal air sinuses, and, entering the cranium, gives off a meningeal branch to the dura mater, and nasal branches; the latter descend into the nasal cavity with the anterior ethmoidal nerve and, running along the groove on the inner surface of the nasal bone, supply twigs to the lateral wall and septum of the nose, and a terminal branch which appears on the dorsum of the nose between the nasal bone and the upper nasal cartilage. Angiographic studies (Kuru 1967) have shown that the meningeal branch may extend in to the falx; Müller (1977, 1978) has confirmed this finding in fetal and adult material and has shown that these '*falciate arteries*' may also be derived from the recurrent meningeal branch of the lacrimal artery.

The *meningeal branch* is a small artery which passes backwards through the superior orbital fissure to the middle cranial fossa, and anastomoses with the middle and accessory meningeal arteries. It supplies bone.



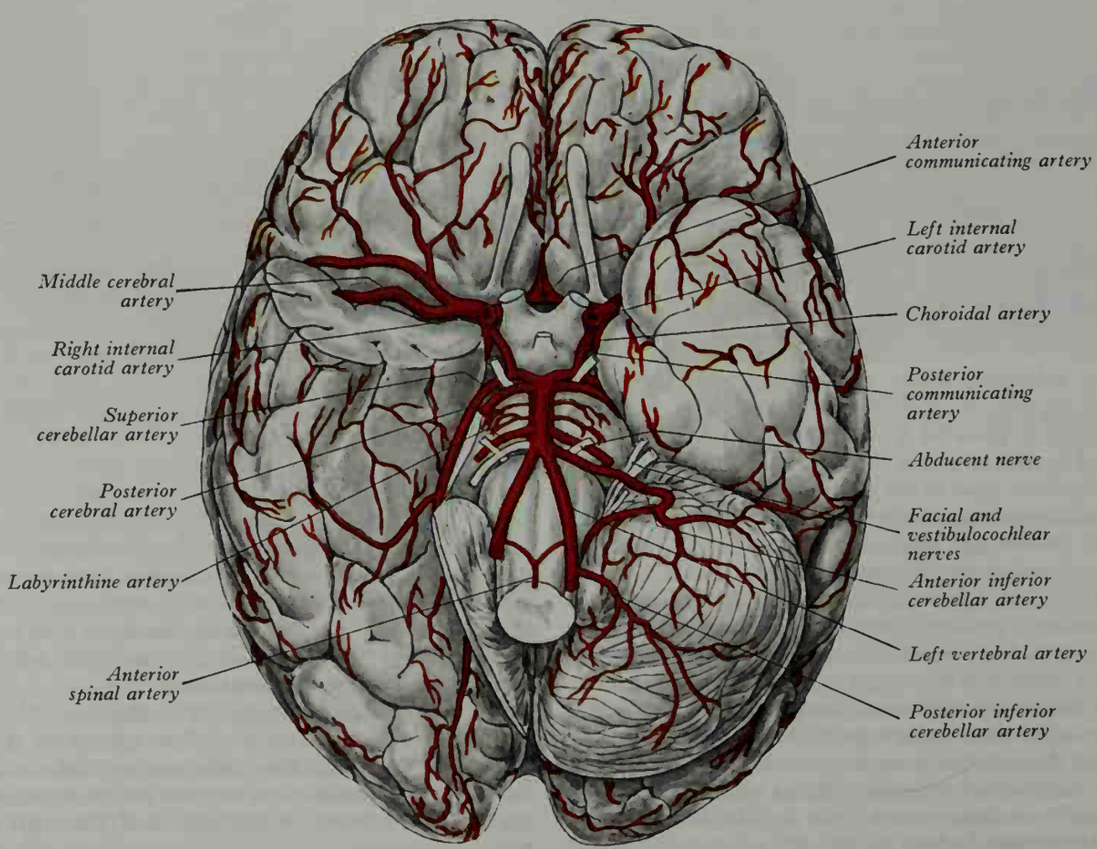
6.56 A dissection to show the course of the right vertebral and internal carotid arteries and some of their branches.

The *medial palpebral arteries*, two in number, superior and inferior, arise from the ophthalmic artery below the trochlea of the obliquus superior. They descend behind the lacrimal sac, and enter the eyelids, where each divides into two branches which course laterally along the edges of the tarsi, thus forming two arches (a superior and an inferior) in each eyelid. The superior palpebral artery anastomoses with the supraorbital artery, and, at the lateral part of the eyelid, with the zygomatico-orbital branch of the superficial temporal artery, and with the upper of the two lateral palpebral branches of the lacrimal artery. The inferior palpebral artery anastomoses at the lateral part of the eyelid with the lower of the two lateral palpebral branches of the lacrimal artery and with the transverse facial artery and, at the medial part of the eyelid, with a twig from the facial artery; from this last anastomosis a branch passes to supply the nasolacrimal duct, ramifying in its mucous membrane.

The *supratrochlear artery*, one of the terminal branches of the ophthalmic artery, leaves the orbital opening at its superomedial angle, with the supratrochlear nerve, and, ascending on the forehead, supplies the skin, muscles and pericranium, anastomosing with the supraorbital artery and with the artery of the opposite side.

The *dorsal nasal artery*, the other terminal branch of the ophthalmic artery, emerges from the orbit between the trochlea of the obliquus superior and the medial palpebral ligament, and,

after giving a twig to the upper part of the lacrimal sac, divides into two branches, one of which anastomoses with the terminal part of the facial artery; the other runs along the dorsum of the nose, supplies its outer surface, and anastomoses with the artery of the opposite side, and with the lateral nasal branch of the facial artery.



6.57 The ophthalmic artery and its branches in the right orbit, as seen from above.

7. The anterior cerebral artery (**6**.58, 59, 60), the smaller of the two terminal branches of the internal carotid artery, starts at the medial end of the lateral cerebral sulcus. It passes forwards and medially above the optic nerve, to the commencement of the longitudinal fissure. Here it comes into close relationship with the opposite artery and is joined to it by a short transverse trunk (sometimes duplicated) named the anterior communicating artery. From this point, the two anterior cerebral arteries run side by side in the longitudinal cerebral fissure, curving round the genu of the corpus callosum, and running backwards along the upper surface of this structure to its posterior extremity, where they end by anastomosing with the posterior cerebral arteries. Occasionally the two arteries join to form a single vessel.

In its course the anterior cerebral artery gives off central and cortical branches.

The *anterior communicating artery* has an average length of about 4 mm and connects the two anterior cerebral arteries across the commencement of the longitudinal fissure; sometimes it is double. It gives off a few anteromedial central branches (p. 1642). According to Crowell and Morawetz (1977) the branches of the anterior communicating artery are constantly present, varying from 3 to 13 in number, and can be seen to supply the optic chiasma, lamina terminalis, hypothalamus, parolfactory areas of Broca, fornix (anterior columns), and the cingulate gyrus.

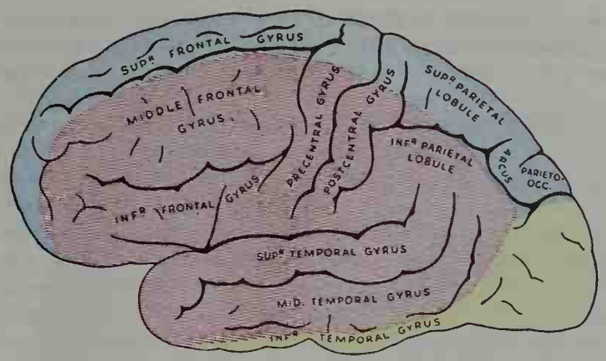
The *central branches* are a group of small arteries which arise from the commencement of the anterior cerebral artery; they pierce the anterior perforated substance and lamina terminalis, and supply the rostrum of the corpus callosum, the septum pellucidum, the anterior part of the putamen of the lentiform nucleus and the head of the caudate nucleus. The *cortical branches* are named according to their distribution. The *orbital branches*, two or three in number, are distributed to the orbital surface of the frontal lobe, where they supply the olfactory lobe, gyrus rectus and medial orbital gyrus. The *frontal branches* supply the corpus callosum, the cingulate gyrus, the medial frontal gyrus and the paracentral lobule, and send twigs over the superomedial border of the cerebral hemisphere to the superior and middle frontal gyri and the upper part of the precentral gyrus. It is to be noted that

6.58 The arteries at the base of the brain. The right temporal pole and most of the right hemisphere of the cerebellum have been removed. Variations in the pattern of these vessels is common.

these branches supply the 'leg area' of the motor cortex (p. 1013). The *parietal branches* supply the precuneus and adjacent lateral surface of the hemisphere.

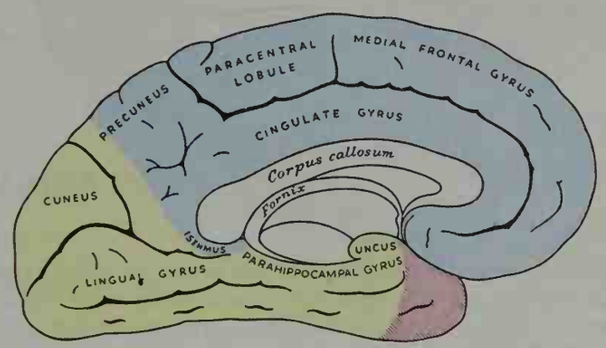
8. The middle cerebral artery (**6**.58, 59, 60), the larger terminal branch of the internal carotid artery, runs first laterally in the lateral cerebral sulcus and then backwards and upwards on the surface of the insula, where it divides into branches which are distributed to the insula and to the lateral surface of the cerebral hemisphere (**6**.59).

The *central branches* are small arteries from the commencement of the middle cerebral artery which enter the substance of the brain through the anterior perforated substance. They are arranged in two sets: one, *medial striate arteries*, ascend through the lentiform nucleus, and supply it, the caudate nucleus, and the internal capsule; the other, *lateral striate arteries*, ascend over the lower part of the lateral aspect of the lentiform nucleus (in the external capsule) and then, bending medially, traverse this nucleus and the internal capsule to supply the caudate nucleus. One of this group is usually larger than the rest, and of special importance as the artery in the brain most susceptible to rupture; it was termed by Charcot the '*artery of cerebral haemorrhage*'. The *cortical arteries* supply *orbital branches* to the inferior frontal gyrus and the lateral part of the orbital surface of the frontal lobe. The *frontal branches* supply the precentral and the middle and inferior frontal gyri. The *parietal branches*, two in number, are distributed to the postcentral gyrus, the lower part of the superior parietal lobule, and the whole of the inferior parietal lobule. The *temporal arteries*, two or three in number, are distributed to the lateral surface of the temporal lobe. It is to be noted that the cortical branches of the middle cerebral artery supply the motor area (excluding the 'leg area') of the cerebral cortex (p. 1013), its corresponding somaesthetic area (p. 1015), and the auditory area (p. 1021).



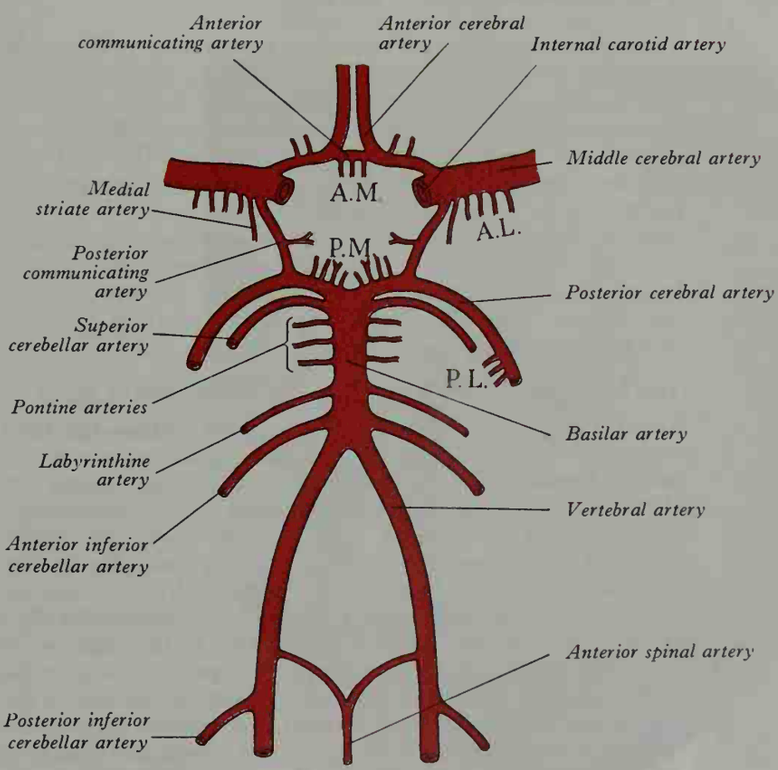
9. The posterior communicating artery (**6**.58, 61) runs backwards from the internal carotid above the oculomotor nerve, and anastomoses with the posterior cerebral, a branch of the basilar artery. It is usually a small vessel, but is occasionally so large that the posterior cerebral may be considered as arising from the internal carotid rather than from the basilar. It is frequently larger on one side than on the other. From its posterior half are given off several small *central branches*, which, with similar vessels from the posterior cerebral artery, pierce the posterior perforated substance and supply the medial surface of the thalamus and the walls of the third ventricle (p. 1043).

10. The anterior choroidal artery, a small but constant ramus, leaves the internal carotid, near the posterior communicating artery (Abbie 1933, 1934). Passing backwards above the medial part of the uncus, it crosses inferior to the optic tract and reaches the crus cerebri, to which it gives several branches. It then turns laterally, recrossing the optic tract, and arrives at the lateral aspect of the lateral geniculate body, to which it supplies a number of branches. Finally it enters the inferior horn of the lateral ventricle through the choroidal fissure and ends in the choroidal plexus. It also supplies branches to the globus pallidus, caudate nucleus, and amygdaloid body. Other branches supply the hypothalamus, tuber cinereum, red nucleus, substantia nigra, posterior limb of the internal capsule, optic radiation, optic tract, hippocampus and fimbria of the fornix.



The Circulus Arteriosus (of Willis)

A considerable part of the brain is supplied by the two vertebral arteries (p. 694) and a remarkable anastomosis, the *circulus arteriosus*, exists between these and the two internal carotid arteries. This circle (which is really more polygonal than circular), is situated in the cisterna interpeduncularis at the base of the brain, and encloses the optic chiasma and the structures in the interpeduncular fossa (p. 966). It is formed as follows: in front, the two anterior cerebral arteries are joined to each other by the anterior communicating artery; behind, the basilar artery (p. 696) divides into the two posterior cerebral arteries, each of which is joined to the internal carotid artery of the same side by the posterior communicating artery (**6**.61).



The arteries forming the arterial 'circle' evince much variation in calibre, being frequently hypoplastic and sometimes absent.

6.59 The lateral surface of the left cerebral hemisphere, showing areas supplied by the cerebral arteries. In this and the next figure the area supplied by the anterior cerebral artery is coloured *blue*, that by the middle cerebral artery, *pink*, and that by the posterior cerebral artery, *yellow*.

6.60 The medial surface of the left cerebral hemisphere, showing the areas supplied by the cerebral arteries (see description of **6**.59).

6.61 A diagram of the arteries at the base of the brain, showing the constitution of the arterial circle. A.L.—Anterolateral central branches, A.M.—Anteromedial central branches, P.L.—Posterolateral central branches, P.M.—Posteromedial central branches. The arteries constituting this so-called arterial 'circle' are commonly asymmetric, and sometimes a constituent vessel is missing.

About 60 per cent of circles display 'anomalies', and hence the arrangement described above is applicable to only a minority of cases. These variations have been much studied, from Windle's account in 1888 of 200 specimens, to that of Puchades-Ort *et al.* (1976) based on 62 dissections, the largest series being those of Fawcett and Blachford (1906)—700 dissections, and Riggs and Rupp (1963)—994 dissections. Fields *et al.* (1965) have summarized the anomalies in such studies, and these authorities should be consulted for details. The cerebral and communicating arteries, both anterior and posterior, may all be absent, hypoplastic to varying degrees, double or even sometimes triple. In about 90 per cent or more of circles there is, nevertheless, a complete 'circular' channel, but in a large majority of these one or other of the formative vessels is sufficiently narrowed in calibre to cast doubt on its functional value as a collateral route. The haemodynamic 'balance' of the circle is more often than not disturbed by variation in the calibres of the communicating arteries, and this is often coupled with variation in the proximal segments of the anterior and posterior cerebral arteries, that is, the segments extending from their origins to their junctions with the corresponding communicating artery. This segment is, in the case of the posterior cerebral artery, particularly 'labile', being often much reduced in calibre or even absent. Where this is coupled, as it often is, with an enlarged posterior communicating artery on the side in question, the posterior cerebral artery is derived, in effect, from the internal carotid. As Abbie (1933), Williams (1936), and Kaplan (1956) have pointed out, this anomaly is in harmony with the ontogenetic and phylogenetic association of the posterior cerebral with the internal carotid artery. In the anterior region of the arterial circle agenesis or hypoplasia of the initial segment of the anterior cerebral artery is more frequent than similar anomalies in the anterior communicating, and is hence a commoner cause of defective collateral circulation. Angiographic evidence suggests that defective or absent collateral circulation of this kind may be encountered in about one third of individuals (Sedzmir 1959). It is therefore clear that the existence of an effective arterial circle cannot be assumed in any patient, and that surgical procedures involving its 'feeders' must depend upon adequate angiographic investigation.

For diagnostic purposes, radio-opaque substances may be injected into the internal carotid or vertebral arteries in the neck and the condition of their intracranial branches studied radiologically (**6**.54, 55, 65, 66).

Further details of the distribution of the arteries and veins of the brain appear on pp. 1042–1045. For the intracranial venous sinuses *see* pp. 744–749.

THE SUBCLAVIAN SYSTEM OF ARTERIES

The stem artery of the upper limb runs as a single trunk as far as the elbow; but it is differently named, according to the regions it traverses. From its origin to the outer border of the first rib it is termed *subclavian*; from this point to the lower border of the tendon of the teres major it is named *axillary*; and from here to its division opposite the neck of the radius it is called *brachial*.

The Subclavian Arteries

The right subclavian artery arises from the brachiocephalic trunk, the left, from the arch of the aorta. To facilitate description, each subclavian artery is divided into three parts; the first extends from the origin of the vessel to the medial border of the scalenus anterior, the second lies behind this muscle, and the third runs from the lateral margin of the muscle across the first rib to its outer border, where it becomes the axillary artery; each artery arches over the cervical part of the pleura and apex of the lung. The first parts of the two vessels differ from one another in their origin, length, course and relations, and therefore require separate descriptions. The relations of the second and third parts are almost alike on the two sides of the neck.

The First Part of the Right Subclavian Artery (**6**.45, 62)

This arises from the brachiocephalic trunk, behind the right sternoclavicular joint, and passes upwards and laterally to the medial margin of the scalenus anterior. It ascends about 2 cm above the clavicle, but the height it reaches varies considerably.

Relations. The artery is deep to skin, superficial fascia, platysma, anterior supraclavicular nerves, deep fascia, the clavicular attachment of the sternocleidomastoid, the sternohyoid and sternothyroid. At its start it is *behind* the origin of the right common carotid; more laterally it is crossed by the vagus nerve and cardiac branches of the vagus and sympathetic, and by the internal jugular and vertebral veins; the subclavian loop of the sympathetic trunk encircles the vessel. The anterior jugular vein diverges *laterally* in front of the artery, but is separated from it by the sternohyoid and sternothyroid. *Below* and *behind*, the artery is related to the pleura and the apex of the lung, but it is separated from them by the suprapleural membrane (p. 1249), the ansa subclavia, a small accessory vertebral vein (p. 742), and the right recurrent laryngeal nerve (which winds round the lower and posterior part of the vessel).

The First Part of the Left Subclavian Artery (**6**.41, 44, 63, 118)

This arises from the arch of the aorta, behind the left common carotid, usually at the level of the disc between the third and fourth thoracic vertebrae; it ascends to the root of the neck and then arches laterally as far as the medial border of the left scalenus anterior.

Relations. Within the thorax it is related, *in front*, to the left common carotid artery and the commencement of the left brachiocephalic vein, from which it is separated by the left vagus, cardiac (p. 1128) and phrenic nerves. Superficial to these structures, the anterior margin of the left lung and pleura and the sternothyroid and sternohyoid intervene between the vessel and the upper, left part of the manubrium sterni. *Behind*, it lies, successively, on the left edge of the oesophagus, the thoracic duct and the longus colli, and it is in contact posterolaterally with the left lung and pleura. *Medially* it is related, successively, to the trachea, the left recurrent laryngeal nerve, the oesophagus and the thoracic duct. *Laterally* the artery grooves the mediastinal surface of the left lung and pleura, and these structures, as already indicated, tend to encroach on its anterior and posterior aspects.

In the neck near the medial border of the scalenus anterior the artery is crossed *anteriorly* by the left phrenic nerve and the terminal part of the thoracic duct. Otherwise the relations are the same as those previously described for the first part of the right subclavian artery. *Posteriorly* and *inferiorly*, the relations of the two vessels are identical, but the left recurrent laryngeal nerve, which is related to the left subclavian artery in the thorax, is not directly related to its cervical part.

The Second Part of the Subclavian Artery (**6**.45, 64)

This lies behind the scalenus anterior; it is very short, and forms the highest part of the arch described by the vessel.

Relations. Deep to skin, superficial fascia, platysma, deep cervical fascia, sternocleidomastoid and scalenus anterior. On the right the phrenic nerve is often said to be separated from the second part by scalenus anterior, on the left side crossing the first part of the artery at the muscles' edge. Qvist (1977) holds that *both* nerves lie anterior to the muscles at this level. *Behind* and *below* are the suprapleural membrane, pleura and lung, and the lower trunk of the brachial plexus; *above*, the upper and middle trunks of the brachial plexus. The subclavian vein lies below and in front of the artery, separated by scalenus anterior (**6**.64).

The Third Part of the Subclavian Artery

This runs slightly downwards and laterally from the lateral margin of the scalenus anterior to the lateral border of the first rib, where it becomes the axillary artery. This is the most superficial portion of the vessel, and is contained in the supraclavicular triangle (p. 686).

Relations. It is deep to the skin, the superficial fascia, the platysma, the supraclavicular nerves and the deep cervical fascia. The external jugular vein crosses its medial part and receives the suprascapular, transverse cervical and anterior jugular veins, which frequently form a plexus in front of the artery. The nerve to the subclavius descends behind the veins and in front of the artery. The terminal part of the artery lies behind the clavicle and the subclavius, and is crossed by the suprascapular vessels. The subclavian vein is in front of, and at a slightly lower level than, the artery. The lower trunk of the brachial plexus lies *behind* and *below* the artery and intervenes between it and the scalenus medius. *Above*, and to its *lateral side*, are the upper and middle trunks of the brachial plexus, and the inferior belly of the omohyoid. *Below*, it rests on the superior surface of the first rib.

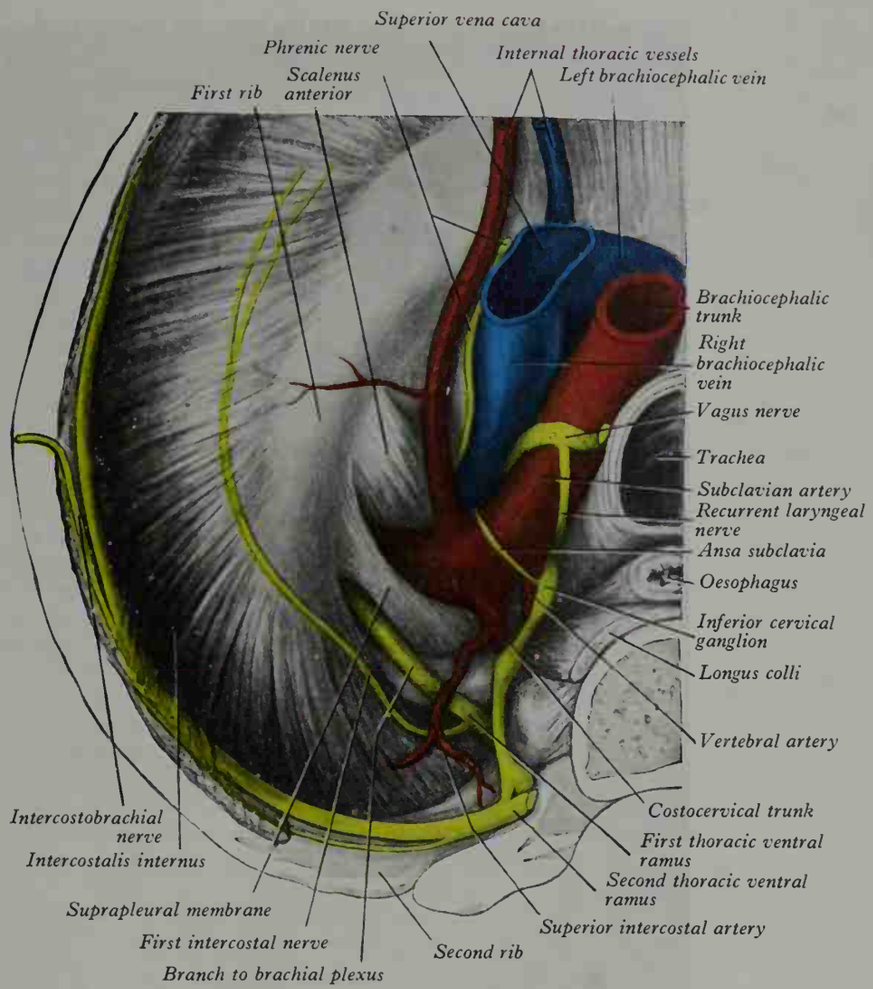
Surface Anatomy. The subclavian artery can be represented by a broad line, convex upwards, drawn from the sternoclavicular joint to the middle of the lower border of the clavicle (**6**.47). The third part of the vessel can be felt pulsating by deep pressure in the lower and anterior angle of the posterior triangle.

Variations. The subclavian arteries vary in their origin, course, and the height to which they rise in the neck.

The right subclavian may arise from the brachiocephalic above or below the level of the sternoclavicular joint. It may be a separate trunk from the arch of the aorta, and may then be either its first or last branch. When it is the first branch, it occupies the ordinary position of the brachiocephalic trunk; and when the last, it arises from the left extremity of the arch, and ascends obliquely towards the right side behind the trachea, oesophagus, and right common carotid to the inner border of the first rib, whence it follows its ordinary course. In these cases, the proximal part of the artery represents a persistent part of the right dorsal aorta, and the right fourth aortic arch takes no part in its formation (p. 188), and hence the right recurrent laryngeal nerve hooks round the lateral side of the common carotid, which is derived from the artery of the third arch. Sometimes, when it arises as the last branch of the arch of the aorta, the right subclavian artery passes between the trachea and the oesophagus.

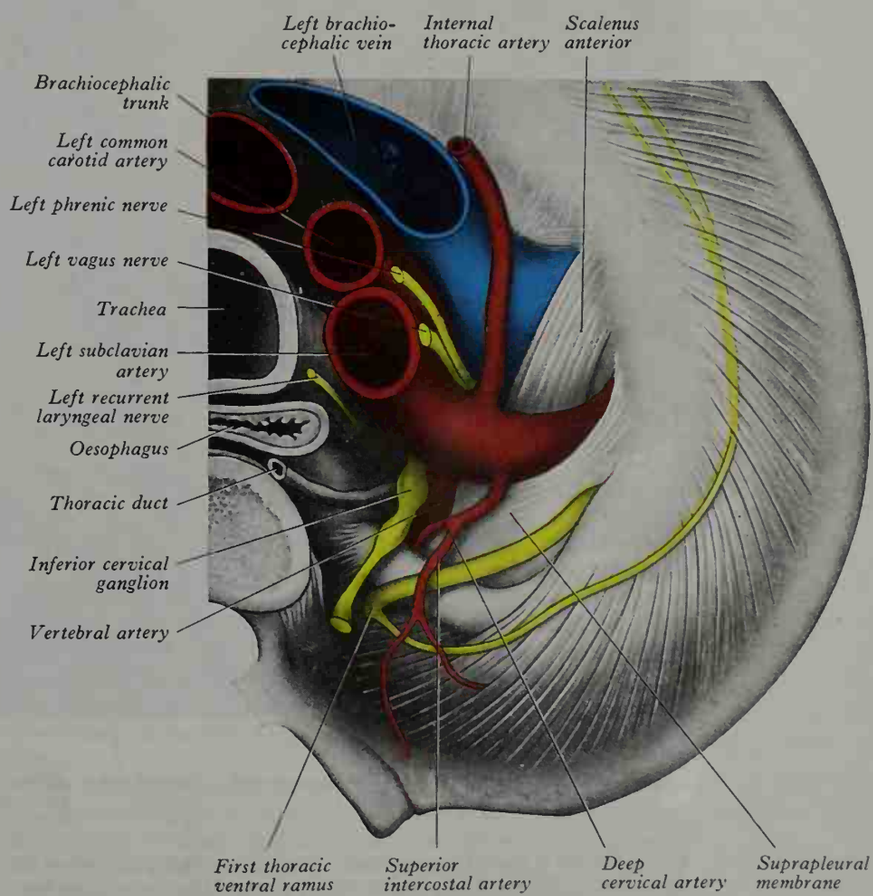
Occasionally the subclavian artery perforates the scalenus anterior; very rarely it passes in front of that muscle. Sometimes the subclavian vein passes with the artery behind the scalenus anterior. The artery may ascend as high as 4 cm above the clavicle or may only reach the level of the upper border of the bone.

The left subclavian is occasionally joined at its origin with the left common carotid. It is more posterior in position than the right subclavian in the first part of its course, and, as a rule, does not reach quite as high a level in the neck.



Applied Anatomy. The third part of the subclavian artery is the most accessible. As the posterior border of the sternocleidomastoid corresponds closely to the lateral border of the scalenus anterior, the artery lies immediately lateral to the former and, with firm pressure, can be felt pulsating in the lower, anterior angle of the posterior triangle.

Effective compression of the subclavian artery can be attained only where it passes across the upper surface of the first rib. To compress the vessel here, the shoulder should be depressed and pressure exercised downwards, backwards and medially in the angle formed by the posterior border of the sternocleidomastoid with the upper border of the clavicle.



BRANCHES OF THE SUBCLAVIAN ARTERY

1. Vertebral.
2. Internal thoracic.
3. Thyrocervical.
4. Costocervical.
5. Dorsal scapular.

On the left side all branches except the dorsal scapular arise close together from the first part of the artery; on the right side the costocervical trunk usually springs from the second part. The

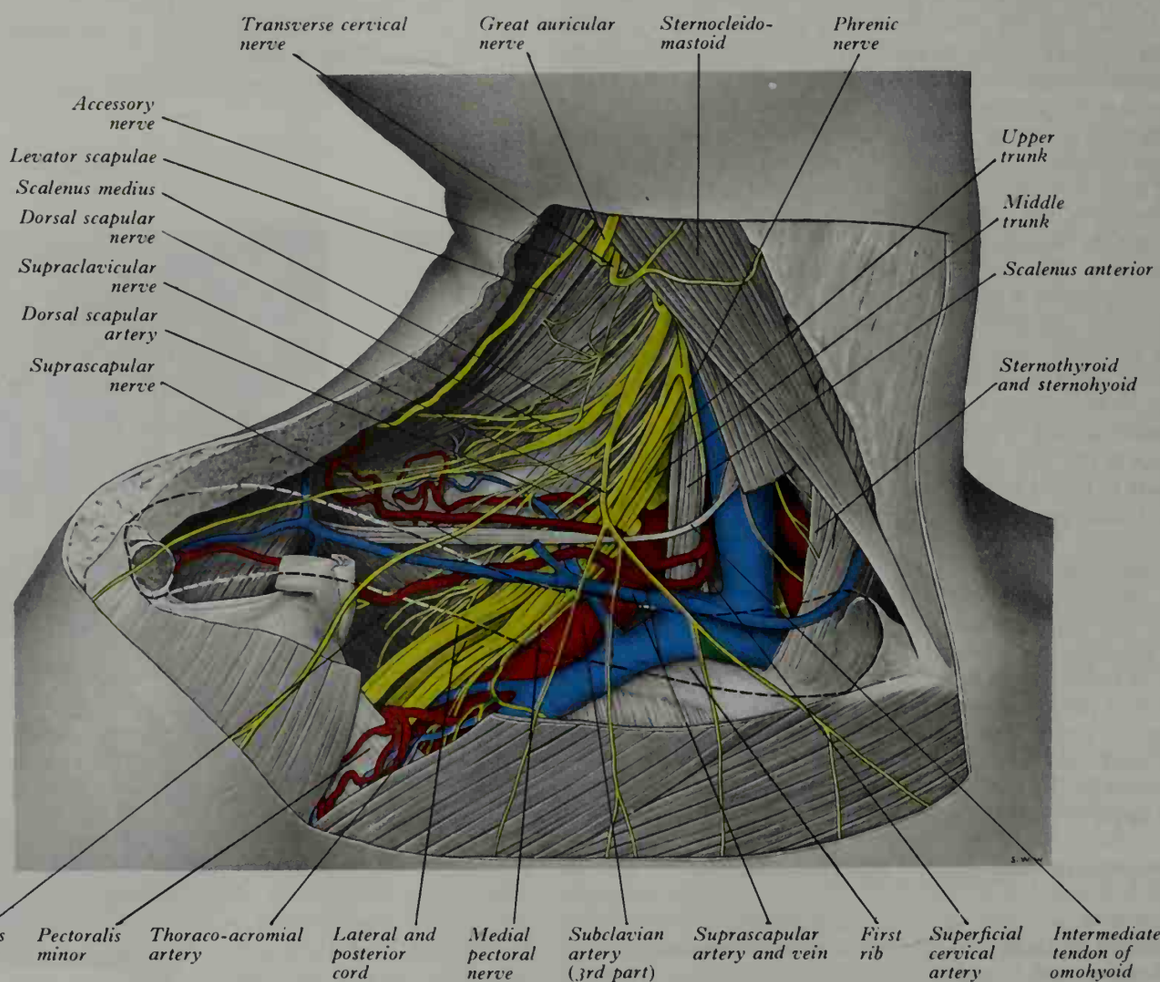
6.62 Structures related to the right cervical pleura, as seen from below.

6.63 Structures related to the left cervical pleura, as seen from below.

origins of the arteries which run into the posterior triangle tend to be variable but their distribution is relatively constant.

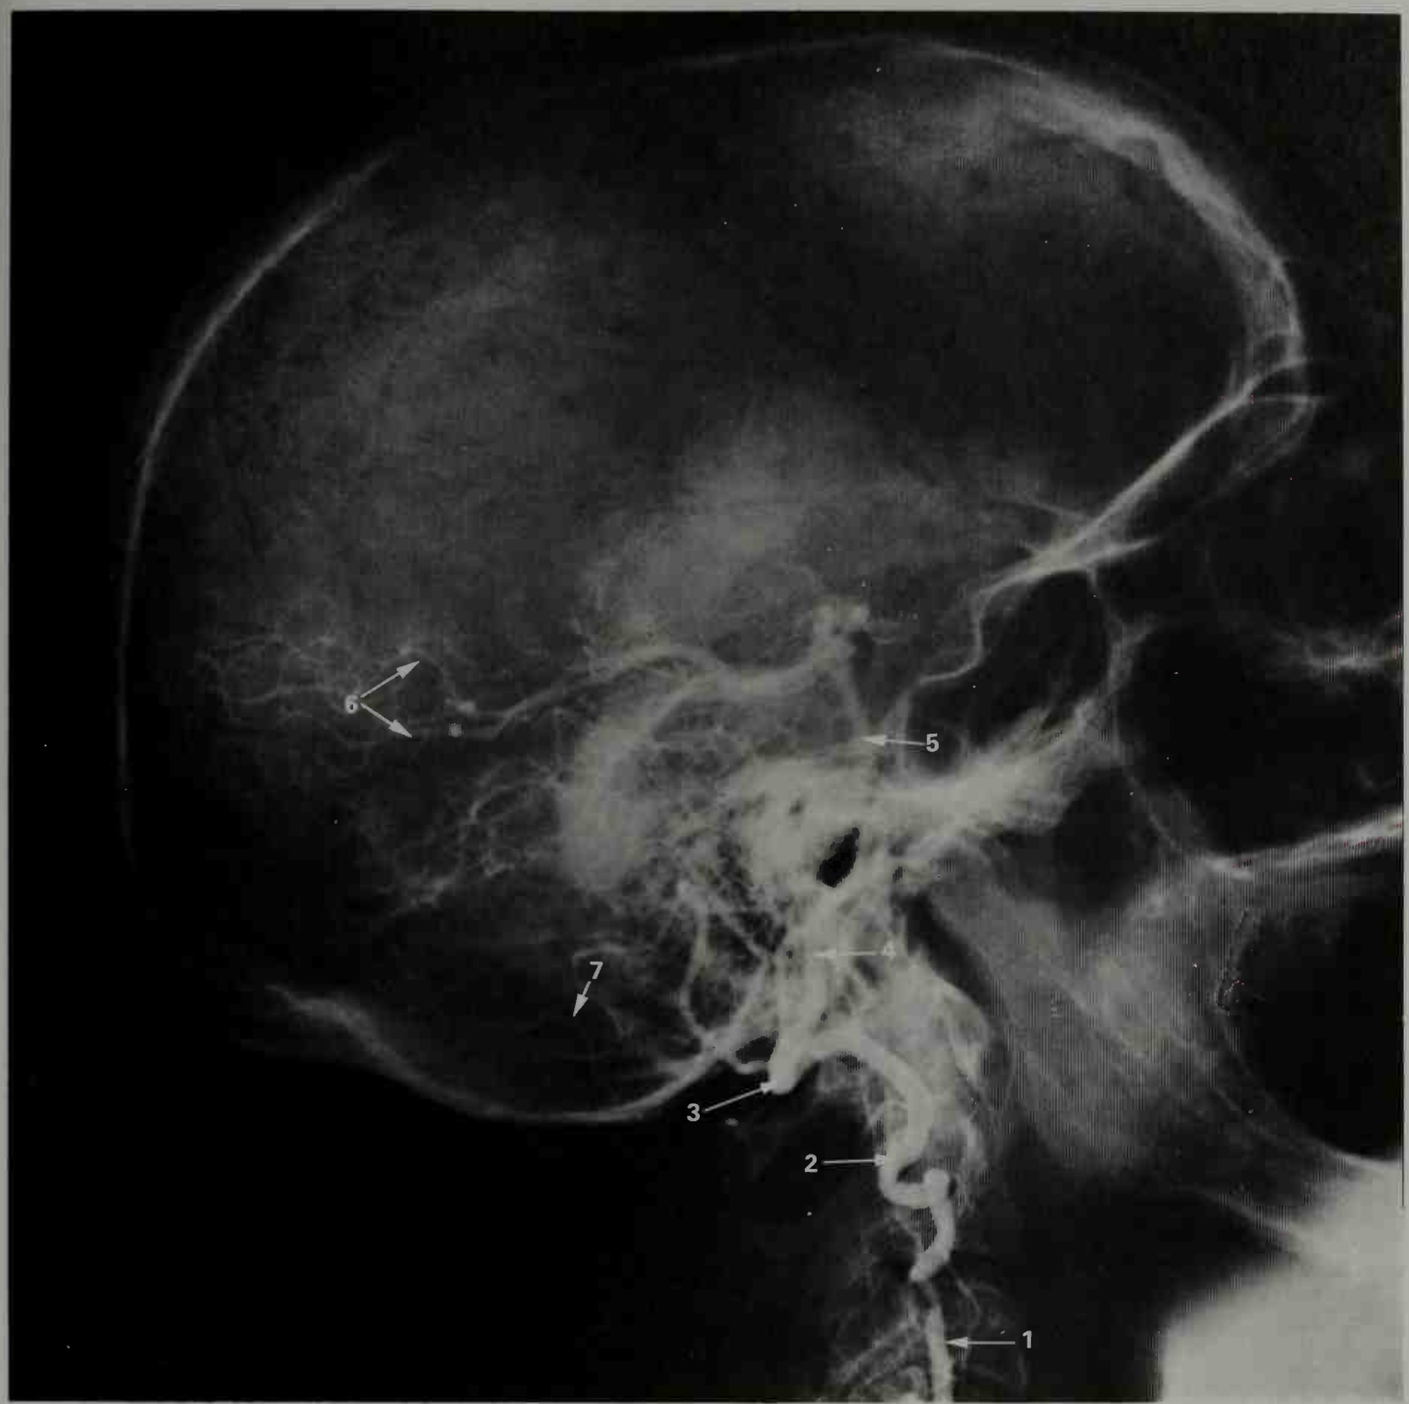
1. The Vertebral Artery (6.56, 61, 65, 66, 118)

This arises from the upper and posterior part of the first part of the subclavian artery. It ascends through the foramina in the transverse processes of all the cervical vertebrae save the seventh, winds behind the lateral mass of the atlas, enters the skull through the foramen magnum, and, at the lower border of the pons, joins the vessel of the opposite side to form the basilar artery. Occasionally the vertebral artery may enter the fifth, fourth, or seventh cervical vertebra. (For other variations *see* p. 675.)



Relations. The vertebral artery consists of four parts. The *first part* runs upwards and backwards between the longus colli and the scalenus anterior and behind the common carotid artery. In front, it is related to the common carotid artery and the vertebral vein, and is crossed by the inferior thyroid artery; on the left side it is crossed also by the thoracic duct. Behind, it is related to the transverse process of the seventh cervical vertebra, the cervicothoracic ganglion (6.62, 63) and the ventral rami of the seventh and eighth cervical nerves. The *second part* ascends through the transverse foramina of the upper six cervical vertebrae, with a large branch derived from the cervicothoracic sympathetic (stellate) ganglion, and by a plexus of veins which unite to form the vertebral vein at the lower part of the neck. It lies in front of the ventral rami of the cervical nerves (C.2–C.6) (6.118), and pursues an almost vertical course as far as the transverse process of the axis, through which it runs upwards and laterally to the transverse foramen of the atlas. The *third part* issues from the foramen on the medial side of the rectus capitis lateralis, and curves backwards behind the lateral mass of the atlas, the ventral ramus of the first cervical nerve being on its medial side; it then lies in the groove on the upper surface of the posterior arch of the atlas, and enters the vertebral canal by passing below the lower, arched border of the posterior atlanto-occipital membrane. This part of the artery is covered by the semispinalis capitis and is contained in the suboccipital triangle. The dorsal ramus of the first cervical nerve lies between the artery and the posterior arch of the atlas (3.30). The *fourth part* pierces the dura and the arachnoid mater, ascends in front of the roots of the hypoglossal nerve (p. 1083) and inclines medially to the front of the medulla oblongata where, at the lower border of the pons, it unites with the opposite artery to form the basilar artery (6.58).

Winckler (1972) has described variations in the elastic and muscular tissues in different parts of the vertebral artery. In its first and third parts it appears to be adapted, by increased elasticity, to the greater mobility and lack of support in these regions.



The branches of the vertebral artery may be divided into two sets—those given off in the neck, and those within the cranium.

Cervical Branches of the Vertebral Artery

Spinal branches enter the vertebral canal through the intervertebral foramina, and each divides into two branches. Of these, one passes along the roots of the nerves to supply the spinal cord (*see* p. 896, 7.54) and its membranes, anastomosing with the other arteries of the spinal cord; the other divides into an ascending and a descending branch, which unite with similar branches from the arteries above and below, so that two lateral anastomotic chains are formed on the posterior surfaces of the bodies of the vertebrae, near the attachment of the pedicles. From these anastomotic chains branches are supplied to the periosteum and the bodies of the vertebrae, and others communicate with similar branches from the opposite side; from these com-

6.64 The lower part of the posterior triangle showing the relations of the third part of the right subclavian artery. *Note.*—The clavicle has been removed but is shown as a dotted outline. The middle trunk of the brachial plexus gives an unusual contribution to the medial cord.

6.65 Vertebral arteriogram (left). Lateral view. 1. Vertebral artery, ascending part. 2. Loop between transverse foramina of axis and atlas. 3. Suboccipital part. 4. Intracranial part. 5. Basilar artery. 6. Posterior cerebral branches. 7. Inferior cerebellar branches.

munications small twigs arise which join similar branches above and below, to form a central anastomotic chain on the posterior surfaces of the bodies of the vertebrae.

Muscular branches arise from the vertebral artery as it curves round the lateral mass of the atlas. They supply the deep muscles of this region and anastomose with the occipital artery, and with the ascending and deep cervical arteries.

Cranial Branches of the Vertebral Artery

One or two **meningeal branches** spring from the vertebral artery opposite the foramen magnum; they ramify between the bone and dura mater in the cerebellar fossa and supply bone and the falx cerebelli.

The posterior spinal artery may arise from the vertebral artery at the side of the medulla oblongata, but is most frequently derived from the posterior inferior cerebellar artery. It passes backwards, and then descends as two branches, one in front of and the other behind the dorsal roots of the spinal nerves; these are reinforced by a succession of spinal twigs which arise from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries, and enter the vertebral canal through the intervertebral foramina; by means of these branches the posterior spinal arteries are continued to the lower part of the spinal cord. (For details of the blood supply of the spinal cord *see* p. 896 and 7·54.)

The anterior spinal artery is a small branch, which arises near the termination of the vertebral artery; it descends in front of the medulla oblongata and unites with its fellow of the opposite side near the level of the lower end of the olives of the medulla oblongata. The single trunk thus formed descends on the front of the spinal cord, and is reinforced by a succession of small spinal branches which enter the vertebral canal through the inter-

vertebral foramina; these branches are derived from the vertebral, the ascending cervical, posterior intercostal, and first lumbar arteries. They unite, by means of ascending and descending branches, to form a single anterior median artery, which extends as far as the lower part of the spinal cord, and is continued as a slender twig on the filum terminale. This vessel is placed in the pia mater along the anterior median fissure; it supplies the substance of the spinal cord, and sends off branches at its lower part to be distributed to the cauda equina. Branches pass from the anterior spinal arteries, and from the beginning of the trunk formed by their union, to the medulla oblongata, where they are distributed to its central portion, being sharply limited dorsally to the region of the trigonum hypoglossi. (*See* p. 1042 and 7.54.)

The posterior inferior cerebellar artery (**6**.58) is the largest branch of the vertebral artery, but is not infrequently absent. It arises near, and winds backwards round, the lower end of the olive of the medulla oblongata; it then ascends behind the roots of the glossopharyngeal and vagus nerves to the lower border of the pons, where it turns downwards along the inferolateral border of the fourth ventricle. Finally, it runs laterally into the vallecula of the cerebellum, where it divides into a medial and a lateral branch. The *medial branch* runs backwards between the cerebellar hemisphere and the inferior vermis, supplying branches to both; the *lateral branch* supplies the under surface of the hemisphere, as far as its lateral border, and anastomoses with the anterior inferior cerebellar and superior cerebellar branches of the basilar artery. The trunk of the artery supplies branches to the medulla oblongata and to the choroid plexus of the fourth ventricle, and sends a branch upwards lateral to the tonsil of the cerebellum to supply the dentate nucleus of the cerebellum. The area supplied in the medulla oblongata lies dorsal to the olivary nucleus and lateral to the nucleus and emerging fila of the hypoglossal nerve.

Applied Anatomy. It is to be noted that the posterior inferior cerebellar artery supplies the lateral part of the medulla. Thrombosis of this artery will therefore cause a loss of function of the following structures (*'lateral medullary syndrome'*): nucleus ambiguus, nuclear solitarius, vestibular and cochlear nuclei, spinocerebellar tracts, lateral spinothalamic tract, spinal nucleus and tract of the trigeminal nerve. The anterior spinal artery supplies the medial part of the medulla and thrombosis of this vessel causes loss of function of the following structures (*'medial medullary syndrome'*): hypoglossal nucleus and nerve, medial lemniscus, the corticospinal (pyramidal) tract. (For the normal functions of the above structures consult the section on the Central Nervous System.)

The medullary arteries are several minute vessels which spring from the vertebral and its branches, and are distributed to the medulla oblongata.

The Basilar Artery

This is formed by the junction of the two vertebral arteries; it extends from the lower to the upper border of the pons, and is in the cisterna pontis. It lies in a shallow, median groove on the ventral surface of the pons. It is placed between the two abducent nerves at the lower border and the two oculomotor nerves at the upper border of the pons, where it divides into the two posterior cerebral arteries.

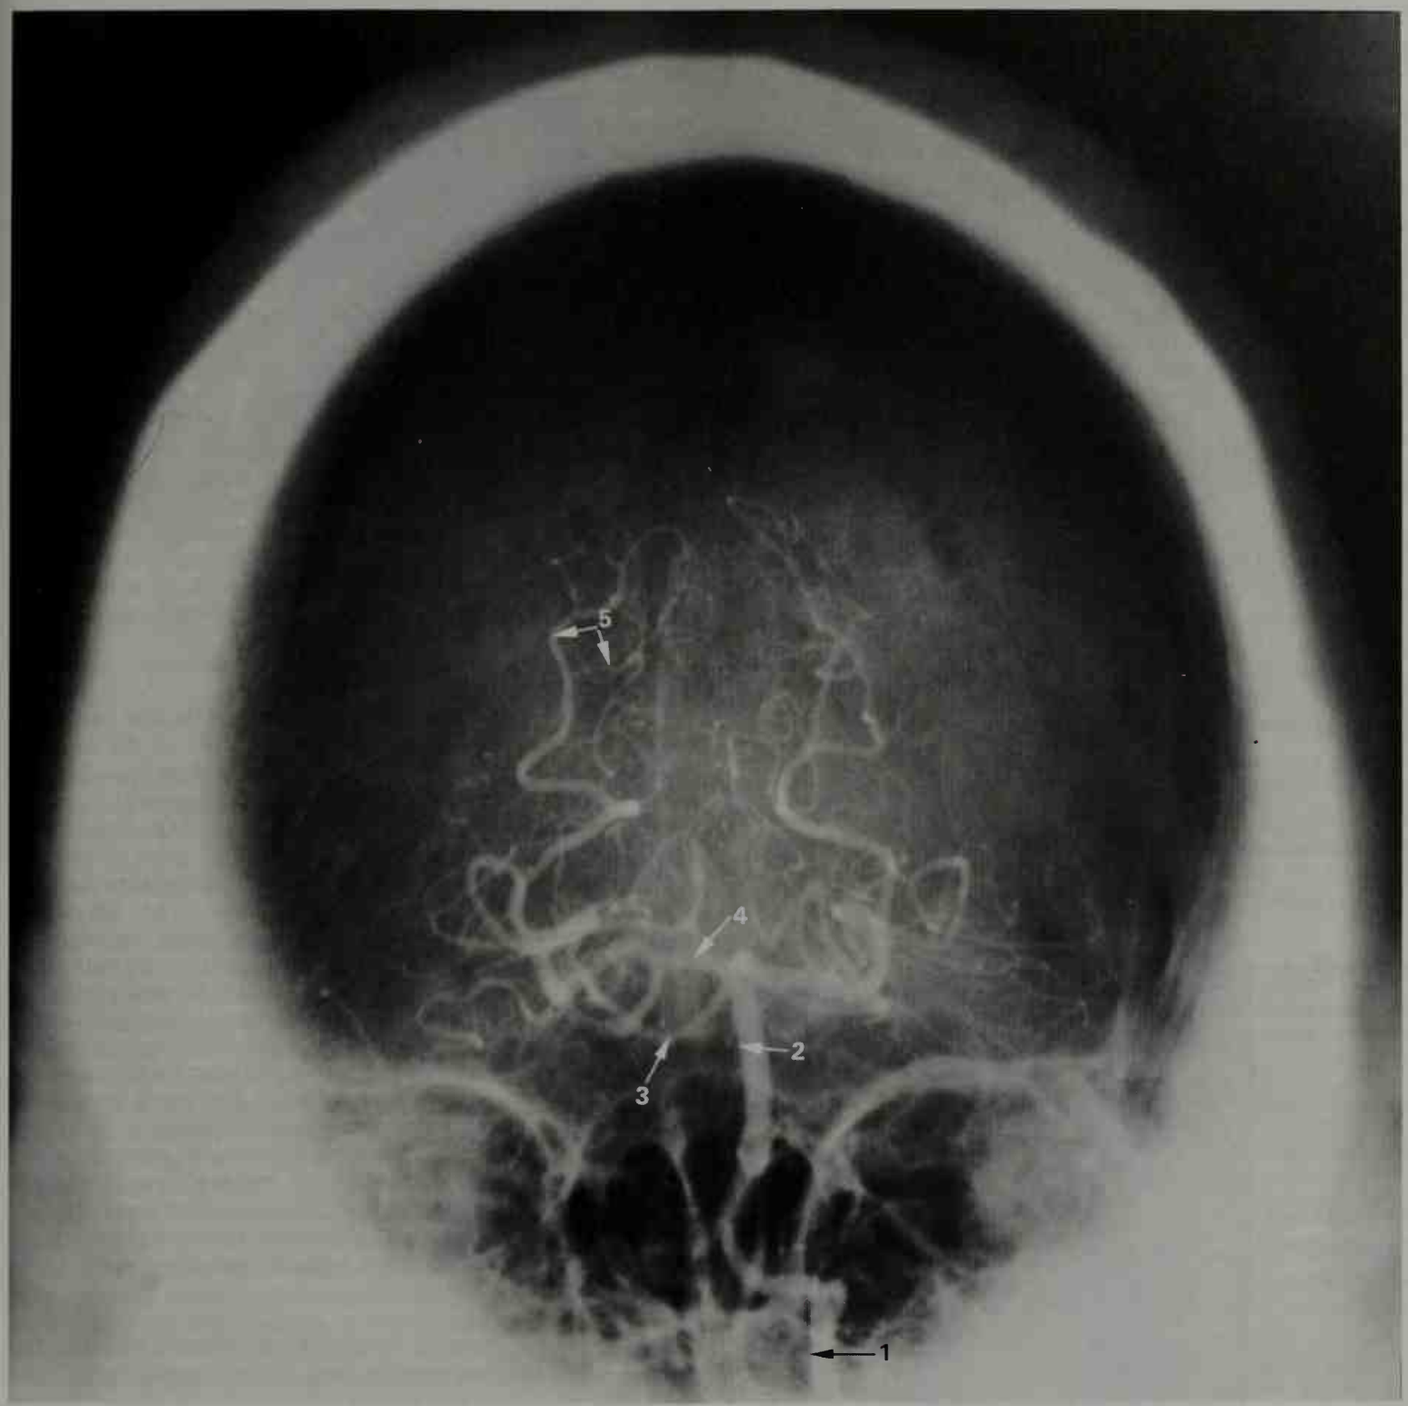
Branches:

The pontine branches are numerous small vessels which come off from the front and sides of the basilar artery, and supply the pons and adjacent parts of the brain.

The labyrinthine (internal auditory) artery, a long slender branch, may arise from the lower part of the basilar artery but is more often derived from the anterior inferior cerebellar artery (see also below); it accompanies the facial and the vestibulocochlear nerves into the internal acoustic meatus, and is distributed to the internal ear (p. 1214).

In a radiographic study of the labyrinthine artery Wende *et al.* (1975) were able to identify the origin of 238 examples. In only 38 (16 per cent) was the origin from the basilar artery, while 108 (45·4 per cent) were derived from the anterior inferior cerebellar. The superior cerebellar artery accounted for 58 (24·4 per cent) and the posterior inferior cerebellar for 13 (5·4 per cent). The remaining 21 (8·8 per cent) examples were reduplicated and were branches, in various combinations, from the basilar artery and one or other of the three cerebellar arteries. The same observers found a labyrinthine artery on one side only in 24 of 316 basilar angiographic examinations. Other workers have recorded different incidences of these variations. For example, Cavatori (1908) observed a basilar origin for the labyrinthine artery in about 70 per cent in Italians, whereas Stopford (1916) and Adachi and Hasche (1928) recorded it as most commonly arising from a common trunk with one of the cerebellar arteries. Gillilan (1972) has suggested that racial variations may exist in this regard.

The anterior inferior cerebellar artery (**6**.58) arises from the lower part of the basilar artery. It runs backwards and laterally, usually ventral to the abducent nerve, the facial and vestibulocochlear nerves, and commonly forms a loop which penetrates for a variable distance into the internal acoustic meatus below the nerves (Sunderland 1945). The labyrinthine artery frequently arises from the summit of the loop. On emerging from the meatus the artery is distributed to the anterolateral parts of the inferior surface of the cerebellum, where it anastomoses with the posterior inferior cerebellar branch of the vertebral artery. A few branches are supplied by the anterior inferior cerebellar artery to the lower and lateral parts of the pons, and sometimes to the upper part of the medulla oblongata.



The superior cerebellar artery (**6**.58) arises near the termination of the basilar. It passes laterally immediately below the oculomotor nerve, which separates it from the posterior cerebral artery, winds round the cerebral peduncle close to and below the trochlear nerve, and, arriving at the superior surface of the cerebellum, divides into branches which ramify in the pia mater, supplying this aspect of the cerebellum and anastomosing with branches of the inferior cerebellar arteries. In addition, branches are given to the pons, the pineal body, the superior medullary velum and the tela choroidea of the third ventricle.

The posterior cerebral artery (**6**.58, 59, 60), frequently double, is larger than the superior cerebellar artery, from which it is separated near its origin by the oculomotor nerve, and on the side of the midbrain by the trochlear nerve. Passing laterally, parallel with the superior cerebellar artery, and receiving the posterior communicating branch from the internal carotid artery, it winds round the cerebral peduncle, and reaches the tentorial surface of the cerebrum, where it breaks up into branches for the supply of the temporal and occipital lobes.

The branches of the posterior cerebral artery are divided into two sets, central and cortical.

Central branches. Several small *posteromedial central branches* (**6**.61) arise at the commencement of the posterior cerebral artery; these, with similar branches from the posterior communicating, pierce the posterior perforated substance, and supply the anterior part of the thalamus, the lateral wall of the third ventricle and the globus pallidus of the lentiform nucleus. The *posterior choroidal rami* vary in number and arrangement (Abbie 1933). One, or more, courses over the lateral geniculate body and helps to supply it, before entering the posterior part of the inferior horn of the lateral ventricle through the lower part of the choroidal fissure. The others curl round the posterior end of the thalamus and pass through the transverse fissure, some to the tela choroidea of the third ventricle, and some to pass through the upper part of the choroidal fissure; they supply the choroid plexuses of the third and lateral ventricles, and give some twigs to the fornix. (For further information on the distribution of the choroidal arteries consult Percheron 1977, and see also p. 1042.) The *posterolateral central branches* are small arteries which arise from the posterior cerebral artery after it has turned round the cerebral peduncle; they supply the cerebral peduncle, the posterior part of the thalamus, the colliculi and the pineal and medial geniculate bodies.

Cortical branches. The *temporal branches*, usually two in number, are distributed to the uncus, the parahippocampal, the medial and lateral occipitotemporal gyri; the *occipital branches* supply the cuneus, lingual gyrus and the posterior part of the lateral surface of the occipital lobe; the *parieto-occipital* supply the cuneus and the precuneus. It is to be noted that the posterior

6.66 Vertebral arteriogram (left). Anteroposterior view. Circular shape of field is due to use of a cone to improve resolution. 1. Left vertebral artery. 2. Basilar artery. 3. Right superior cerebellar artery. 4. Right posterior cerebral artery. 5. Branches of right posterior cerebral artery.

cerebral artery supplies the visual area of the cerebral cortex (p. 1042), and many other structures associated with the visual pathway.

2. The Internal Thoracic (Mammary) Artery (6.67)

This arises about 2 cm above the sternal end of the clavicle from the inferior surface of the first part of the subclavian artery, opposite the thyrocervical trunk. It descends behind the cartilages of the upper six ribs about 1·25 cm from the lateral border of the sternum, and at the level of the sixth intercostal space divides into the musculophrenic and superior epigastric arteries.

Relations. It runs at first downwards, forwards, and medially behind the sternal end of the clavicle, the internal jugular and brachiocephalic veins, and the first costal cartilage. As the artery enters the thorax, the phrenic nerve crosses it obliquely from the lateral to the medial side, the nerve usually passing in front of the artery. Below the first costal cartilage it descends almost vertically to its bifurcation. It is covered in front by the pectoralis major, the cartilages of the upper six ribs and the intervening external intercostal membranes and internal intercostals, and is crossed by the terminal parts of the upper six intercostal nerves. It is separated from the pleura, as far as the second or third costal cartilage, by a strong layer of fascia, below this level, by the transversus thoracis. It is accompanied by a chain of lymph nodes and by venae comitantes which unite at the third costal cartilage to form a single vessel, medial to the artery.

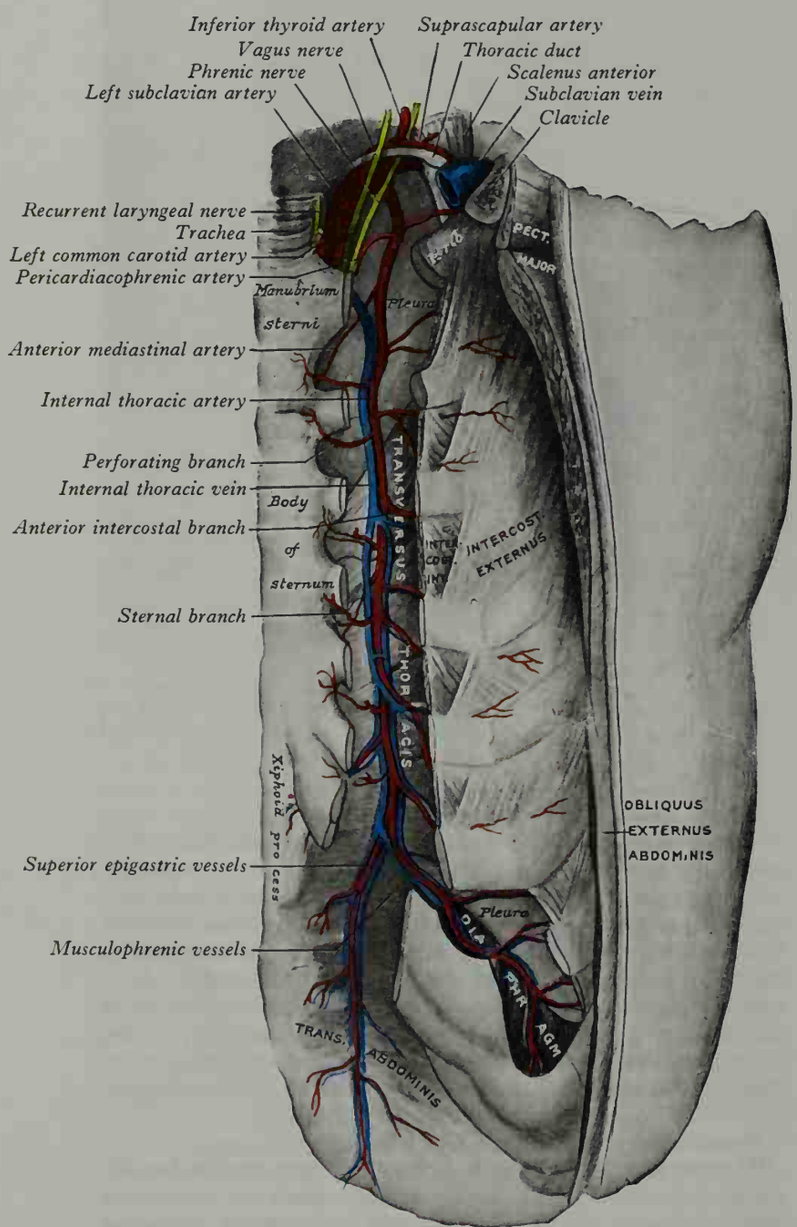
Branches:

The pericardiacophrenic artery is a long, slender branch which accompanies the phrenic nerve, between the pleura and pericardium, to the diaphragm, and anastomoses with the musculophrenic and phrenic arteries.

The mediastinal arteries are small vessels, distributed to the areolar tissue and lymph nodes in the anterior mediastinum, and to the remains of the thymus.

The pericardial branches supply the upper part of the anterior surface of the pericardium.

The sternal branches are distributed to the transversus thoracis and to the posterior surface of the sternum.



The mediastinal, pericardial and sternal branches, together with some twigs from the pericardiacophrenic, anastomose with branches from the posterior intercostal and bronchial arteries, and form a *subpleural mediastinal plexus*.

The anterior intercostal branches are distributed to the upper six intercostal spaces. Two in each space, they pass laterally, one lying near the lower margin of the upper rib, and the other near the upper margin of the lower rib, and anastomose with the posterior intercostal arteries. They are first situated between the pleura and the internal intercostals, and then between the intercostales intimi and the internal intercostals. They supply the intercostals and send branches through them to the pectoral muscles, the breast, and to skin.

The perforating branches emerge through the upper five or six intercostal spaces, with the anterior cutaneous branches of the corresponding intercostal nerves. They pierce the pectoralis major and, curving laterally, supply that muscle and the skin. In the female, those of the second, third and fourth spaces give branches to the breast, and during lactation are of large size.

The musculophrenic artery passes obliquely downwards and laterally, behind the seventh, eighth and ninth costal cartilages; it perforates the diaphragm near the ninth costal cartilage, and ends opposite the last intercostal space. It anastomoses with the inferior phrenic artery, the lower two posterior intercostal arteries and the ascending branch of the deep circumflex iliac artery. It gives off two anterior intercostal branches to each of the seventh, eighth and ninth intercostal spaces; these are distributed in a manner similar to the anterior intercostals from the internal thoracic. The musculophrenic also supplies the lower part of the pericardium and the abdominal muscles.

The superior epigastric artery descends through the interval between the costal and xiphoid origins of the diaphragm, anterior to the lower fibres of the transversus thoracis and the upper fibres of the transversus abdominis. It enters the sheath of the rectus abdominis, at first lying behind the muscle, and then perforating and supplying it, and anastomosing with the inferior epigastric artery from the external iliac. Branches perforate the sheath of the rectus, and supply the skin of the abdomen, and a small branch passes in front of the xiphoid process and anastomoses with the opposite artery. The superior epigastric artery gives some twigs to the diaphragm, while from that of the right side small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

698 **6.67** The left internal thoracic artery and vein and their main branches.

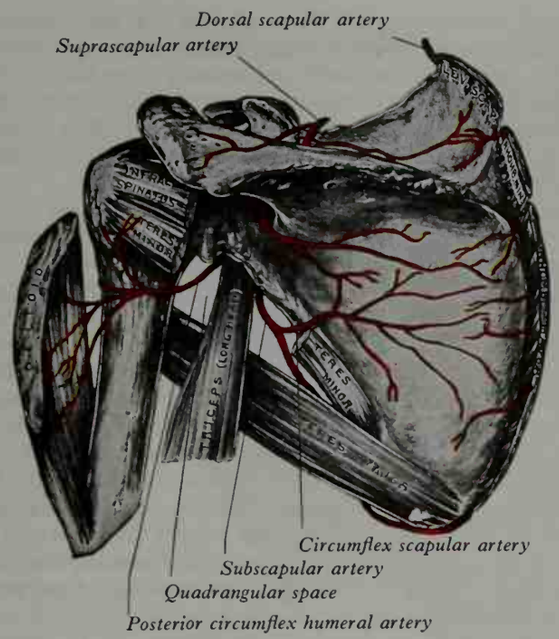
3. The Thyrocervical Trunk (6.45, 118)

This short, wide vessel arises from the front of the first part of the subclavian artery, close to the medial border of the scalenus anterior, and divides almost immediately into three branches, the inferior thyroid, suprascapular and superficial cervical.

The inferior thyroid artery runs upwards in front of the medial border of the scalenus anterior; it then turns medially in front of the vertebral vessels and behind the carotid sheath and its contents, and usually behind the sympathetic trunk, the middle cervical ganglion of which generally rests upon the vessel; it finally descends on the longus colli to the lower border of the lobe of the thyroid gland. As it approaches the thyroid gland, the relation of the artery to the recurrent laryngeal nerve is of surgical importance (see also p. 1080). At a little distance from the gland the artery usually passes behind the nerve, but near the gland, on the right side the nerve may lie with equal frequency anterior or posterior to, or intermingled amongst, the branches of the artery, while on the left side the nerve is most commonly posterior to the artery. The relationship between the terminal branches of the artery and those of the nerve is very variable (Bowden 1955). On the *left side*, close to its origin, the artery is crossed anteriorly by the thoracic duct as it curves laterally and downwards to its termination.

Branches:

The *muscular branches* supply the infrahyoid muscles, the longus colli, scalenus anterior and inferior constrictor of the pharynx.



The *ascending cervical artery* is a small branch which arises from the inferior thyroid artery as that vessel turns medially behind the carotid sheath; it ascends on the anterior tubercles of the transverse processes of the cervical vertebrae in the interval between the scalenus anterior and longus capitis. It gives twigs to the muscles of the neck, and sends one or two *spinal branches* into the vertebral canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebrae, in the same manner as the spinal branches of the vertebral artery. It anastomoses with branches of the vertebral, ascending pharyngeal, occipital and deep cervical arteries.

The *inferior laryngeal artery* ascends upon the trachea in company with the recurrent laryngeal nerve; it enters the larynx deep to the lower border of the inferior constrictor, and supplies its muscles and mucous membrane, anastomosing with the artery from the opposite side, and with the superior laryngeal branch of the superior thyroid artery.

The *pharyngeal branches* supply the lower part of the pharynx.

The *tracheal branches* are distributed to the trachea and anastomose below with the bronchial arteries.

The *oesophageal branches* supply the oesophagus and ana-

6.68 The scapular anastomosis of the left side, dorsal aspect.

stomose with the oesophageal branches of the thoracic aorta.

The large *glandular branches* comprise an inferior and an ascending branch; they are distributed to the posterior and inferior parts of the thyroid gland, and anastomose with the superior thyroid artery and with the opposite inferior thyroid artery; the ascending branch supplies the parathyroid glands.

The suprascapular artery (**6**.64, 68) passes at first downwards and laterally across the scalenus anterior and the phrenic nerve, behind the internal jugular vein and the sternocleidomastoid; it then crosses in front of the subclavian artery and the brachial plexus, and runs behind and parallel with the clavicle and subclavius, and deep to the inferior belly of the omohyoid, to the superior border of the scapula; here it passes above (occasionally below) the superior transverse ligament, which separates it from the suprascapular nerve, and enters the supraspinous fossa (**6**.68). In this situation it lies on the bone, and supplies branches to the supraspinatus. It then descends behind the neck of the scapula, through the great scapular notch and deep to the inferior transverse ligament, to reach the deep surface of the infraspinatus, where it anastomoses with the circumflex scapular artery, and the deep branch of the transverse cervical artery. Besides distributing branches to the sternocleidomastoid, subclavius, and neighbouring muscles, it gives off a *suprasternal branch*, which crosses over the sternal end of the clavicle to the skin of the upper part of the chest and, an *acromial branch*, which pierces trapezius and supplies the skin over the acromion, anastomosing with the thoraco-acromial and posterior circumflex humeral arteries. As the suprascapular artery passes above the superior transverse ligament, it sends a branch into the subscapular fossa, where it ramifies beneath the subscapularis, and anastomoses with the subscapular artery and with the deep branch of the transverse cervical artery. The suprascapular artery also sends articular branches to the acromioclavicular and shoulder joints, and nutrient arteries to the clavicle and scapula. Not infrequently the suprascapular artery arises from the third part of the subclavian artery.

The superficial cervical artery (**6**.64) lies at a higher level than the suprascapular artery; it crosses in front of the phrenic nerve and the scalenus anterior, and in front of the brachial plexus, and is covered by the internal jugular vein, sternocleidomastoid and platysma. It crosses the floor of the posterior triangle of the neck, to reach the anterior margin of the levator scapulae. It then ascends deep to the anterior part of the trapezius, distributing branches to it and the neighbouring muscles, and to the lymph nodes in the neck; it anastomoses with the superficial branch of the descending branch of the occipital artery.

4. The Costocervical Trunk (**6**.62)

This arises from the back of the second part of the subclavian artery on the right, but from the first part of the artery on the left. It arches backwards above the cervical pleura to the neck of the first rib, and divides into the superior intercostal and deep cervical arteries.

The superior intercostal artery descends between the pleura and the necks of the first and second ribs, and anastomoses with the third posterior intercostal artery. As it crosses the neck of the first rib it is medial to the ventral ramus of the first thoracic nerve, which it crosses at a lower level (**6**.62), and lateral to the cervicothoracic ganglion of the sympathetic trunk. In the first intercostal space, it gives off the first posterior intercostal artery, which is arranged in a manner similar to the distribution of the lower posterior intercostals. It then descends to become the second posterior intercostal artery and usually joins with a branch from the third. The second posterior intercostal artery is not constant, but is more commonly found on the right side; when absent, its place is supplied by a branch from the aorta.

The deep cervical artery (**6**.56) arises, in most cases, from the costocervical trunk, and is analogous to the posterior branch of a posterior intercostal artery: occasionally it is a separate branch from the subclavian artery. Passing backwards above the eighth cervical nerve and between the transverse process of the seventh cervical vertebra and the neck of the first rib (sometimes between the transverse processes of the sixth and seventh cervical vertebrae) it ascends in the back of the neck, between the semispinales capitis et cervicis, as high as the second cervical vertebra. It supplies the adjacent muscles, and anastomoses with the deep division of the descending branch of the occipital artery (p. 681) and with branches of the vertebral artery. It gives off a spinal twig which enters the vertebral canal through the foramen between the seventh cervical and first thoracic vertebrae.

5. The Dorsal Scapular Artery (**6**.64, 68)

This arises from the third or, less frequently, the second part of the subclavian artery. It passes laterally through the brachial plexus and in front of the scalenus medius. It then goes deep to the levator scapulae to the superior angle of the scapula where it descends in company with the dorsal scapular nerve under cover of the rhomboids along the medial border of the scapula as far as the inferior angle of the bone. It supplies branches to the rhomboids, latissimus dorsi and trapezius, and anastomoses with the suprascapular and subscapular arteries, and with the posterior branches of some of the posterior intercostal arteries.

Variations. In about one-third of cases the superficial cervical and dorsal scapular arteries have a common origin from the thyrocervical trunk termed the *transverse cervical artery*. This gives rise to a *superficial branch* (superficial cervical artery) and a *deep branch* (dorsal scapular artery); the latter passes laterally in front of the brachial plexus before going deep to the levator scapulae.

The Axilla

The axilla is a pyramidal region, situated between the upper parts of the chest wall and of the medial side of the arm.

The blunted *apex* of the axilla is directed upwards into the root of the neck (sometimes termed the *cervico-axillary canal*), and corresponds to the interval between the outer border of the first rib, the superior border of the scapula, the posterior surface of the clavicle, and the medial aspect of the coracoid process; through it the axillary vessels and nerves enter the space from the neck. The *base*, directed downwards, is broad at the chest but narrow and pointed at the arm; it is formed by the skin and a thick layer of fascia, termed the *axillary fascia*, extending between the lower border of the pectoralis major in front, and the lower border of the latissimus dorsi behind. It is of course convex upwards, conforming to the concavity of the armpit. The *anterior wall* is formed by the pectorales major et minor, the former covering the whole of this wall, the latter only its intermediate part. The space between the upper border of the pectoralis minor and the clavicle is occupied by the clavipectoral fascia. The *posterior wall* is

formed by the subscapularis above, the teres major and latissimus dorsi below. On the *medial side* are the first four ribs with their corresponding intercostal muscles, and the upper part of the serratus anterior. This 'wall' displays the convexity of the thorax. On the *lateral side*, where the anterior and posterior walls converge, the space is narrow, and is bounded by the intertubercular sulcus of the humerus, the coracobrachialis and the biceps.

The axilla contains the axillary vessels, the infraclavicular part of the brachial plexus with its branches, the lateral branches of some of the intercostal nerves, a large number of lymph nodes, and a quantity of fat and loose areolar tissue. The axillary vessels and the brachial plexus of nerves run from the apex to the base along the lateral wall of the axilla; they are nearer to the anterior than the posterior wall, the axillary vein lying anteromedial to the axillary artery. Owing to the obliquity of the upper ribs, the neurovascular bundle, just after it emerges from behind the clavicle, crosses the first intercostal space. The relations of the bundle are therefore somewhat different in the upper portion of the axilla from those in the lower parts. The thoracic branches of the axillary artery are in contact with the pectoral muscles, and along the lateral margin of the pectoralis minor the lateral thoracic artery passes to the side of the thorax. The subscapular vessels descend on the posterior wall in contact with the lower margin of the subscapularis, and the subscapular nerves and the thoracodorsal nerve (to latissimus dorsi) cross the anterior surface of the muscle with different degrees of obliquity; the circumflex scapular vessels wind round the lateral border of the scapula, and the posterior circumflex humeral vessels and the axillary (circumflex) nerve curve backwards close to the surgical neck of the humerus. No vessel of any importance lies on the medial or thoracic side, the upper part of the space being crossed merely by a few small branches form the superior thoracic artery. The long thoracic nerve (to serratus anterior) descends on the surface of the muscle which it supplies; and the intercostobrachial nerve perforates the upper and anterior part of this wall, and passes across the axilla to the medial side of the upper arm.

The position and arrangement of the lymph nodes are described on p. 789.

Applied Anatomy. When suppuration occurs in the axilla, the arrangement of the fascia plays an important part in the direction in which pus may spread. As described on p. 568, the clavipectoral fascia, after filling the space between the clavicle and the medial border of the pectoralis minor, splits to enclose it and blends at its lateral border with the axillary fascia at the anterior fold of the axilla. Suppuration may take place either superficial or deep to this layer of fascia; that is, either between the pectoral muscles or behind the pectoralis minor; in the former case, the abscess would point either at the border of the anterior axillary fold, or in the groove between the deltoid and the pectoralis major; in the latter case, pus would tend to surround the vessels and nerves, and ascend into the neck, that being the direction in which there is least resistance. Instances have been recorded where the pus found its way along the vessels into the arm.

When an axillary abscess is opened, the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space so as to avoid the lateral thoracic, subscapular, and axillary vessels which are in contact respectively with the anterior, posterior and lateral walls of the axilla.

The relations of the vessels and nerves in the several parts of the axilla are important, for it is still a frequent procedure to remove the lymph nodes from the axilla in operating for cancer of the breast. When such an operation is performed, it is necessary to proceed with much caution in the direction of the lateral wall and apex of the space, because of the axillary vessels.

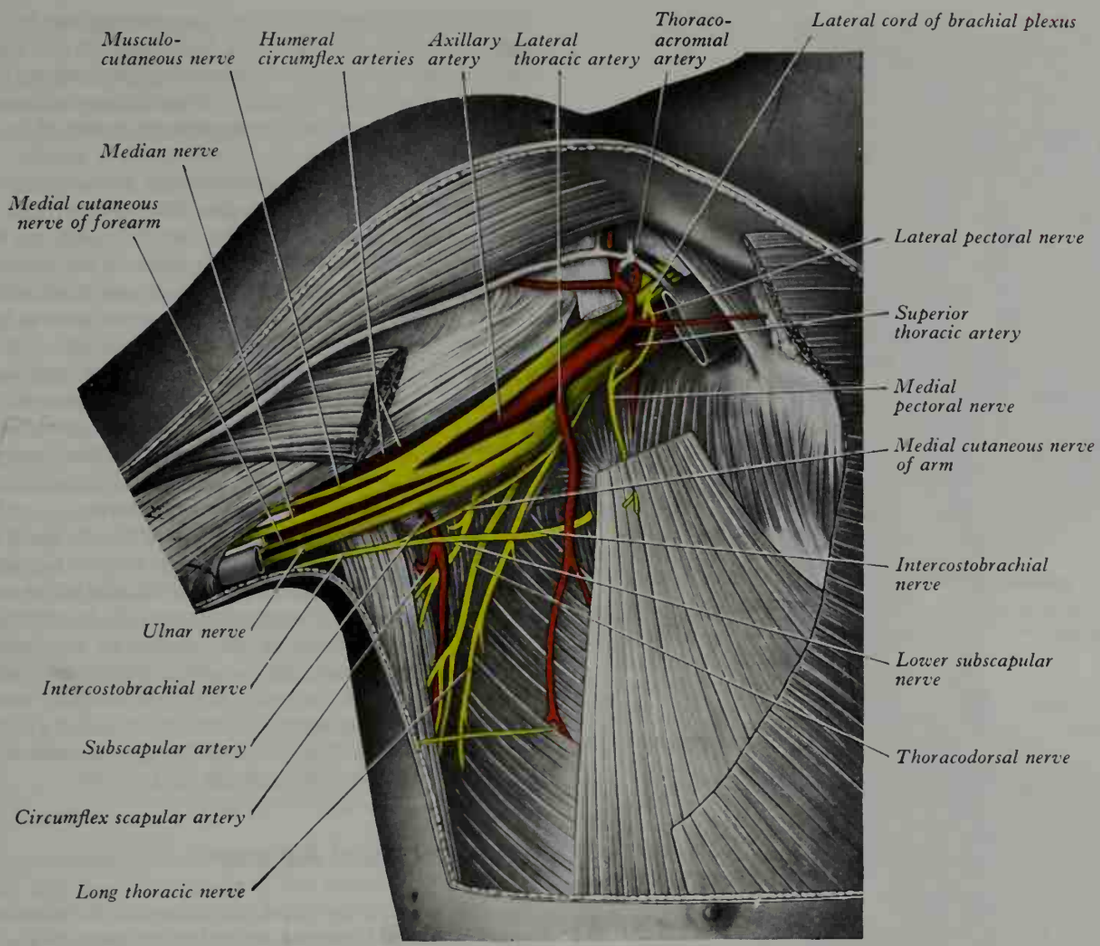
The Axillary Artery

The axillary artery (**6**.69), the continuation of the *subclavian*, begins at the outer border of the first rib, and nominally ends at the lower border of the teres major, where the artery becomes the *brachial*. Its direction varies with the position of the limb: thus the vessel is nearly straight when the arm is at right angles with the trunk, concave upwards when the arm is elevated above the shoulder, and convex upwards and laterally when the arm lies by the side. At first deeply situated, the artery becomes superficial, covered only by skin and fasciae. The pectoralis minor crosses the vessel and divides it into three parts; the first part is proximal, the second posterior, and the third distal, to the muscle.

Relations of the first part. The first part of the axillary artery is covered *in front* by the skin, superficial fascia, platysma, supraclavicular nerves, deep fascia, clavicular fibres of the pectoralis major and the clavipectoral fascia. This part of the artery is crossed anteriorly by the lateral pectoral nerve, the loop of communication between it and the medial pectoral nerve, and by the thoraco-acromial and cephalic veins. *Behind*, the artery is related to the first intercostal space and external intercostal, the first and second digitations of the serratus anterior, the long thoracic nerve and medial pectoral nerve, and the medial cord of the brachial plexus. On the *lateral side* it is related to the lateral and posterior cords of the brachial plexus, on the *medial side*, to the axillary vein, which also overlaps in front. The first part of the artery is enclosed, together with the axillary vein and the brachial plexus, in the fibrous *axillary sheath*, continuous above with the prevertebral layer of the deep cervical fascia.

Relations of the second part. In *front* of the second part are skin, superficial and deep fascia, and pectoralis major and minor, *behind*, the posterior cord of the brachial plexus and some areolar tissue, both of which intervene between it and the subscapularis, on the *medial side*, the axillary vein, separated from it by the medial cord of the brachial plexus and the medial pectoral nerve, on the *lateral side*, the lateral cord of the brachial plexus, which separates it from the coracobrachialis. The cords of the brachial plexus thus surround the second part of the artery on three sides, and separate it from direct contact with the vein and adjacent muscles.

Relations of the third part. The third part of the axillary artery extends from the lateral border of the pectoralis minor to the lower border of the teres major. Its upper part is covered *in front* by the lower part of the pectoralis major; its lower part by the skin and fasciae only. *Behind* it are the lower part of the subscapularis and the tendons of the latissimus dorsi and teres major. On its *lateral side* is the coracobrachialis, and *medially*, the axillary vein. The nerves of the brachial plexus bear the following relations to this part of the artery; *laterally* are the lateral root and the trunk of the median, and, for a short distance, the musculocutaneous; *medially*, the medial cutaneous nerve of the forearm lies between the axillary artery and vein anteriorly, and the ulnar nerve between the artery and vein posteriorly; the medial cutaneous nerve of the upper arm is on the medial side of the vein; *in front* is the medial root of the median nerve, and *behind*, the radial and axillary nerves, the latter only as far as the lower border of the subscapularis.



Branches:

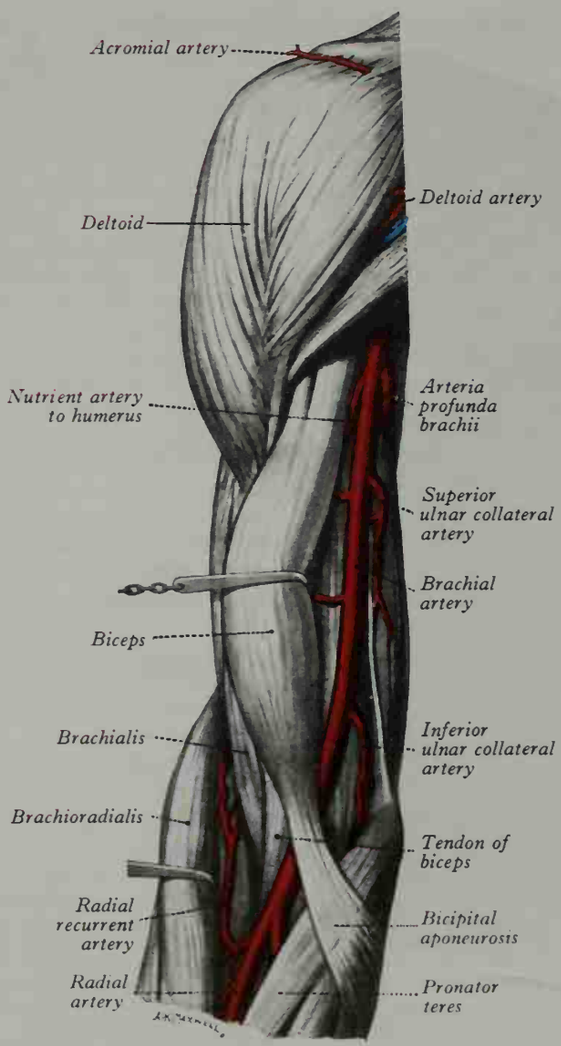
Superior thoracic.	Subscapular.
Thoraco-acromial.	Anterior circumflex humeral.
Lateral thoracic.	Posterior circumflex humeral.

The superior thoracic artery (**6**.69), a small vessel, arises from the first part of the axillary artery near the lower border of the subclavius, but it may branch from the thoraco-acromial artery. Running forwards and medially above the medial border of the pectoralis minor, it passes between it and the pectoralis major to the thoracic wall. It supplies branches to these muscles, and to the thoracic wall, and anastomoses with the internal thoracic upper and intercostal arteries.

The thoraco-acromial (acromiothoracic) artery (**6**.64, 69) is a short branch from the second part of the axillary artery, at first overlapped by the upper edge of the pectoralis minor. Skirting the medial border of this muscle, it pierces the clavipectoral fascia and divides into four branches—pectoral, acromial, clavicular and deltoid.

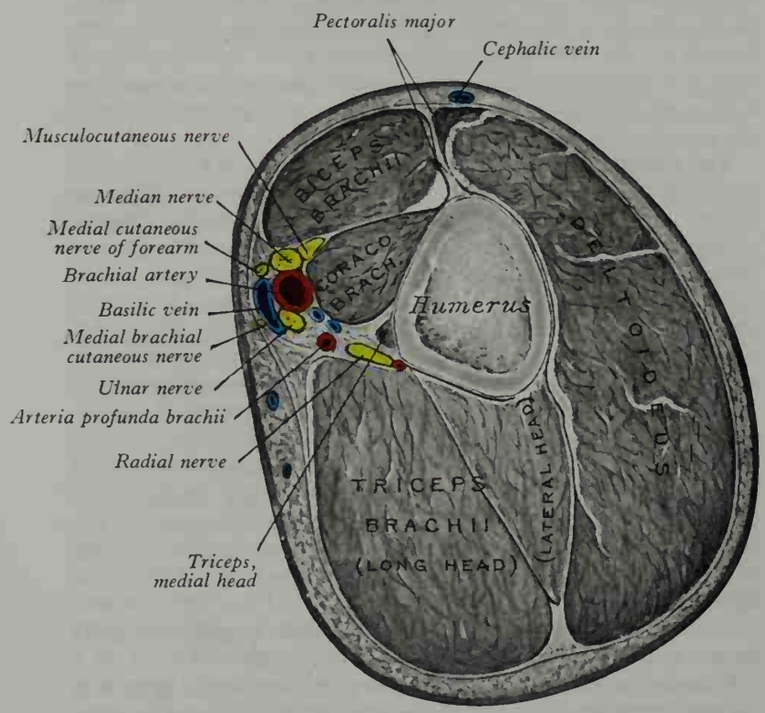
The *pectoral branch* descends between the two pectoral muscles, and is distributed to them and to the breast, anastomosing with the intercostal branches of the internal thoracic artery and with the lateral thoracic artery. The *acromial*

6.69 The right axillary artery and its branches. The pectoralis major and part of the pectoralis minor have been removed.



branch runs laterally over the coracoid process and under the deltoid, to which it gives branches; it then pierces that muscle and ends on the acromion, where it anastomoses with the branches of the suprascapular, the deltoid branch of the thoraco-acromial and the posterior circumflex humeral arteries. The *clavicular branch* runs upwards and medially between the clavicular part of the pectoralis major and the clavipectoral fascia; it gives branches to the sternoclavicular joint, and to the subclavius. The *deltoid branch* often arises with the acromial branch; it crosses over the pectoralis minor and runs with the cephalic vein in the interval between the pectoralis major and deltoid, supplying both muscles.

The lateral thoracic artery (**6**.69) follows the lateral border of the pectoralis minor to the side of the chest, supplies the serratus anterior and the pectoral muscles, the axillary lymph nodes, and subscapularis; it anastomoses with the internal thoracic, subscapular, and intercostal arteries, and the pectoral branch of the thoraco-acromial artery. In the female, the lateral thoracic artery is large, and gives off *lateral mammary branches*, which turn round the lateral border of the pectoralis major to reach the mamma.



The subscapular artery (**6**.69) is the largest branch of the axillary artery; usually it arises at the lower border of the subscapularis, which it follows to the inferior angle of the scapula, where it anastomoses with the lateral thoracic and intercostal arteries and with the deep branch of the transverse cervical artery; finally it ends in the neighbouring muscles and adjacent part of the chest wall. In the lower part of its course it is accompanied by the nerve to the latissimus dorsi; about 4 cm from its origin it gives off the *circumflex scapular artery*. This is generally larger than the continuation of the subscapular. It curves round the lateral border of the scapula, traversing the triangular space between the subscapularis above, the teres major below, and the long head of the triceps laterally (**6**.68); it enters the infraspinous fossa under cover of the teres minor, and gives off two branches: one (*infrascapular*) enters the subscapular fossa deep to the subscapularis, and anastomoses with the suprascapular artery and the dorsal scapular (or deep branch of the transverse cervical) artery; the other is continued along the lateral border of the scapula between the teres major and the teres minor, and at the dorsal surface of the inferior angle anastomoses with the deep branch of the transverse cervical artery. In addition, small branches are distributed to the posterior part of deltoid and the long head of triceps, and anastomose with an ascending branch of the arteria profunda brachii.

The anterior circumflex humeral artery (**6**.69) is a small branch from the lateral side of the axillary artery at the lower border of the subscapularis. It runs horizontally, behind coracobrachialis and short head of biceps, in front of the surgical neck of the humerus. On reaching the intertubercular sulcus (bicipital groove), it gives off a branch which ascends in it to supply the head of the humerus and the shoulder joint. The artery then continues laterally under the long head of biceps and deltoid, and anastomoses with the posterior circumflex humeral artery.

The posterior circumflex humeral artery (**6**.68) is considerably larger than the anterior. It branches from the third part of the axillary artery at the lower border of subscapularis, and runs backwards with the axillary nerve through the quadrangular space, which is bounded by subscapularis, the capsule of the shoulder joint and teres minor above, teres major below, the long head of triceps medially, and the surgical neck of the humerus laterally. It winds round the surgical neck of the humerus and distributes branches to the shoulder joint, deltoid, teres major and minor, and the long and lateral heads of triceps, and gives off a descending branch which anastomoses with the deltoid branch of the arteria profunda brachii. It also anastomoses with the anterior circumflex humeral, and with the acromial branches of the suprascapular and thoraco-acromial arteries.

6.70 The right brachial artery and its branches.

6.71 A transverse section through the right arm at the junction of the proximal and middle thirds of the humerus. Proximal aspect.

Surface Anatomy. The axillary artery can be felt pulsating against the lateral wall of the lower part of the axilla. Its upper portion can be mapped out when the arm is raised to a right angle with the trunk, if the point of pulsation indicating the lower portion of the vessel is joined to the midpoint of the lower surface of the clavicle.

Variations. The branches of the axillary artery vary considerably in different subjects. One, named *alar thoracic*, and frequently derived from the second part of the artery, is distributed to the fat and lymph nodes in the axilla. Occasionally the subscapular, circumflex humeral and profunda arteries arise from a common trunk, and when this occurs the branches of the brachial plexus surround this trunk instead of the main vessel. The posterior circumflex humeral artery may arise from the arteria profunda brachii; it then passes backwards below the teres major, instead of accompanying the axillary nerve through the quadrangular space. Sometimes the axillary artery divides into the radial and ulnar arteries, and occasionally it gives off the anterior interosseous artery of the forearm.

Applied Anatomy. Compression of the axillary artery may be required in injuries, in the removal of tumours, or in amputations. Compression can be made most effectually in the lower part of its course, by pressing the artery against the humerus.

With the exception of the popliteal, the axillary artery is perhaps more frequently lacerated by violent movements than any other artery in the body, being particularly susceptible when diseased. It has occasionally been ruptured in attempts to reduce old dislocations of the shoulder joint, especially when the artery has become fixed to the capsule of the joint.

The Brachial Artery

The brachial artery (**6**.70, 71, 72, 73) is the continuation of the axillary artery. It begins at the lower border of the tendon of the teres major, runs down the arm, and ends about a centimetre or so below the elbow joint by dividing into radial and ulnar arteries. At first it lies medial to the humerus, but it gradually spirals to the front of the arm and the midpoint between the humeral epicondyles at the elbow. Its pulsations can be felt throughout its length.

Relations. The artery is superficial throughout, covered only by skin and superficial and deep fasciae; the bicipital aponeurosis lies in front of it at the elbow and separates it from the median cubital vein; the median nerve crosses the artery from lateral to medial side near the insertion of coracobrachialis. *Posteriorly*, it lies at first on the long head of the triceps, separated by the radial nerve and the profunda brachii artery. It then lies successively on the medial head of the triceps, the insertion of the coracobrachialis, and brachialis. *Laterally*, it is related above to the median nerve and coracobrachialis, below to biceps, the two muscles overlapping the artery to some extent. *Medially*, its upper half is next to the medial cutaneous nerve of the forearm and ulnar nerve, its lower half to the median nerve. The basilic vein lies medially, but is separated from it in the lower part of the arm by the deep fascia. The artery is closely accompanied by two venae comitantes, connected at intervals by short transverse branches.

At the bend of the elbow the brachial artery sinks deeply into a triangular intermuscular depression which is named the *cubital fossa*. The base of the triangle is represented by a line connecting the two humeral epicondyles; the sides are formed by the medial edge of brachioradialis and the lateral margin of pronator teres; the 'floor' consists of brachialis and supinator. This fossa contains the tendon of biceps, the terminal part of the brachial artery, and its accompanying veins, the commencement of the radial and ulnar arteries, and parts of the median and radial nerves. The brachial artery occupies the middle of the fossa, and divides opposite the neck of the radius into its radial and ulnar branches. In *front* of it are the skin, superficial fascia, and median cubital vein, the last separated from the artery by the bicipital aponeurosis. *Behind*, brachialis separates it from the elbow joint. The median nerve lies close to the *medial* side of the artery above, but is separated from its ulnar branch below by the ulnar head of pronator teres. The tendon of biceps is *lateral* to the artery; the

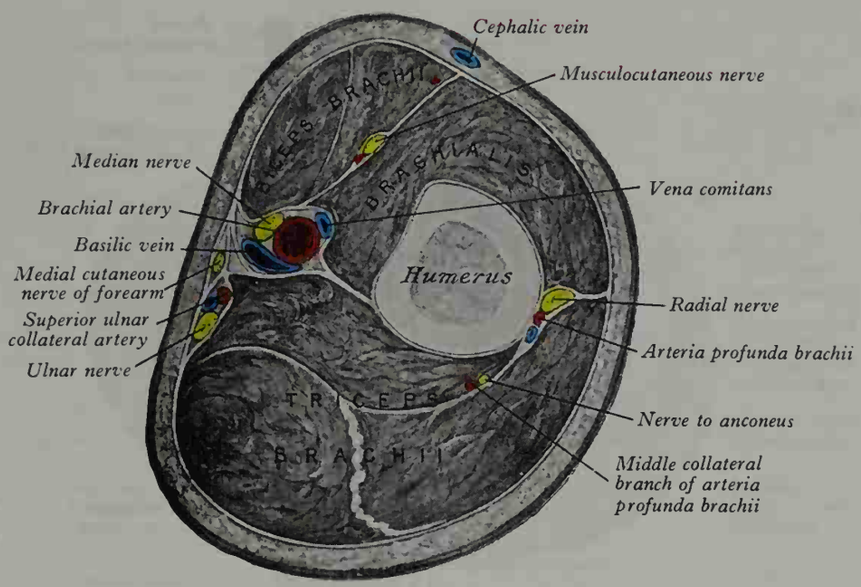
radial nerve is concealed, more laterally, between supinator and brachioradialis.

Variations. The brachial artery, accompanied by the median nerve, may leave the medial border of the biceps, and descend towards the medial epicondyle of the humerus; in such cases it usually passes behind a *supracondylar process* of the humerus, from which a fibrous arch is most often thrown over the artery; it then runs behind or through the substance of the pronator teres, to the bend of the elbow. This variation resembles the normal condition in some carnivores (p. 363). Occasionally, the artery splits at a high level into two trunks which re-unite. Frequently it divides at a higher level than usual, and the vessels resulting from this high division are three: viz. radial, ulnar and common interosseous arteries. Most frequently the radial is given off high up, the other limb of the division consisting of the ulnar and common interosseous; in some instances the ulnar originates above the ordinary level, and the radial and common interosseous form the other limb of the division; occasionally the common interosseous alone arises high up.

Sometimes long, slender vessels, termed *vasa aberrantia*, connect the brachial to the axillary artery or with one or other of the arteries of the forearm. These vessels usually join the radial.

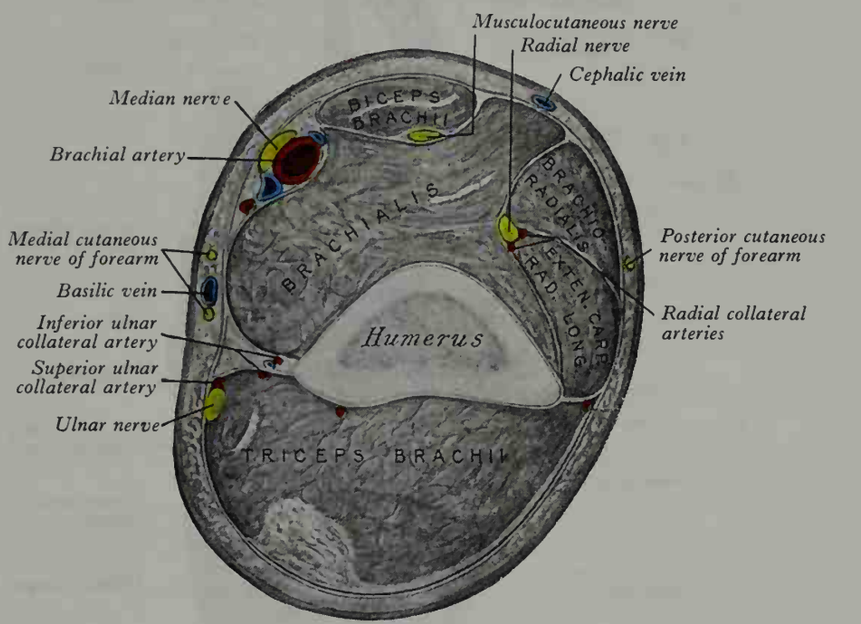
The brachial artery is occasionally crossed in some part of its course by muscular or tendinous slips derived from the coracobrachialis, biceps, brachialis or pronator teres.

Branches:



Profunda brachii.	Superior ulnar collateral.
Nutrient.	Inferior ulnar collateral.
Muscular.	Ulnar and radial.

The arteria profunda brachii (**6**.70, 71, 74) is a large branch from the medial and posterior aspect of the brachial artery, just below the lower border of teres major. It follows the radial nerve closely, running at first backwards between the long and medial heads of triceps, then along the groove for the radial nerve where it is covered by the lateral head of triceps; here it divides into its terminal branches (**6**.74). Apart from muscular branches it supplies the following named vessels: nutrient, deltoid, middle collateral and radial collateral arteries. The *nutrient artery* enters the humerus just posterior to the deltoid tuberosity; it may be absent. The *deltoid (ascending) branch* ascends between the lateral and long heads of triceps and anastomoses with the descending branch of the posterior humeral circumflex artery. The *middle collateral (posterior descending) branch*, the larger of the two terminal branches, arises behind the humerus and descends in the substance of the medial head of triceps to the elbow where it anastomoses with the interosseous recurrent artery behind the lateral epicondyle; it often gives a fine vessel which accompanies the nerve to anconeus. The *radial collateral*, the other terminal branch, is the continuation of the profunda brachii. It accompanies the radial nerve through the lateral intermuscular septum and then descends between brachialis and brachioradialis to the front of the lateral epicondyle where it anastomoses with the radial recurrent artery.

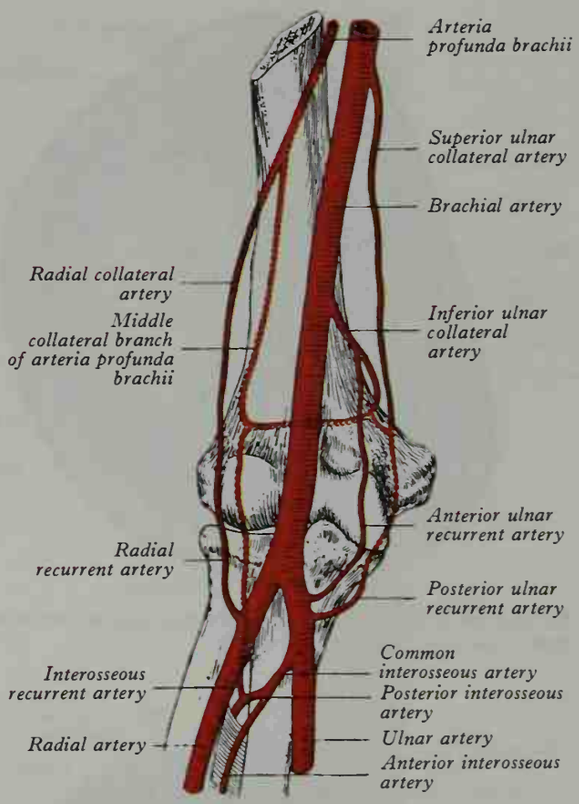


The main nutrient artery of the humerus arises usually about the middle of the arm; it enters the nutrient canal near the insertion of coracobrachialis, and is directed downwards.

The superior ulnar collateral artery (**6**.70, 72, 74), a small vessel, arises a little below the middle of the arm; it frequently springs from the upper part of the arteria profunda brachii. It accompanies the ulnar nerve, pierces the medial intermuscular septum, descends between the medial epicondyle and the olecranon, and ends deep to flexor carpi ulnaris by anastomosing with the posterior ulnar recurrent and inferior collateral arteries. It sometimes sends a branch in front of the medial epicondyle, to anastomose with the anterior ulnar recurrent artery.

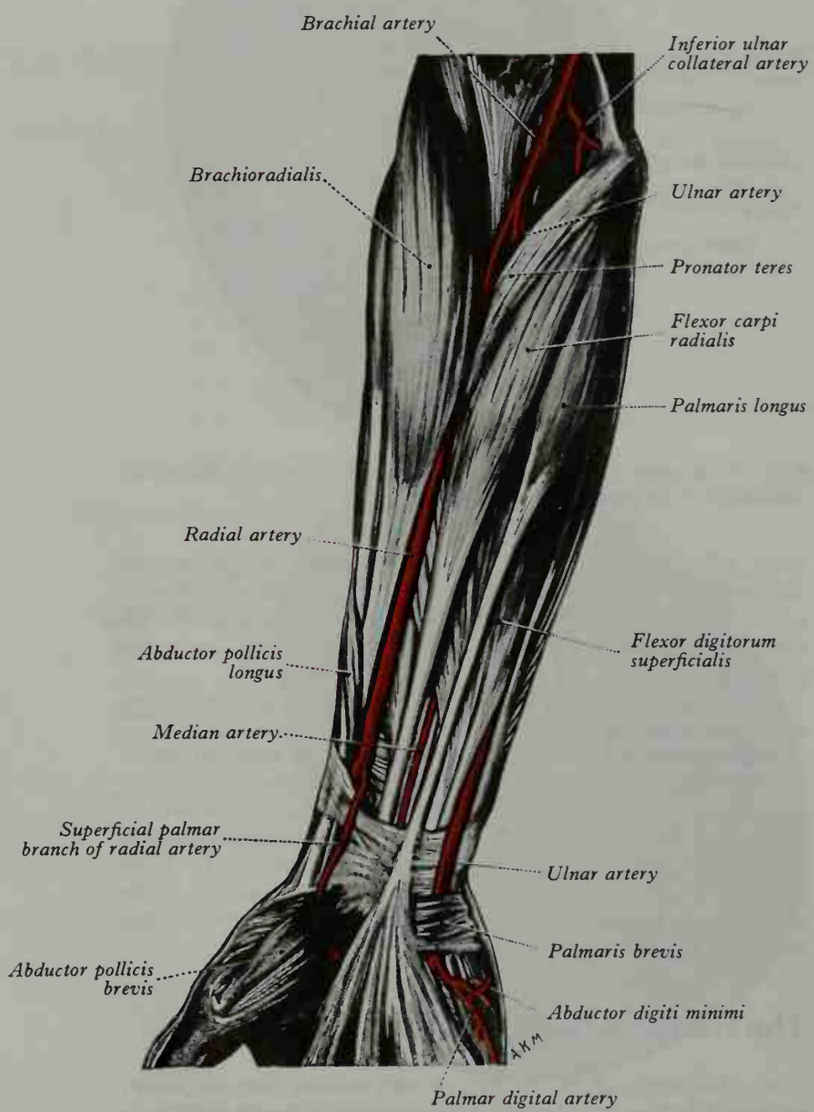
The inferior ulnar collateral (supratrochlear) artery (**6**.70, 74, 75) starts about 5 cm above the elbow. It passes medially between the median nerve and brachialis behind and, piercing the medial intermuscular septum, winds round the back of the humerus between triceps and bone, forming, by its junction with the middle collateral branch of the arteria profunda brachii, an arch above the olecranon fossa. As the vessel lies on brachialis, it gives off branches which descend in front of the medial epicondyle, to anastomose with the anterior ulnar recurrent artery. Behind the medial epicondyle a branch anastomoses with the superior ulnar collateral and posterior ulnar recurrent arteries.

6.72 A transverse section through the right arm, a little below the middle of the shaft of the humerus. Proximal aspect.



6.73 A transverse section through the right arm, 2 cm above the medial epicondyle of the humerus. Proximal aspect.

Muscular branches, three or four in number, are distributed to coracobrachialis, biceps and brachialis.



Applied Anatomy. Compression of the brachial artery in case of injury or operation may be effected in almost any part of its course in the arm. If pressure be made in the upper part of the arm, it should be directed laterally, if in the lower part, backwards, because the artery lies medial to the humerus above, and in front below. The most favourable situation is about the middle of the arm, where the artery lies on the tendon of the coracobrachialis medial to the humerus.

The Radial Artery

The radial artery (**6**.75, 76, 77), though smaller than the ulnar, appears to be the more direct continuation of the brachial trunk. It begins at the division of the brachial, about 1 cm below the bend of

6.74 The arterial anastomoses around the elbow joint.

6.75 The right radial and ulnar arteries, superficial dissection.

the elbow, and passes along the radial side of the forearm to the wrist, where its pulsation can readily be felt in the interval between flexor carpi radialis tendon medially and the salient lower part of the anterior border of the radius laterally. It then winds backwards, round the lateral side of the carpus, beneath the tendons of abductor pollicis longus and extensores pollicis brevis et longus, to the proximal end of the space between the first and second metacarpal bones, where it swerves medially between the two heads of the first dorsal interosseous into the palm of the hand; it crosses towards the ulnar side and forms the deep palmar arch by uniting with the deep branch of the ulnar artery. The radial artery is therefore divisible into three parts, one in the forearm, a second at the wrist, and a third in the hand.

Relations:

In the forearm (**6**.75, 76, 77), the radial artery extends from the medial side of the neck of the radius to the front part of its styloid process, being medial to the shaft of the bone above, and in front of it below. Its upper part is overlapped by the fleshy belly of the brachioradialis; the rest of the artery is covered only with the skin, and the superficial and deep fasciae. It lies successively upon the tendon of biceps, supinator, the insertion of pronator teres, the radial origin of flexor digitorum superficialis, flexor pollicis longus, pronator quadratus, and the lower end of the radius. The pronator teres is medial, and brachioradialis lateral, to the upper one-third of the artery; the tendon of flexor carpi radialis is medial, and that of brachioradialis lateral to its lower two-thirds. The superficial branch of the radial nerve is close to the lateral side of the middle third of the vessel; and some filaments of the lateral cutaneous nerve of the forearm run along the lower part of the artery as it winds round the wrist. Throughout its course the vessel is accompanied by a pair of venae comitantes. The part of the radial artery which lies in front of the lower end of the radius and on the lateral side of the tendon of the flexor carpi radialis is used clinically for observations on the pulse.

At the wrist (**6**.78, 80), the radial artery passes on to the dorsal aspect of the carpus between the lateral ligament of the wrist and the tendons of the abductor pollicis longus and extensor pollicis brevis. It then crosses the scaphoid bone and the trapezium, where its pulsation is obvious, and, before disappearing between the heads of the first dorsal interosseous, it is crossed by the tendon of the extensor pollicis longus. In the interval between the two extensores pollicis it is crossed by the origin of the cephalic vein, and by the digital branches of the radial nerve which go to the thumb and index finger.

In the hand (**6**.77), the radial artery, having travelled through the proximal end of the first interosseous space between the heads of the first dorsal interosseous, runs transversely across the palm; it passes at first deep to the oblique head of adductor pollicis and then between its oblique and transverse heads, or through the transverse head. At the base of the fifth metacarpal it anastomoses with the deep branch of the ulnar artery, to complete the *deep palmar arch* (**6**.77).

Variations. Sometimes the origin of the radial artery is higher than usual; it then branches more often from the axillary or upper part of the brachial artery than from the lower part of the latter. In the forearm it is sometimes superficial to the deep fascia instead of beneath it; in turning round the wrist, it is occasionally superficial instead of deep to the extensor tendons of the thumb.

Branches:

The radial recurrent artery (**6**.74, 77) arises immediately below the elbow. It passes between the superficial and deep branches of the radial nerve and ascends behind brachioradialis, in front of supinator and brachialis; it supplies these muscles and the elbow joint, and anastomoses with the radial collateral branch of the arteria profunda brachii.

The muscular branches are distributed to the muscles on the radial side of the forearm.

The palmar carpal branch (**6**.77) is a small vessel which arises near the lower border of pronator quadratus, and, running medially across the palmar surface of the carpus, anastomoses behind the flexor tendons with the palmar carpal branch of the ulnar artery. This anastomosis is joined by a branch from the anterior interosseous artery, and by recurrent branches from the deep palmar arch, thus forming a *palmar carpal arch*, which

supplies the articulations of the wrist and carpus and the bones involved.

The superficial palmar branch (**6**.81) arises from the radial artery where this vessel is about to wind round the lateral side of the wrist. It passes through, occasionally over, the muscles of the thenar eminence, which it supplies, and sometimes anastomoses with the terminal part of the ulnar artery, completing the *superficial palmar arch.*

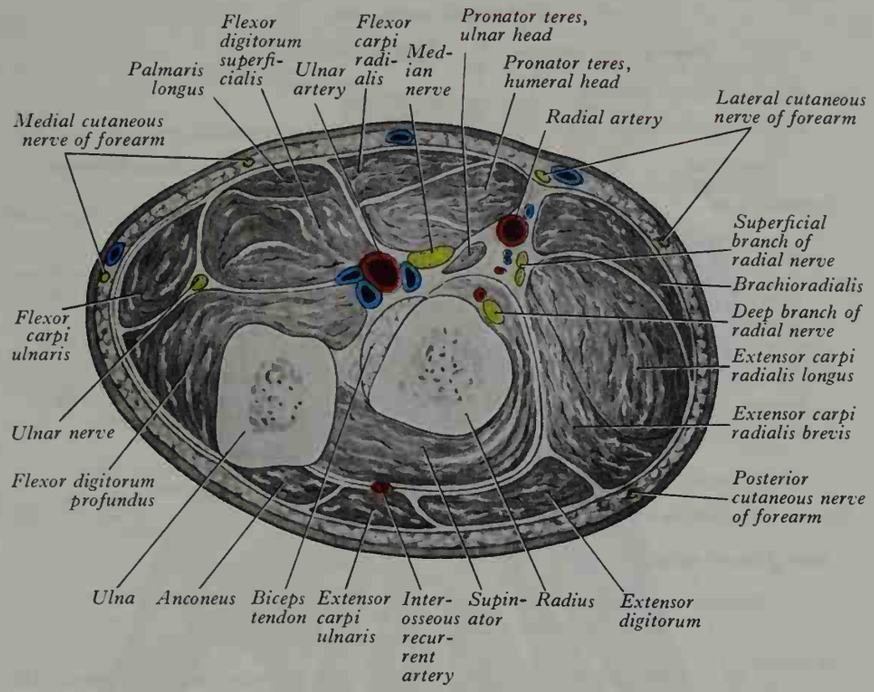
The dorsal carpal branch (**6**.80) is small and arises deep to the extensor tendons of the thumb; running medially across the dorsal carpal surface under these tendons, it anastomoses with the dorsal carpal branch of the ulnar artery, and with the anterior and posterior interosseous arteries, to form a *dorsal carpal arch.* The dorsal and palmar carpal arches are both close to bone and supply the lower, epiphysial parts of the radius and ulna. Arising from the dorsal arch, three slender *dorsal metacarpal arteries* descend on the second, third and fourth dorsal interosseous muscles and bifurcate into dorsal digital branches for the adjacent sides of the index, middle, ring and little fingers; they anastomose with the palmar digital branches of the superficial palmar arch; near their origins they anastomose with the deep palmar arch by the *proximal perforating arteries*, and, near their points of bifurcation, with the palmar digital vessels of the superficial palmar arch by the *distal perforating arteries.*

The first dorsal metacarpal artery (**6**.80) arises just before the radial artery passes between the two heads of the first dorsal interosseous, and divides almost immediately into two branches, which supply the adjacent sides of the thumb and index finger; the radial side of the thumb receives a branch directly from the radial artery (*vide infra*).

The arteria princeps pollicis (**6**.77) arises from the radial artery, as it turns medially into the palm; it descends on the palmar aspect of the first metacarpal bone under the oblique head of the adductor pollicis and lateral to the first palmar interosseous muscle. At the base of the proximal phalanx, where it lies deep to the tendon of the flexor pollicis longus, it divides into two branches. These make their appearance between the medial and lateral insertions of the oblique head of adductor pollicis, and run along the sides of the thumb, forming, on the palmar surface of the distal phalanx, an arch from which branches are distributed to the skin and subcutaneous tissue of the thumb. The arteria princeps pollicis is the usual source of supply of the nutrient artery to the first metacarpal.

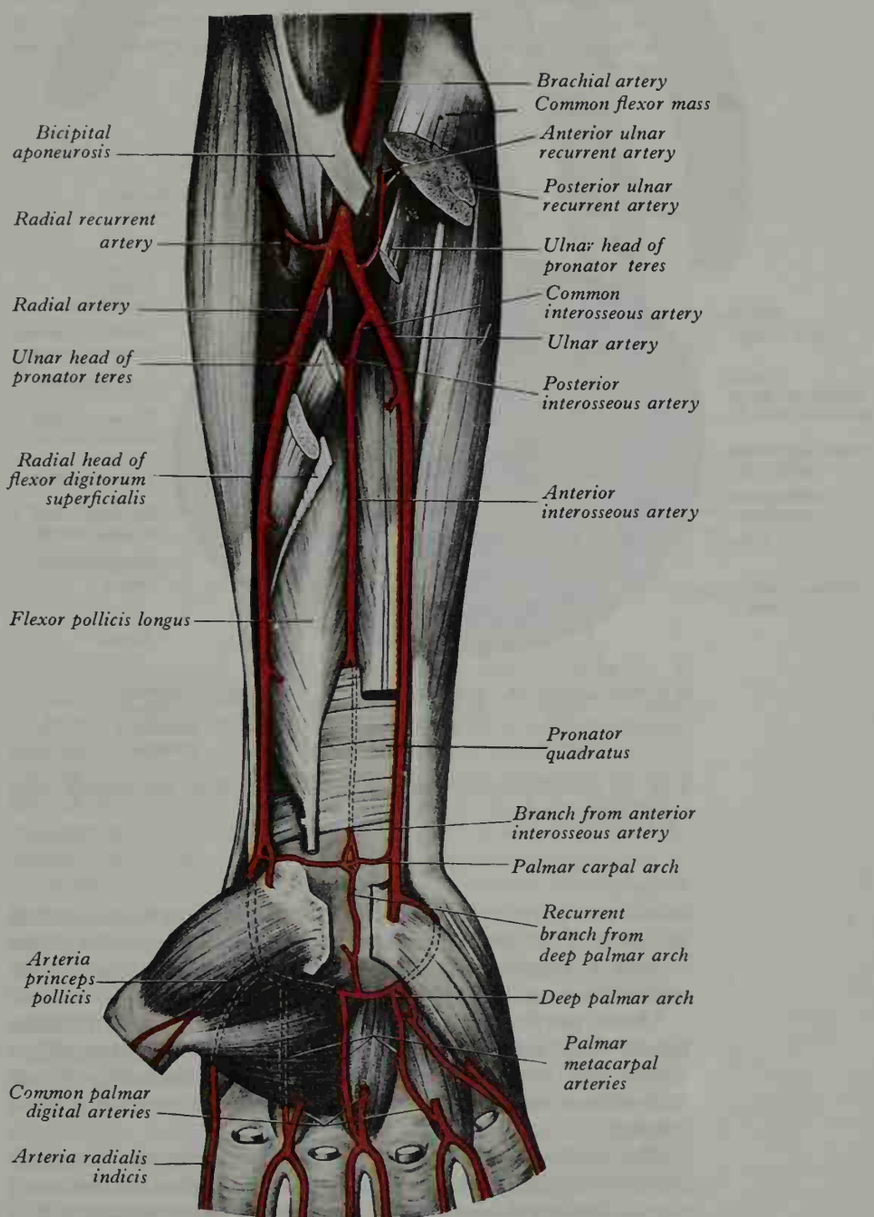
The arteria radialis indicis (**6**.77, 81), which frequently arises from the proximal part of the arteria princeps pollicis, descends between the first dorsal interosseous and transverse head of the adductor pollicis, running along the lateral side of the index to its extremity; it anastomoses with the digital artery supplying the medial side of the finger. At the distal border of the transverse head of the adductor pollicis this vessel anastomoses with the arteria princeps pollicis, and gives a communicating branch to the superficial palmar arch.

The arteriae princeps pollicis and radialis indicis may start in common as the *first palmar metacarpal artery.*



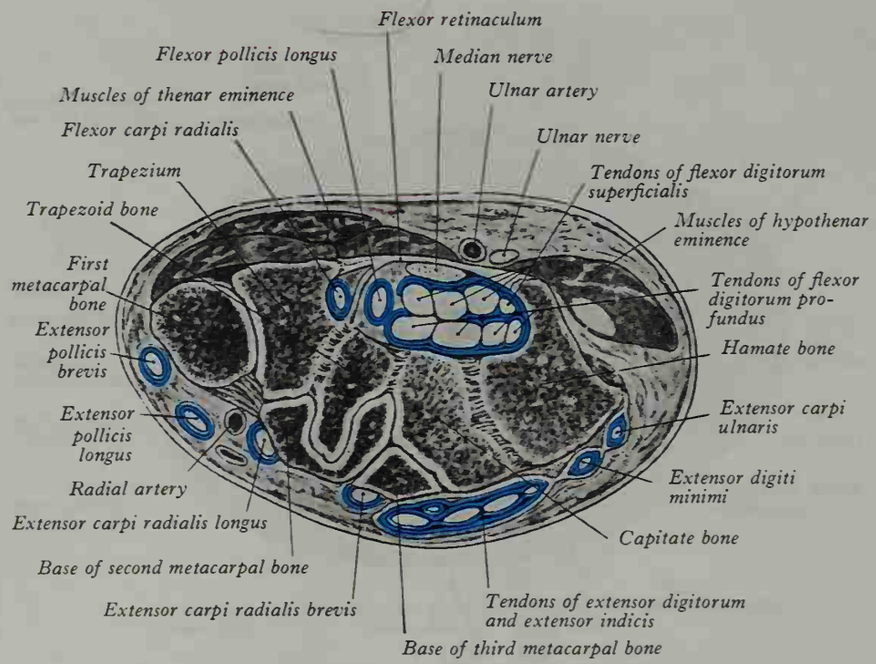
The Deep Palmar Arch (**6**.77)

This is formed by anastomosis of the terminal part of the radial artery with a deep palmar branch of the ulnar. It lies on the proximal ends of the metacarpal bones and the interossei, and is covered by the oblique head of adductor pollicis, flexor tendons of the fingers and lumbricals. In its concavity, but running towards the lateral side of the hand, is the deep branch of the ulnar nerve. Some variation occurs in the formation of this anastomotic arch, which is sometimes incomplete—in 6 of 200 arches, according to Coleman and Anson (1961). The variation is chiefly in the size of the contribution from the ulnar artery.



Surface Anatomy. The deep palmar arch can be represented by a horizontal line about 4 cm long drawn from a point just distal to the hook of the hamate bone; it lies about 1 cm proximal to the superficial arch (**6**.82).

The branches of the deep palmar arch are palmar metacarpal, perforating and recurrent.



The three palmar metacarpal arteries (**6**.77), arise from the convexity of the deep palmar arch; they run distally upon the

6.77 The arteries of the right forearm and hand, deep dissection.

6.78 A transverse section through the left wrist, superior aspect. The section is slightly oblique and divides the distal row of the carpus, and the bases of the first, second and third metacarpal bones. The arrangement of the tendons of the flexors of the fingers shown in the figure represents the actual condition in the specimen. Observe that the carpometacarpal joint of the thumb is separate from the joint between the trapezium and the base of the second metacarpal bone.

6.79 A transverse section through the middle of the left forearm, seen from proximal aspect.

interosseus muscles of the second, third and fourth spaces, and, at the clefts of the fingers, join the common digital branches of the superficial palmar arch. They supply nutrient branches to the medial four metacarpals.

Three perforating branches pass dorsally from the deep palmar arch, through the second, third and fourth interosseous spaces and between the heads of the corresponding dorsal interosseous muscles, to anastomose with the dorsal metacarpal arteries.

The recurrent branches (**6**.77) arise from the proximal aspect of the deep palmar arch; they ascend in front of the wrist, supply the carpal bones and intercarpal articulations, and end in the palmar carpal arch.

The Ulnar Artery

The ulnar artery (**6**.75–81), the larger of the two terminal branches of the brachial artery, begins level with the neck of the radius, about 1 cm below the bend of the elbow, and, passing downwards and medially, reaches the medial side of the forearm at a point about midway between the elbow and the wrist. It then runs straight to the medial side of the wrist, and crosses the flexor retinaculum lateral to the ulnar nerve and pisiform bone. Immediately beyond this bone it gives off a deep branch, and is then continued across the palm as the superficial palmar arch.

Relations:

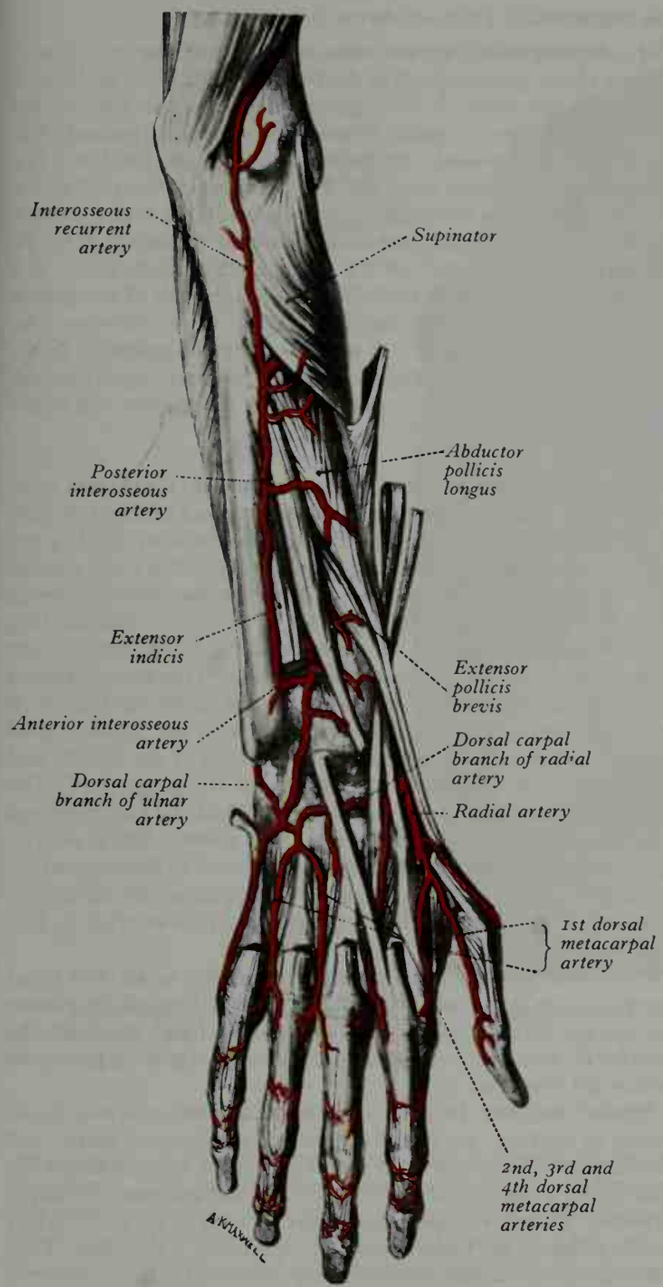
In the forearm the *upper half* of the vessel (**6**.75, 76, 79) passes obliquely deep to pronator teres, flexor carpi radialis, palmaris longus and flexor digitorum superficialis to the medial side of the forearm, where it is overlapped in its middle third by the flexor carpi ulnaris; it lies in front of brachialis and the flexor digitorum profundus. Below the elbow the median nerve is medial to the artery for about 2·5 cm and then crosses it, but is separated from it by the ulnar head of pronator teres. The *lower half* of the vessel (**6**.75, 81) lies upon flexor digitorum profundus, covered by the skin, superficial and deep fasciae, and is between flexor carpi ulnaris and flexor digitorum superficialis.

The ulnar artery is accompanied by two venae comitantes, the ulnar nerve is adjacent and medial to the lower two-thirds of the artery, and the palmar cutaneous branch of this nerve descends on the lower part of the vessel to the palm of the hand.

At the wrist (**6**.77, 78, 81) the ulnar artery is covered by skin and fasciae and palmaris brevis, and lies between the superficial and the main part of the flexor retinaculum (p. 583). The ulnar nerve and the pisiform bone are on its medial side.

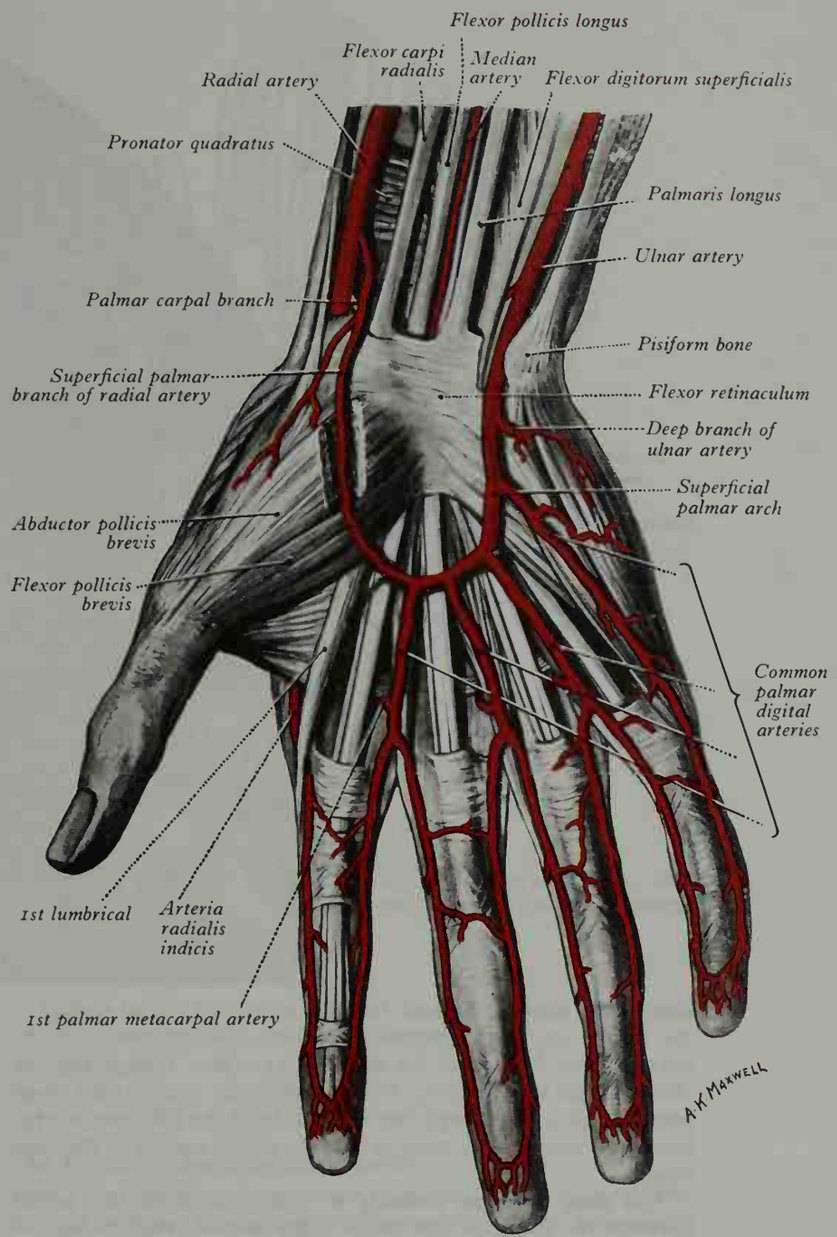
Surface Anatomy. The vessel commences in the midline of the limb opposite the neck of the radius. From this point the upper part passes to a point at the junction of the upper and middle thirds of a line drawn from the base of the medial epicondyle of the humerus to the lateral edge of the pisiform bone; this line represents the lower two-thirds of the ulnar artery.

Variations. The ulnar artery varies in its origin; it sometimes arises above the elbow, the brachial being more often the source of origin than the axillary. When its origin is normal, the course of the vessel is rarely changed. When the artery arises high up, it is usually superficial to the flexor muscles in the forearm, lying commonly beneath the deep fascia, more rarely between it and skin; the brachial artery then supplies the common interosseous artery, and the latter, the anterior and posterior ulnar recurrent arteries. Occasionally it is subcutaneous in the upper part of the forearm, and subfascial in the lower part.



Branches. The ulnar artery supplies the muscles on the medial side of the forearm and hand, the common flexor synovial sheath and the ulnar nerve (Blunt 1959). It supplies the following named branches:

The anterior ulnar recurrent artery (**6**.74, 77), a small branch, arises immediately below the elbow joint, runs upwards between the brachialis and pronator teres, supplies these muscles, and, in front of the medial epicondyle, anastomoses with the inferior ulnar collateral artery.



The posterior ulnar recurrent artery (**6**.74, 77) is larger, and arises lower than the anterior artery. It passes backwards and medially between flexor digitorum profundus and flexor digitorum superficialis, and ascends behind the medial epicondyle of the humerus. In the interval between this process and the olecranon, it lies deep to flexor carpi ulnaris, and ascends between the two heads of this muscle, in contact with the ulnar nerve; it supplies the neighbouring muscles, bone and elbow joint, and anastomoses with the two ulnar collateral and the interosseous recurrent arteries (**6**.74).

The common interosseous artery (**6**.77), about a centimetre long, arises immediately below the tuberosity of the radius, and, passing backwards to the upper border of the interosseous membrane, divides into two branches, the *anterior* and *posterior interosseous arteries.*
